As a consequence, there was developed a pressure-sensing instrument capable of measuring pressure at low levels with high sentivity and accuracy.

It occurred to Davis G. Durham, M.D., an ophthalmologist, that this basic concept could be extended to the measurement of intraocular pressure through the outer coats of the eye. As a result, the pressure balance Applamatic Tonometer was developed.

Validation of the original model was reported in Nov.-Dec. 1965 Transactions American Academy of Ophthalmology and Otolaryngology, pages 1029-1047. Validation of the performance of model immediately preceding the present instrument was reported in the April 1968 issue of Archives of Ophthalmology pages 389-399. The initial published study validating the Applamatic has appeared in Contacto, September 1970.

# measures intraocular pressure by air flow for exciting new reaches in glaucoma detection.

# Applamatic Tonometer

Opens whole new worlds in accurate, rapid measurement of intraocular pressure and aqueous humor dynamics.
Thanks to an air bearing in the sensor, the head of the sensor moves independently of the probe, responds in milliseconds, takes a reading on sclera or cornea automatically.

BAUSCH & LOMB
Mark of Leadership

# measures intraocular pressure with high sensitivity and accuracy without (or with) anesthesia

With the APPLAMATIC TONOMETER, you can do more complete examinations as part of your routine procedures . . . perform scleral tonometry without anesthesia. Your patients are less apprehensive because they don't see the sensor and hardly feel its feather-light touch.

**Versatile, simple, fast**

- May be used for scleral tonometry without anesthesia
- May also be used in corneal tonometry (with anesthesia)
- Audible signal verifies correct sensor placement
- Provides permanent record of intraocular pressure
- Simple to use . . . reliable, fast, accurate measurements

**More convenience for you and your patients**

- Tonometry examinations may be included in routine visits
- Complete examination takes only a few minutes
- Permanent graphic record provided for patient's file
- Unit is totally portable, simple to use

Housed in an attractive metal cabinet, the APPLAMATIC TONOMETER includes a shock-proof Auto-Sensor; retractable tubing; foot switch (optional); Amplifier-Recording Unit. Sensitive electronics monitor the pneumatic pressure. Operated with inexpensive, easy-to-replace canned liquid gas supply. For complete information ask your B & L Representative or B & L Ophthalmic Instrument Dealer, or write Bausch & Lomb, Dept. 3506, Rochester, N.Y. 14602.

# Jet or Drop

***DACRIOSE gives you complete control of ocular irrigation. You can provide a gentle but thoroughly cleansing "jet-like" action . . . or you can use it drop-by-drop.***

This modern irrigating solution, in the unique *Jet-Stream* dispenser, is ready-to-use and self-sterilizing.

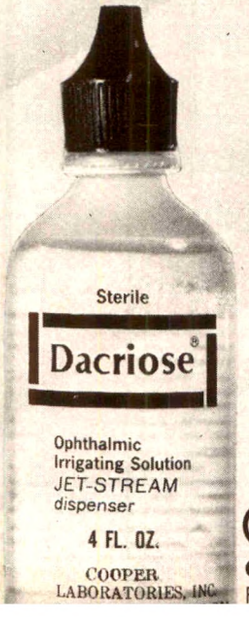
Use DACRIOSE

☐ *In the office:* after tonometry and gonioscopy — to wash away fluorescein — to wash out secretions and discharges.

☐ *In the emergency room:* for quick, safe removal of foreign bodies.

☐ *In the operating room:* for sterile and convenient irrigation of the eye pre- and post-operatively.

☐ *At the bedside:* to clean and irrigate eyes — to save staff time.



**Formula:** A sterile, stable, buffered isotonic solution of boric acid, sodium carbonate, potassium chloride. Preserved with benzalkonium chloride, 0.01%; with 0.01% disodium ethylenediamine tetraacetate.

**Warning:** Do not dilute or reuse the solution. Do not touch dropper tip to eye or any surface as this may contaminate solution.

**Supply:** 0.95 fl. oz. and 4 fl. oz. plastic Irrigator bottles.

## DACRIOSE®

you control the flow — sterile and self-sterilizing — isotonic

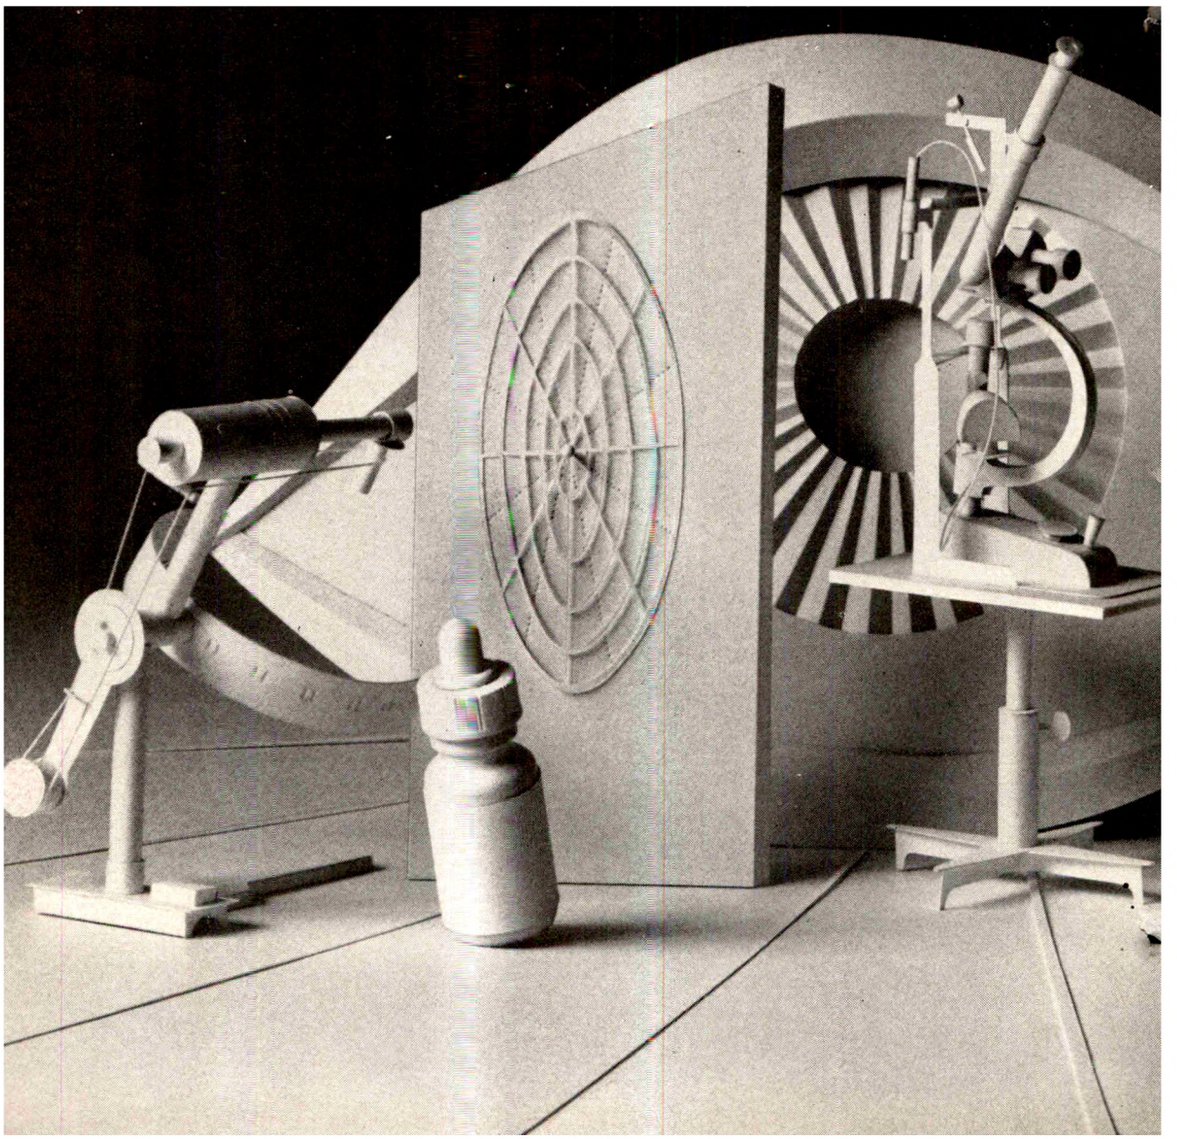
# THE 10 MOST QUESTIONS ABOUT

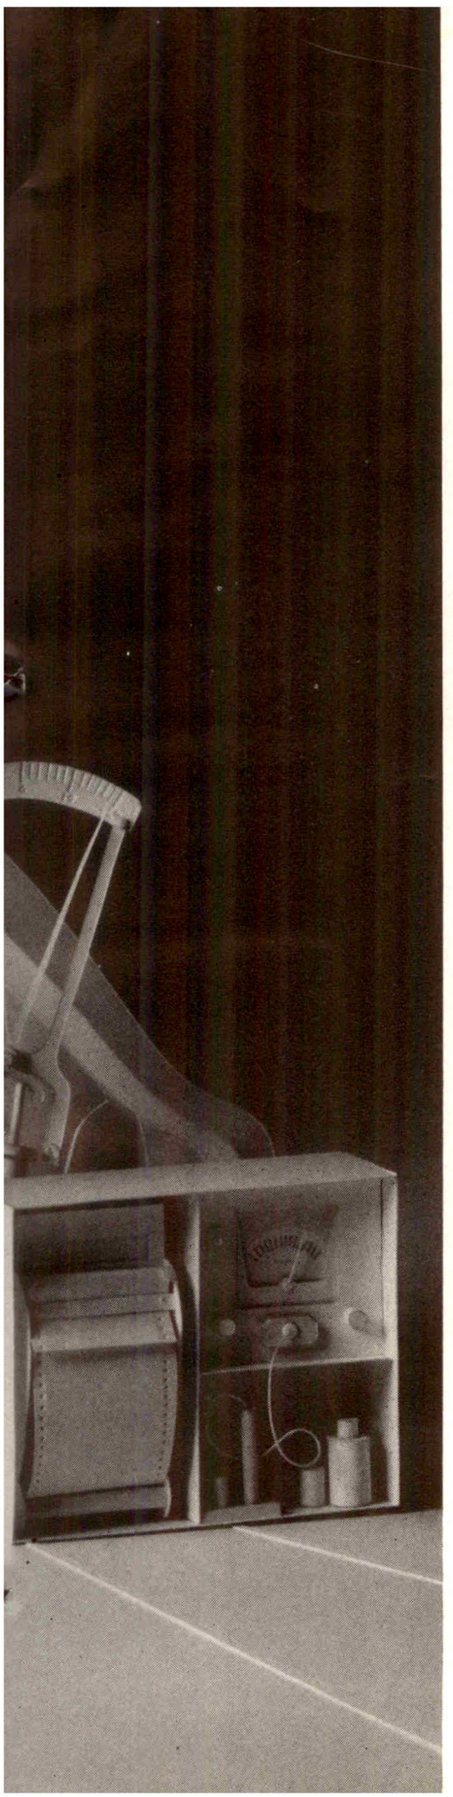
## THE QUESTIONS

1. What makes PHOTOGRAY lenses work?
2. How fast do PHOTOGRAY lenses change?
3. Will the darkening-fading process wear out?
4. Do PHOTOGRAY lenses need breaking in?
5. Can PHOTOGRAY lenses be hardened or toughened?
6. How do PHOTOGRAY lenses work in a car?
7. In what types of lenses is PHOTOGRAY glass available?
8. Is the darkening-fading process comfortable to the wearer?
9. Do PHOTOGRAY glasses have a residual tint indoors?
10. Will PHOTOGRAY glass be available in a darker sunglass version?

**Note:** If you get asked other questions by your patients about PHOTOGRAY glasses that you think would be of broad interest, please send them to us. When we get enough new ones, we'll answer them in another ad.



If you'd like complete technical information on PHOTOGRAY lenses, just write to: Corning Optical Products Dept., Corning, New York 14830.



# FTEN ASKED
# PHOTOGRAY® LENSES.

## THE ANSWERS

1. PHOTOGRAY lenses are photochromic: sensitive to ultraviolet light. When sunlight strikes them, invisible microcrystals of silver halide become darkened. When the light is removed, the crystals clear again.
2. Quite rapidly. In 60 seconds the lens is 75% darkened by sunlight and virtually fully darkened in 5 minutes. Removed from sunlight the lens clears half way in 5 minutes and 75% in 20 minutes. At their darkest, PHOTOGRAY lenses have a light transmittance of 45%. When clearest they have a light transmittance of 85%.
3. No. The photochromic reaction is locked into the composition of the glass and is completely reversible. It will keep performing for a lifetime without changing its characteristics.
4. Yes. Several complete darken-fade cycles are needed to bring PHOTOGRAY lenses up to their normal operating performance.
5. Yes, Most definitely. PHOTOGRAY lenses can be heat-treated or tempered. The tempering time is slightly different from that needed for clear lenses. Corning publishes heat-treating tables that give settings for the more popular units available.
6. Not too well. The window glass will screen out a lot of the ultraviolet light which activates the photochromic property of the lenses. This keeps the glass from darkening as fully as when it is exposed to direct sunlight.
7. PHOTOGRAY lenses come in a full range of sizes—in both single-vision and 1 piece multi-focal types.
8. Yes. The process, while quite rapid, is gradual enough to be imperceptible to the wearer. This, combined with the protection given by the darkened glass, is why PHOTOGRAY is known as the "comfort glass".
9. Yes. It's a very light, hardly noticeable tint.
10. Yes. Corning is currently in the final stages of developing a sunglass companion to PHOTOGRAY glass. Called PHOTOSUN™ glass, it's a true variable sunglass. PHOTOSUN lenses will be ready for introduction shortly.

CORNING
OPTICAL PRODUCTS

# When epinephrine is indicated for the management of chronic simple (open-angle) glaucoma

# Ayerst Epitrate® BRAND OF epinephrine bitartrate

BRIEF SUMMARY

*(For full prescribing information, see package circular.)*

**Epitrate**® (epinephrine bitartrate)

***For management of chronic simple (open-angle) glaucoma***

**Description:** A sterile aqueous solution of levorotatory epinephrine bitartrate 2% (equivalent to 1.1% base), it is stable, retains its potency throughout use, and requires no refrigeration. It has a low surface tension.

**Action:** Intraocular pressure is lowered by reducing the rate of aqueous formation. Improvement in outflow facility is also observed in certain cases following prolonged therapy.

**Indications:** Useful in management of chronic simple (open-angle) glaucoma, either alone or in combination with miotics. In selected cases, it may also be used with carbonic anhydrase inhibitors.

**Contraindications:** Prior to peripheral iridectomy, an epinephrine preparation is contraindicated in eyes that are capable of angle closure since its relatively weak mydriatic action may, nevertheless, precipitate angle block. Gonioscopy should be carried out on all patients before initiating therapy.

**Warnings:** Topical use of epinephrine in any form should be interrupted prior to general anesthesia with certain anesthetics such as cyclopropane or halothane which sensitize the myocardium to sympathomimetics.

**Precautions:** EPITRATE (epinephrine bitartrate) should be used with caution in the presence of hypertension, diabetes, hyperthyroidism, heart disease, and cerebral arteriosclerosis because of the possibility of systemic action.

**Adverse Reactions:** As with other epinephrine solutions, transitory stinging on initial instillation may be expected. Headache or browache frequently occur on beginning EPITRATE therapy, but usually diminish as treatment is continued. Conjunctival allergy occurs occasionally. Pigmentary deposits in the lids, conjunctiva or cornea may occur after prolonged use of epinephrine eyedrops. In rare cases, maculopathy with a central scotoma may result from the use of topical epinephrine in aphakic patients; prompt reversal generally follows discontinuance of the drug. Systemic effects have occasionally been reported, such as: palpitation, tachycardia, extrasystoles, hypertension, trembling, sweating, and pallor.

**Dosage and Administration:** 1 drop, with frequency of instillation being individualized, from every two or three days to twice daily. More frequent instillation than one drop four times daily does not usually elicit any further improvement in therapeutic response.

**How Supplied:** No. 1015—EPITRATE—ophthalmic solution of epinephrine bitartrate 2% (equivalent to 1.1% base). [Also contains chlorobutanol (chloral derivative) 0.5%, methylaminoaceto pyrocatechol HCl, sodium bisulfite, sodium chloride, polyoxypropylene-polyoxyethylene-diol, and disodium edetate.] Package containing 7.5 cc. bottle with separate dropper-screw cap attachment.

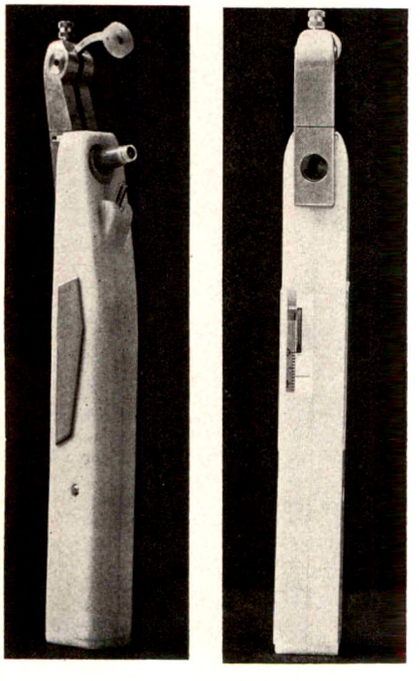
# NEW DEVELOPMENTS . . .



## ORA SERRATA ATTACHMENT TO THE GOLDMANN 3 MIRROR LENS

The periphery of the fundus near the ora serrata and the ciliary body cannot be examined under normal conditions with the 3-mirror lens alone. The ora serrata attachment along with the 3-mirror lens allows the observation of these most peripheral parts in its entire circumference.

The attachment is shaped like the 3-mirror lens. Half a steel-ball is fixed to the scleral part of the attachment which presses on the sclera above the ora serrata so that the fundus at its periphery near the ora serrata can be seen in the gonio mirror of the 3-mirror lens. The ora attachment can be used either with the 3-mirror lens in a locked or moveable position.

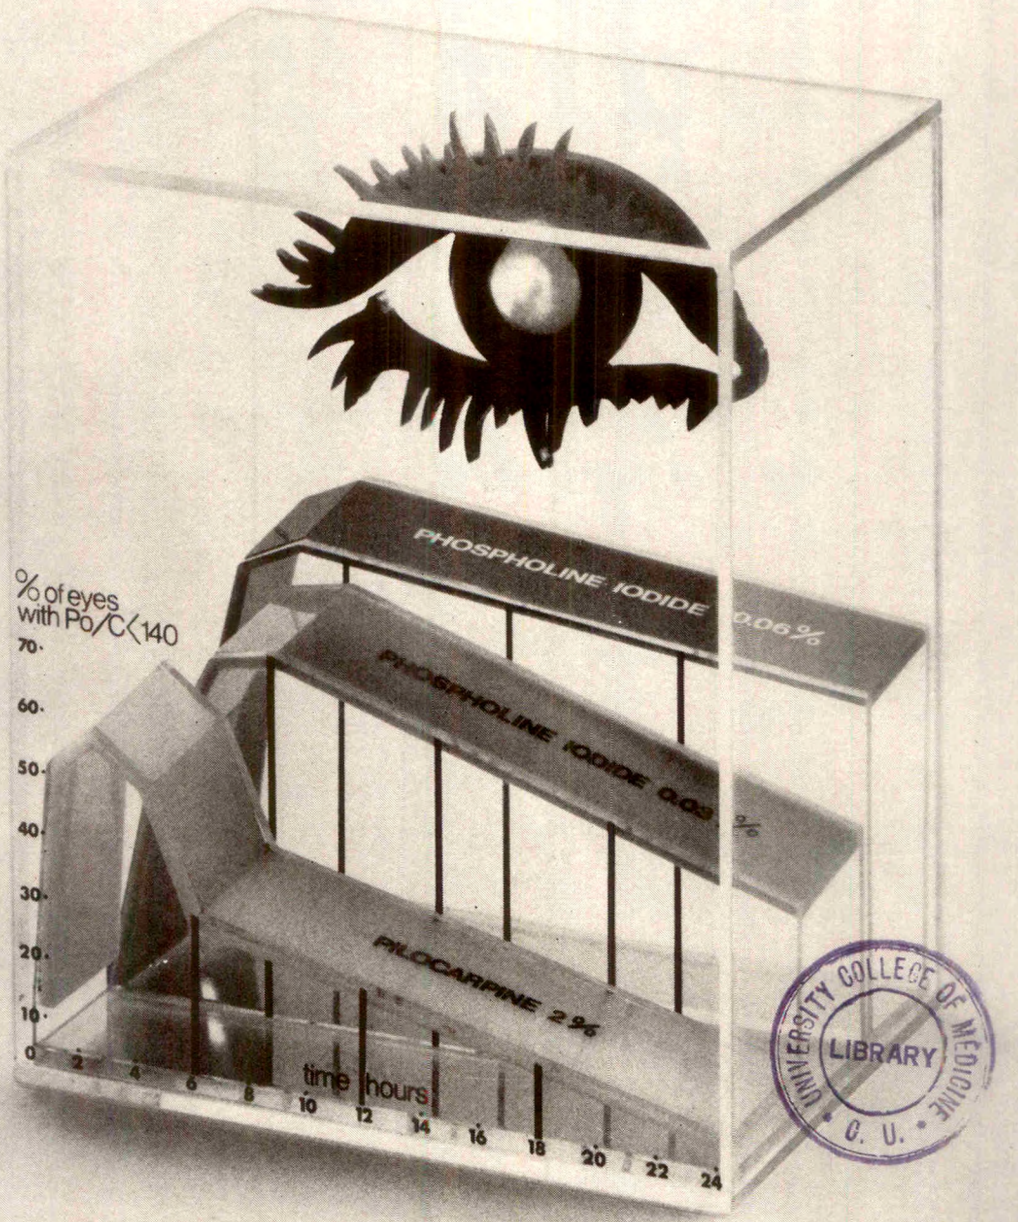
# Not more potent, but longer acting*...

PHOSPHOLINE IODIDE 0.03% and 0.06% were compared with pilocarpine 2% in a study of the time course of changes in outflow facility and intraocular pressure after single dose administration in patients with open-angle glaucoma. While Phospholine Iodide 0.06% showed little diminution in effect on intraocular pressure after 24 hours, the effect of pilocarpine 2% declined markedly in the first few hours, and was almost completely dissipated after 24 hours. The action of Phospholine Iodide 0.03% was intermediate between that of pilocarpine 2% and Phospholine Iodide 0.06%.

## An important consideration in the management of glaucoma



When treated with short acting miotics, the patient with open-angle glaucoma runs the risk of an undetected intraocular pressure buildup during the night—a "silent emergency."

The longer acting Phospholine Iodide® (echothiophate iodide) may protect against this nightly insult. A single instillation of the 0.03% or 0.06% strength before retiring will act through the critical hours, and is especially recommended when you have found pilocarpine to be inadequate.

When initiating therapy... Phospholine Iodide 0.03% can often maintain 24 hour control of intraocular pressure with a single instillation at bedtime. It provides a smooth transition to the higher strengths—0.06%, 0.125%, 0.25% —when necessary. When indicated, epinephrine or carbonic anhydrase inhibitors may be prescribed with any strength of Phospholine Iodide.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide for ophthalmic solution)

UNIVERSITY COLLEGE OF MEDICINE
LIBRARY
G. U.

Effect of Phospholine Iodide and pilocarpine on intraocular pressure control.

*Adapted from Barsam, P. C., Boston U. School of Med.: Time Curves of the Effect of Miotics on Intraocular Pressure and Outflow Facility, Scientific Exhibit, Annual Convention, American Academy of Ophthalmology and Otolaryngology, Las Vegas, Oct. 5-9, 1970.

See next page for Brief Summary of prescribing information.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide)

for 24 hour control in chronic simple (open-angle) glaucoma and glaucoma secondary to aphakia

just 1 or 2 instillations a day
- for long lasting effect on ocular tension—
helps protect against a "silent emergency" at night
- may be substituted for the bedtime dose of a short acting miotic
that controls intraocular pressure by day, but
fails to provide adequate control during the night and early morning
- choice of four strengths for individualized therapy—
may be used alone or as a complementary agent

**BRIEF SUMMARY (for full prescribing information, consult package circular)**
**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE (echothiophate iodide) concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, browache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local)* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE (echothiophate iodide) therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic)* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

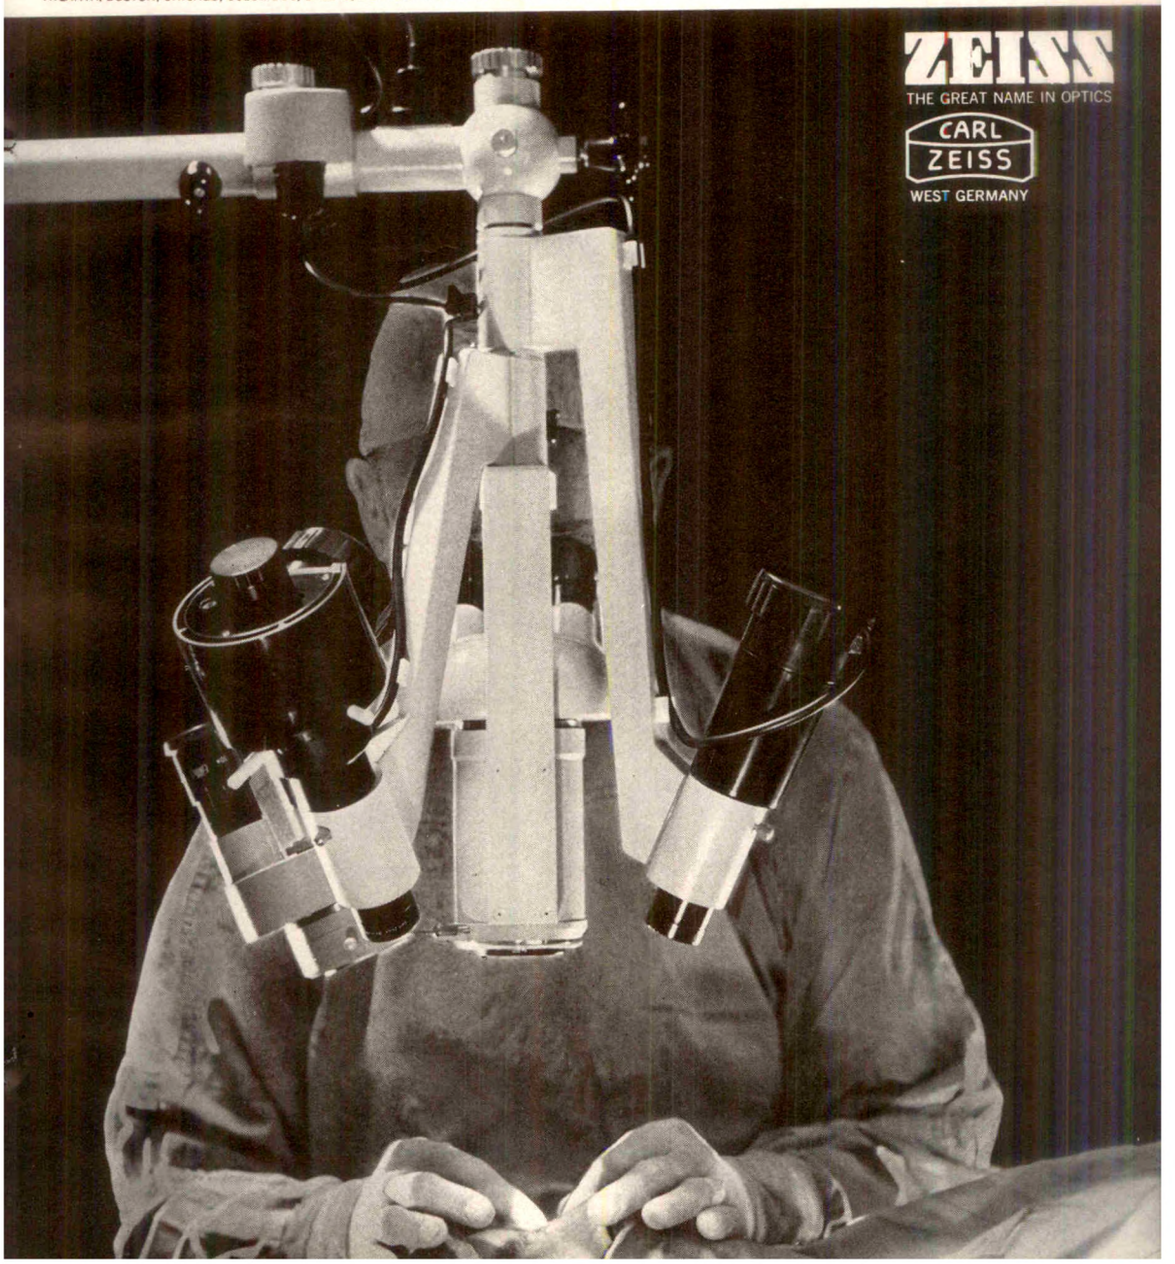
# The new Zeiss Zoom OpMi 7... a true ophthalmological specialist.

The new OpMi 7 is truly special in every sense of the word. It's special in that it is designed only for ophthalmological microsurgery. And special too in price—its many outstanding design features are shared only with instruments costing considerably more.

**Wide field of view:** 55 mm at 3.6x — 95% more area than other instruments in its price range.

**Building block design:** it accepts all the valuable Zeiss accessories, including the Beam Splitter System for still and motion picture photography and TV, the unique high-eyepoint eyepieces for spectacle wearers, a fiber-optic "cool-light" illumination system, the assistant's stereo microscope with the same high quality optics as the surgeon's, and the 2x operating field magnifier.



**Choice of 3 stands:** including the new Ceiling Suspension System.

**Choice of 3 working distances:** 6", 7" or 8" to your specification.

That's only a start. For complete details, write or call Carl Zeiss, Inc., 444 5th Ave., New York, N. Y. 10018. (212) 736-6070.

Nationwide Service.

# BY ALL MEANS!

Armorlite originated the world's first hard resin lenses in 1947 and has been perfecting them ever since. We make more types of these modern lenses than any one else, and they have a reputation for unsurpassed quality. We make only hard resin lenses and we do it in earnest; they are not a side-line with us.

When you think patient care and protection, think Armorlite, by all means.

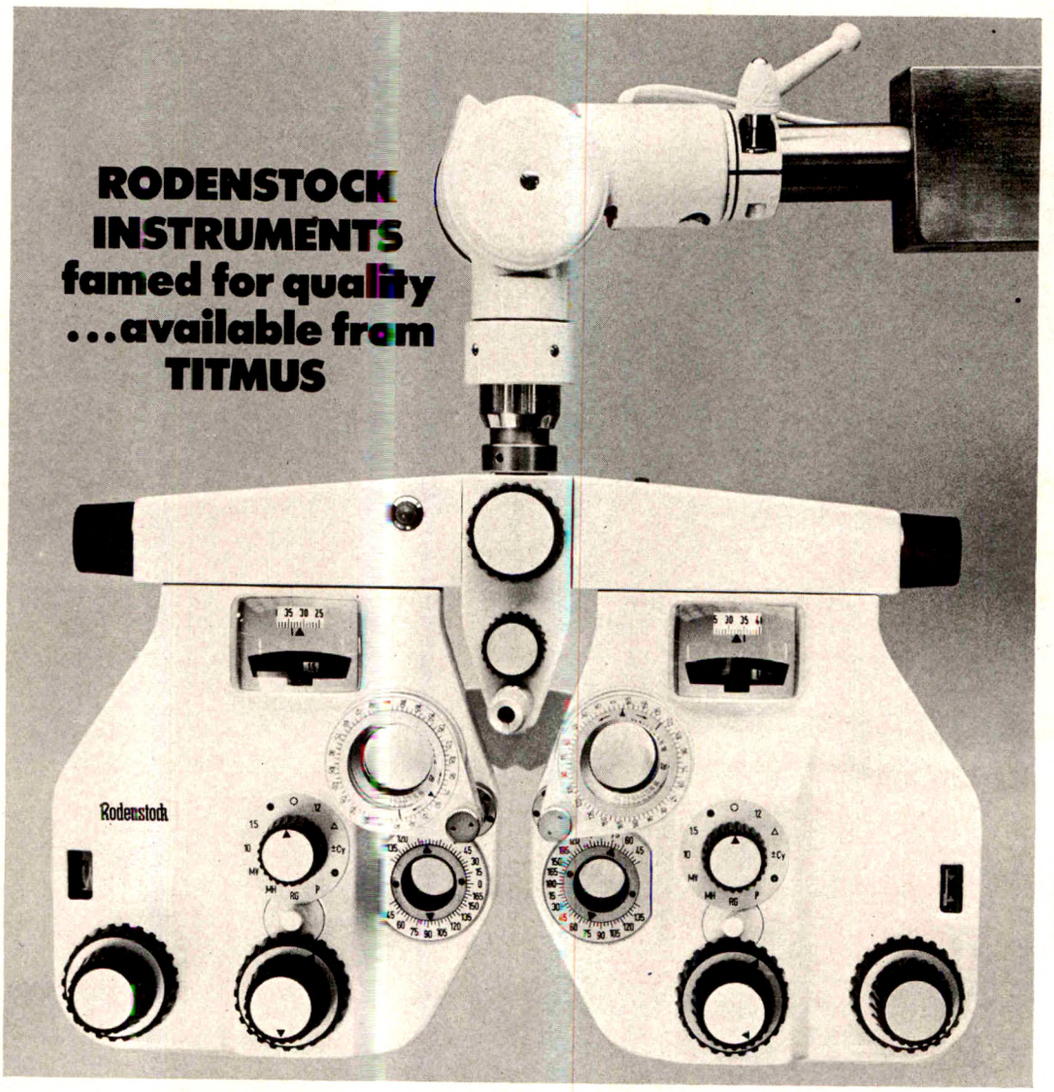
**ARMORLITE, INC.**

THE NEXT LOGICAL STEP IN GLAUCOMA THERAPY...
if patients become refractory or intolerant to acetazolamide

# NEPTAZANE® Tablets
## Methazolamide, 50 mg.

also an outstanding anti-glaucoma drug

For patients who can no longer be effectively controlled with acetazolamide—or cannot tolerate it over an extended period—NEPTAZANE Methazolamide is the next logical therapeutic step. Logical, because NEPTAZANE Methazolamide and acetazolamide are equally effective as ocular tension reducers due to their identical mode of action. So, with NEPTAZANE Methazolamide available as an alternate carbonic anhydrase inhibitor, it is possible for you to switch when necessary, and control many cases on long-term glaucoma therapy.



**Contraindications:** Severe (absolute) or hemorrhagic glaucoma; chronic noncongestive angle-closure glaucoma; adrenocortical, hepatic, or renal insufficiency; electrolyte imbalance states; sodium and potassium depletion states.

**Warning:** Although teratogenic effects demonstrated in rats at high doses have not been evidenced in humans, Methazolamide should not be used in women of childbearing age or in pregnancy, especially in the first trimester, unless the expected benefits outweigh these potential adverse effects.

**Precautions:** Use with caution in patients with cirrhosis or hepatic insufficiency to forestall hepatic coma; those on steroid therapy; those with pulmonary obstruction or emphysema. Electrolyte balance should be maintained. Although not reported thus far with this drug, reactions common to sulfonamide derivatives, such as fever, leukopenia, hemolytic anemia, bone marrow depression or renal calculi, may occur.

**Adverse Reactions (mostly mild and dose-related):** anorexia, nausea, vomiting; malaise, fatigue, drowsiness, headache, vertigo, mental confusion, depression; paresthesia. Urinary citrate excretion and uric acid output is decreased during use of this drug, but urinary calculi have not been reported.

Most ophthalmic solutions start out sterile. But the OCUMETER® helps this one stay that way.
OCUMETER helps steroid solution stay sterile by eliminating a major cause of contamination —the eye dropper. Sterile, highly stable
Ophthalmic Solution
DECADRON®
Phosphate
(Dexamethasone Sodium Phosphate, MSD)
0.1% Dexamethasone Phosphate Equivalent
for mild acute iritis and nonpurulent conjunctivitis
For prescribing information, please see next page.

## for mild acute iritis and nonpurulent conjunctivitis

Sterile, highly stable
Ophthalmic Solution
**DECADRON**® Phosphate
(Dexamethasone Sodium
Phosphate | MSD)

Not all steroid ophthalmic solutions stay sterile during the days and weeks of therapy. But this one is more apt to—Ophthalmic Solution DECADRON Phosphate (Dexamethasone Sodium Phosphate, MSD) in the OCUMETER® eliminates a common source of contamination—the eye dropper.

*Uniform dosage, drop after drop*

Each drop of Ophthalmic Solution DECADRON Phosphate contains the same dosage of steroid. And, with a gentle squeeze, the OCUMETER measures out one drop at a time. So your patient can conveniently get the steroid dose you want her to have, wherever she is.

Each cc. contains dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate. Also available as DECADRON® Phosphate Ophthalmic Ointment (0.05%); and as NeoDECADRON® Ophthalmic Solution containing dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base in each cc.; and NeoDECADRON® Ophthalmic Ointment, containing dexamethasone sodium phosphate equivalent to 0.5 mg. (0.05%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base per gram.

CONTRAINDICATIONS: DECADRON and NeoDECADRON should not be used in the presence of infectious tuberculous lesions of the eye, chickenpox, early acute herpes simplex, vaccinia, the early acute stages of most viral diseases of the cornea and conjunctiva, acute purulent untreated infections of the conjunctiva and lids, suspected ocular or aural fungal infection, perforated ear drum. Sensitivity to components is also a contraindication.

PRECAUTIONS: DECADRON: Like all adrenal corticosteroids, may sometimes mask, activate, or enhance incipient infection. Whenever possibility of infection exists, suitable antibiotic agents or a steroid-antibiotic preparation (such as NeoDECADRON) should be considered. If infections do not respond promptly, therapy should be discontinued until the infection has been adequately controlled by other measures.

Systemic side effects may occur with extensive use of steroids. Rarely, ocular herpes simplex has been reported in patients receiving adrenocortical steroids systemically or locally in the eye for other conditions.

As with other corticosteroids, increased intraocular tension can follow extended local use (1-2 weeks or more) of dexamethasone sodium phosphate. Since increased intraocular tension can lead to loss of vision, this possibility should be kept in mind and topical administration used only under adequate tonometric supervision, particularly in patients known to have glaucoma, or whose family history includes glaucoma.

In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids. Reports in the literature indicate that, rarely, protracted use of topical corticosteroids in the eye may be associated with the development of posterior subcapsular cataracts. Hereditary and degenerative eye diseases in general do not show any response to treatment with these preparations.

Stubborn cases of anterior segment eye disease may require systemic adrenocortical hormone therapy. When the deeper ocular structures are involved, systemic therapy is necessary.

NeoDECADRON: A few individuals may be sensitive to one or more of the components of NeoDECADRON. If any reaction indicating sensitivity is observed, discontinue use. Sensitivity to neomycin may occasionally develop, especially when it is applied to abraded skin. Some reports in the current literature point to an increase in the number of persons sensitive to neomycin.

Use of any antibiotic agent may result in overgrowth of fungi or other organisms not susceptible to the antibiotic, necessitating prompt medical attention for such new infections.

As the safety of topical steroids during pregnancy has not been confirmed, they should not be used for extended periods during pregnancy.

**For more detailed information, consult your MSD Representative or see the Direction Circular. Merck Sharp & Dohme Division of Merck & Co., Inc., West Point, Pa. 19486**

**MSD** MERCK SHARP & DOHME

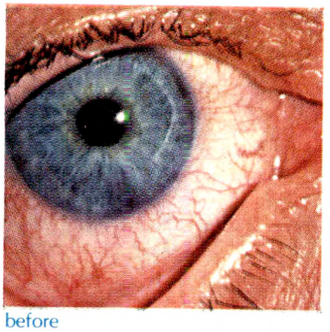
# A singular new antibiotic for the eye that works the way you think it should

## GARAMYCIN® brand of GENTAMICIN SULFATE OPHTHALMIC SOLUTION/OINTMENT

Each cc. or gram contains gentamicin sulfate equivalent to 3.0 mg. gentamicin.

## You think it should have a wide antibacterial spectrum

GARAMYCIN's wide range of antibacterial action is equal to the spectrum commonly prescribed in the combinations of neomycin, polymyxin and bacitracin or gramicidin in the treatment of external eye infections due to susceptible organisms. It has activity against a wide variety of both gram-positive and gram-negative organisms, including the "difficult" ones—*Pseudomonas aeruginosa* strains and Proteus.



## You think it should be a single entity antibiotic

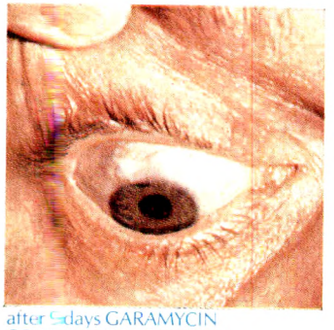
GARAMYCIN is a single entity antibiotic with a low incidence of sensitization or resistance*—can be used repeatedly with continued effectiveness, less concern about allergic potential (*Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.)

## You think it should be clinically effective

GARAMYCIN OPHTHALMIC has been described as appearing to be "...an antibiotic of choice for the initial treatment of external ocular infections."[1] It has "proved highly effective...for a wide variety of common bacterial eye infections..."[2] (due to susceptible organisms).
(1. Gordon, D.M.: Amer. J. Ophthal. 69:300 [Feb.] 1970. 2. Magnuson, R. H., and Suie, T.: JAMA 199:427 [Feb. 6] 1967.)

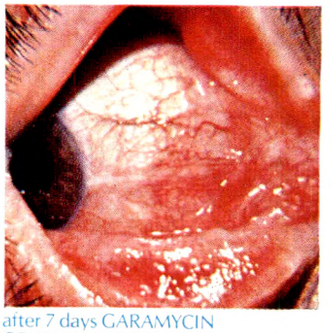
In acute catarrhal conjunctivitis and episcleritis† due to *Staphylococcus aureus* coagulase negative

before

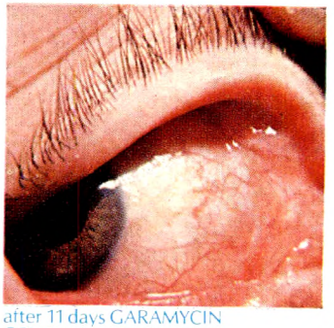


after 7 days GARAMYCIN OPHTHALMIC SOLUTION

In infected bleb (post-glaucoma surgery)† due to *Staphylococcus aureus* coagulase negative and *Streptococcus viridans*



before



after 5 days GARAMYCIN OPHTHALMIC SOLUTION

In acute conjunctivitis and dacryocystitis†† due to pneumococcus

after 7 days GARAMYCIN OPHTHALMIC SOLUTION

after 11 days GARAMYCIN OPHTHALMIC SOLUTION

# New GARAMYCIN® ophthalmic

brand of
GENTAMICIN SULFATE SOLUTION/OINTMENT

†Photographs courtesy of D. Gordon, M.D., N.Y., N.Y. ††Photographs courtesy of S. Fox, M.D., Baltimore, Md.

# You think it should have flexibility in dosage forms

GARAMYCIN OPHTHALMIC SOLUTION, sterile, isotonic, and buffered to pH of tears, does not blur vision, is well suited to daytime use—supplied in an unbreakable, easy-to-handle dispenser.

GARAMYCIN OPHTHALMIC OINTMENT provides gentle emollient action and keeps medication in contact with tissues for longer periods. It is particularly advantageous for nighttime use or in non-ambulatory patients—supplied in easy-to-use ophthalmic tube.

## Clinical Considerations

**Description:** GARAMYCIN is an antibiotic of the aminoglycoside group active against a wide variety of pathogenic gram-negative and gram-positive bacteria.

GARAMYCIN Ophthalmic Solution is a sterile aqueous solution buffered to approximately pH 6.7 for use in the eye. Each cc. contains gentamicin sulfate (equivalent to 3.0 mg. gentamicin), disodium phosphate, monosodium phosphate, sodium chloride, and benzalkonium chloride as a preservative.

GARAMYCIN Ophthalmic Ointment contains, in each gram of ointment, gentamicin sulfate (equivalent to 3.0 mg. gentamicin), and methylparaben and propylparaben as preservatives in a bland base of clear petrolatum.

Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.

**Indications:** GARAMYCIN Ophthalmic Solution and Ointment are indicated in the topical treatment of infections of the external eye and its adnexa caused by susceptible bacteria. Such infections embrace conjunctivitis, keratitis and keratoconjunctivitis, corneal ulcers, blepharitis and blepharoconjunctivitis, acute meibomianitis, and dacryocystitis.

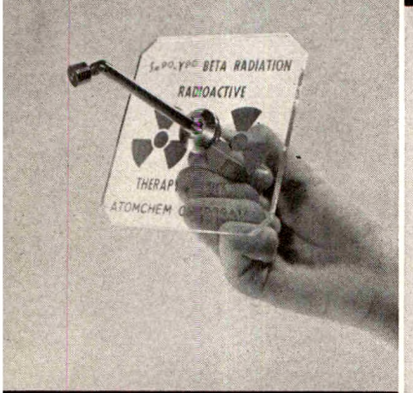
**Contraindications:** GARAMYCIN Ophthalmic Solution and Ointment are contraindicated in patients with known hypersensitivity to any of the components of these preparations.

**Precautions:** Prolonged use of topical antibiotics may give rise to overgrowth of nonsusceptible organisms such as fungi. Should this occur, or if irritation or hypersensitivity to any component of the drug develops, discontinue use of the preparation and institute appropriate therapy.

**Dosage and Administration:** GARAMYCIN Ophthalmic Solution: One or two drops every four hours. In severe infections, dosage may be increased to as much as two drops once hourly.

GARAMYCIN Ophthalmic Ointment: Apply a small amount to the affected eye two to three times daily.

**How Supplied:** GARAMYCIN Ophthalmic Solution, 5 cc. plastic dropper bottle, sterile, box of 1. GARAMYCIN Ophthalmic Ointment, 1/8 ounce tube, box of 1.



Note: Store away from heat.

GENERAL OFFICES: 6600 WEST TOUHY AVENUE, CHICAGO, ILLINOIS 60648

And now HUMORSOL is available in an improved dispenser—the easy-to-use, nonbreakable plastic OCUMETER® with a metered tip to help assure that your patient gets the precise dosage you prescribe.

In addition, the Direction Circular has been significantly revised. We urge you to consult it before prescribing.

We emphasize, however, that the formulation, Ophthalmic Solution HUMORSOL, remains exactly the same.

Supplied in two dosage strengths, 0.125 percent and 0.25 percent, each in a 5-cc OCUMETER® Ophthalmic Dispenser, with benzalkonium chloride 1:5000 added as preservative.

**For additional prescribing information, please see following page.**

# HUMORSOL® (DEMECARIUM BROMIDE | MSD) IS BACK

in OCUMETER® Ophthalmic Dispensers for greater accuracy and patient-convenience

## REVISED PRESCRIBING INFORMATION

**FOR TOPICAL APPLICATION INTO THE CONJUNCTIVAL SAC ONLY**

**Indications:** Open-angle glaucoma; conditions obstructing aqueous outflow that are amenable to miotic therapy, such as synechial formation; following iridectomy; accommodative esotropia (accommodative convergent strabismus).

**Contraindications:** Known hypersensitivity; active uveal inflammation; most cases of narrow-angle glaucoma.

**Warnings:** Should be administered with extreme caution to patients with myasthenia gravis who are on systemic anticholinesterase therapy; conversely, systemic anticholinesterase drugs for myasthenia gravis should be added cautiously. Succinylcholine should be administered with extreme caution before or during general anesthesia, because of possible respiratory and cardiovascular collapse.

*Use in Pregnancy:* Safe use in pregnancy has not been established, nor has the absence of adverse effects on the fetus or on respiration of the neonate. During pregnancy weigh potential benefits against possible hazards.

**Precautions:** Gonioscopy is recommended before therapy. Do not use, or use cautiously, when an intraocular inflammatory process is present.

Compression of the lacrimal sac during and following instillation for a minute or two minimizes drainage into the nasal chamber. Wash hands immediately after instillation. Discontinue use if salivation, urinary incontinence, diarrhea, profuse sweating, muscle weakness, respiratory difficulties, shock, or cardiac irregularities occur.

Persons exposed to organophosphate-type insecticides and pesticides (gardeners, organophosphate-manufacturing plant or warehouse workers, farmers, residents of communities which are undergoing insecticide spraying or dusting, etc.) should be warned of added systemic effects possible from absorption through the respiratory tract or skin. Wearing of respiratory masks, frequent washing, and clothing changes may be advisable.

Use with extreme caution, if at all, in patients with marked vagotonia, bronchial asthma, spastic gastrointestinal disturbances, peptic ulcer, pronounced bradycardia and hypotension, recent myocardial infarction, epilepsy, parkinsonism, and other disorders that may respond adversely to vagotonic effects. Use extreme caution before intraocular surgery because of the possibility of hyphema.

Despite observance of all precautions, repeated administration may cause depression of the concentration of cholinesterase in the serum and erythrocytes, with resultant systemic effects.

**Adverse Reactions:** Stinging, burning, lacrimation, lid muscle twitching, conjunctival and ciliary redness, brow ache, headache, and induced myopia with visual blurring; activation of latent iritis or uveitis; retinal detachment has been reported occasionally. Iris cysts may form, enlarge, and obscure vision, more frequently in children; cysts usually shrink when the miotic is discontinued but, rarely, may rupture or break free into the aqueous. Frequent examination is advisable.

Prolonged use may cause conjunctival thickening and obstruction of nasolacrimal canals. If systemic effects occur (e.g., salivation, urinary incontinence, nausea, abdominal cramps, vomiting, diarrhea, dyspnea, bradycardia, cardiac irregularities), parenteral administration of atropine is indicated: 0.4 to 0.6 mg or more for adults, proportionately less for children; artificial respiration may be required. Similar therapy is indicated for overdosage.

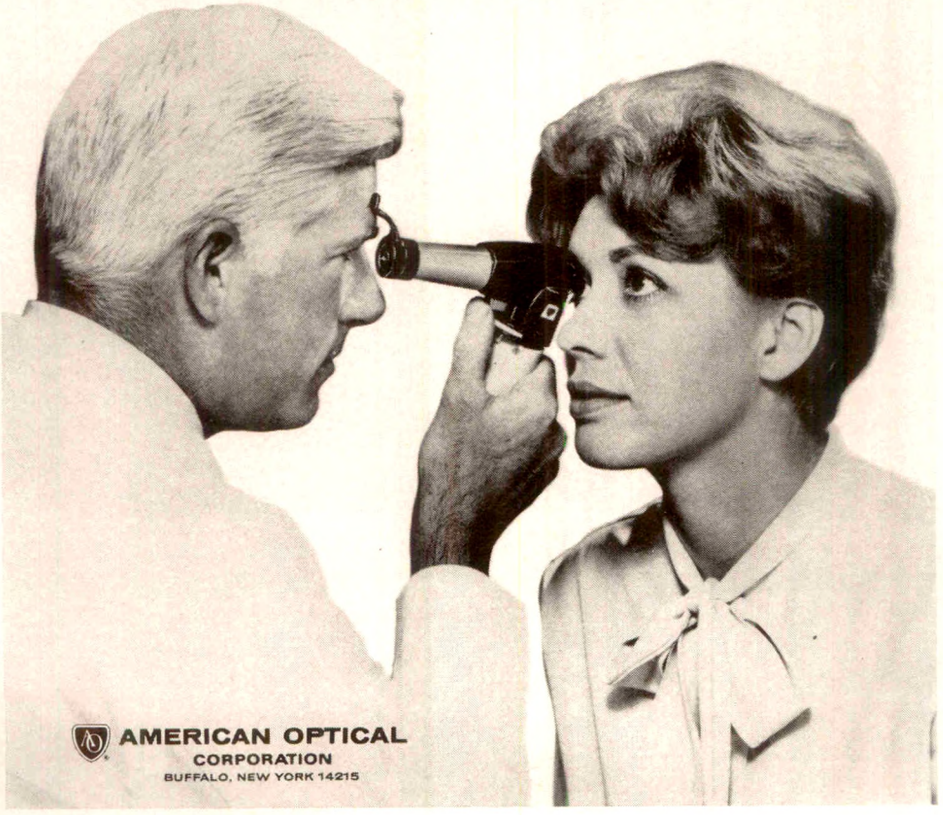
Lens opacities have been reported, and routine slit-lamp examinations should accompany prolonged use. Paradoxical increase in intraocular pressure may occur and be alleviated by a mydriatic.

**Dosage and Administration:** Initial titration and dosage adjustments must be individualized to obtain maximal therapeutic effect. Patient must be observed closely during initial period. If response is not adequate within first 24 hours, consider other measures. Keep frequency of use to a minimum in all patients, but especially in children.

Since technic is crucial to proper and safe administration, consult Direction Circular for full details.

**Supplied:** In 5-cc OCUMETER® Ophthalmic Dispenser containing 0.125 or 0.25 percent solution and sodium chloride; benzalkonium chloride 1:5000 added as preservative.

*For more detailed information, consult your MSD representative or see the Direction Circular. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486*



MSD MERCK SHARP & DOHME

The AO 305 Monocular Indirect Ophthalmoscope offers a brightly illuminated erect image over a field of view five times greater in area than is viewable with a direct ophthalmoscope. It is especially effective for viewing through small pupils or for routine examinations through undilated pupils.

For extra convenience you have a focusing eyepiece, variable field size control and built-in filters. All are easily and quickly adjusted with one hand.

You will find it a most remarkable diagnostic aid. Write for more information or better still, ask your AO representative for a convincing demonstration of the new 305 Monocular Indirect Ophthalmoscope.

# Now, an indirect ophthalmoscope with an erect image, ideal for routine examination.

# CONTACT LENSES AND THE APHAKIC PATIENT

## Part 1: Factors in Lens Selection

The important advantages of contact lenses over spectacles, for aphakics, are well understood: greater field of view, elimination of aberrations, reduced magnification and major cosmetic improvement. To gain these benefits, the patient is willing to tolerate considerable discomfort and visual disturbance. The apparent successes achieved with such highly motivated patients have misled some practitioners into thinking that aphakics are the easiest to fit of all contact lens wearers.

In fact, however, proper fitting of the aphakic eye is a highly complex matter, because of: (1) Tendency of high-plus lenses to ride down and be moved excessively by the lids, due to their greater thickness and weight and their more forward center of gravity; (2) Often flaccid or low lower lids of older patients, unable to support the weight of some low-riding lenses, may allow them to dig into and irritate the lower limbus; (3) Pupillary irregularities, such as keyhole or upward-displaced pupils, which are still quite common; and (4) High degree of corneal cylinder 'against the rule' often found after cataract surgery.

To avoid visual disturbances such as flare, ghost images or double vision, it is imperative to position the contact lens *so that the optical zone covers the entire exposed pupil at all times*. Proper choice from among the following three corneal lens constructions will help the practitioner to achieve the desired lens positioning:

(1) MINUS-CARRIER LENTICULAR LENS
(2) TP (TANGENTIAL PERIPHERY) LENS
(3) SINGLE-CUT LENS

The correct selection depends on the pupil and lid characteristics of each individual case. For example: keyhole pupils require lenses which ride somewhat above center, to completely cover the exposed pupil, unless the upper lid extends down far enough to cover virtually all of the iridectomy, *making the exposed pupil almost round*. Larger pupils require lenses with larger optical zones, as do lenses which tend to be displaced laterally because of 'against the rule' astigmatism or decentered corneal apical caps. For flaccid lower lids, thick lens edges are deliberately constructed to better support the weight of low-riding lenses; or, the lenses may be designed to ride up, held there by the upper lids. With tight upper lids, lenses least affected by upper lid pressures are needed. The practitioner must consider all these factors: upper and lower lid position and tension, and size, shape and position of the pupils.

# Now Alcon makes accurate tonography easy to do in your office

**ALCON introduces the EDT-103™—the first electronic digital tonograph and automated recorder. Only the EDT-103 provides accurate, simplified tonography for routine office use. And any member of your staff can be trained to use it in less than half an hour.**

**easy to read:**
direct digital display of tonometric scale readings conveniently...at tonometer head

**easy to operate:**
self-activating recorder, automatically controlled and timed permanent patient record on "fan-fold" strip chart
automatic chart drive—maximum accessibility for easy loading

**easy to maintain:**
- self contained tonography system is compact, lightweight, portable, in its own carrying case
- all solid state circuitry
- carries a one-year warranty, easily serviced
- meets or exceeds all requirements of Specification 5

Write for additional information, or to have our representative arrange for a personal demonstration.

## EDT-103

A new dimension in the detection and management of glaucoma—

Surgical Products Division, Alcon Laboratories, Inc./ P.O. Box 1959, Fort Worth, Texas 76101

**Indications:** Relief and management of nonpurulent Blepharitis and Conjunctivitis.

**Dosage:** Initially, 1 or 2 drops placed in the conjunctival sac every hour until improvement occurs.

Thereafter, 1 or 2 drops 2 to 4 times daily.

**Composition:**

Prednisolone-21-phosphate sodium .....0.25%
(Equivalent to Prednisolone 0.2%)
Sulfacetamide sodium ....10.0%
Phenylephrine HCl .....0.125%
Methylparaben .....0.02%
Propylparaben .....0.005%

In a stabilized aqueous solution containing sodium thiosulfate and *SMP-68 (a combination of polyoxypropylene compound and polysorbate 80).

**Effectiveness:** The antibacterial spectrum of Vasocidin is particularly effective against the gram positive pyogenic cocci; E. coli, N. gonorrhoeae, Koch-Weeks bacillus and other bacteria susceptible to sulfacetamide. Because Vasocidin is a true solution, dosage is uniform and each drop is free of any irritating particles. The Vasocidin vehicle enhances the dispersion of active components. Sulfacetamide combats a wide range of pathogens; prednisolone reduces inflammatory reaction; phenylephrine relieves hyperemia. Local effects of active therapeutic agents appear to be prolonged by phenylephrine-induced vasoconstriction.

**Caution:** Federal law prohibits dispensing without prescription.

**Contraindications:** Steroids are contraindicated in dendritic ulcers (herpes simplex), vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, as well as in fungal and tubercular ocular disease. Contraindicated in the treatment of purulent conjunctivitis or blepharitis. Should not be used by persons with narrow-angle glaucoma or those sensitive to sulfonamides. If irritation persists or increases, discontinue use and consult physician.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.

Vasocidin is sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area with the dropper tip of bottle. Keep container tightly closed.

**Supplied:** Plastic dropper-tipped vials, 5 cc.

# LAST YEAR W TOLD Y-U AB-UT TH "PRESSURE-SPARING" EFFECT OF HMS...

(medrysone)

# ...APPARENTLY YOU WANT TO KNOW MORE.

# SO TAKE THIS NEW LOOK AT HMS.

Drawing on nearly seven years of extensive clinical research experience, let's consider those questions you have asked most frequently.

### "Is HMS too mild to benefit my patients with inflammatory conditions?"

In the past five years, numerous independent studies on HMS (medrysone) have been published including those by Becker, and Thygeson.[1-4] Virtually all have reached the same conclusions: HMS is an effective treatment for superficial ocular inflammations.

Additionally, in a recent survey, 76% of the ophthalmologists interviewed who had tried HMS, found it effective when used for the recommended conditions.[5]

### "What therapeutic possibilities are now open to me, with HMS, that were not available with other mild steroids?"

First, over 30% of the population is likely to respond to steroids with an intermediate to high increase in intraocular pressure; steroid use with these patients must therefore be selective and cautious.[6] With HMS, most of these patients now can safely receive long-term steroid treatment.

Secondly, there are those glaucoma patients who must be treated specifically with epinephrine but are nevertheless sensitive to this drug. With HMS as concomitant therapy, Becker and Kolker reported that there was "sufficient improvement in glaucoma control so as to avoid surgery" by allowing continuation of epinephrine therapy.[7]

### "I haven't seen a rise in IOP with mild steroids. Isn't the real concern with the more potent steroids?"

There is ample evidence that .1% dexamethasone produces significant increases in IOP[1,4,8], and even .12% prednisolone, the mildest of the commercially available ophthalmic steroids, has the potential to increase IOP. Conversely, Doctors Becker and Kolker found in their investigational study that "medrysone (HMS) can be administered to patients four times a day for periods of several months with essentially no elevation of intraocular pressure even in individuals highly susceptible to such elevation."[7]

### "Can I treat uveitis and iritis with HMS?"

It is *not* indicated for these conditions. Its merits should only be judged in those conditions where indicated: allergic and vernal conjunctivitis, episcleritis, and epinephrine sensitivity.

### "Is HMS uncomfortable for the patient to use?"

Results of a recent patient study showed that 96% of those tested found HMS completely comfortable in the eye.[9] Though early batches of the product did cause some minor irritation to the eyes of a few patients, this has not been a recurring problem.

HMS® (medrysone)
LIQUIFILM® OPHTHALMIC SUSPENSION

ALLERGAN

Please see next page for Prescribing Information.

Prescribing Information for

# HMS® (medrysone)

LIQUIFILM® OPHTHALMIC SUSPENSION

DESCRIPTION: Contains:
medrysone.....1.0%
Liquifilm® (polyvinyl alcohol).....1.4%
with: benzalkonium chloride, disodium edetate, sodium chloride, potassium chloride, sodium phosphate monobasic monohydrate, sodium phosphate dibasic anhydrous, methylcellulose, purified water, and sodium hydroxide or hydrochloric acid if needed to adjust pH. HMS (medrysone) is related structurally more to progesterone than to other available corticosteroids.

INDICATIONS: HMS (medrysone) is effective in the treatment of allergic conjunctivitis, vernal conjunctivitis, episcleritis and epinephrine sensitivity. HMS (medrysone) is not indicated in iritis or uveitis as its therapeutic effectiveness has not been demonstrated.

CONTRAINDICATIONS:
HMS (medrysone) is contraindicated in the following conditions:

1. Acute untreated purulent ocular infections.
2. Acute herpes simplex (dendritic) keratitis.
3. Viral diseases of the conjunctiva and cornea.
4. Ocular tuberculosis.
5. Fungal diseases of the eye.
6. Hypersensitivity to any of the components of the drug.

WARNINGS:

1. Infectious diseases of the eye may be masked, enhanced or activated by steroids.
2. Corneal or scleral perforation occasionally has been reported with prolonged use of topical steroids. In high dosage they have been associated with corneal thinning.
3. Prolonged use of topical steroids may increase intraocular pressure although data from 2 uncontrolled studies[4,5] indicate that in patients with increased intraocular pressure and in those susceptible to a rise in intraocular pressure upon application of topical steroids, there is less effect on pressure with HMS than with dexamethasone or betamethasone.
4. Prolonged use of topical corticosteroids may rarely be associated with development of posterior subcapsular cataracts.
5. Systemic absorption and systemic side effects may result with the use of topical steroids.

PRECAUTIONS:

1. HMS (medrysone) is not recommended for use in iritis and uveitis as its therapeutic effectiveness has not been demonstrated in these conditions.
2. With prolonged use of HMS (medrysone) the intraocular pressure and lens should be examined periodically.
3. In persistent corneal ulceration where a steroid has been used, or is in use, fungal infection should be suspected.
4. The use of topical steroids in pregnancy should be limited to conditions serious enough to warrant such treatment, so that possible risk to the fetus may be justified by the expected benefit to the mother.

ADVERSE REACTIONS: Occasional transient stinging and burning may occur on instillation.

DOSAGE AND ADMINISTRATION: One drop instilled in the conjunctival sac up to every four hours.

SUPPLY:
As a 5 cc. sterile suspension in plastic dropper bottles on prescription only.

NOTE: Bottles filled to one-half capacity for proper drop control. Do not freeze.

# the measure of success...

**orally effective, potent carbonic anhydrase inhibitor**
**onset of action usually within an hour; maximal effect is observed in two to four hours**
**lowered intraocular pressure is often maintained for six to twelve hours**
**usually most successful when given in conjunction with miotics**
Compared to other carbonic anhydrase inhibitors, DARANIDE has a lesser propensity for causing metabolic acidosis. Please note, however, that this and other side effects associated with carbonic anhydrase inhibitors may occur.

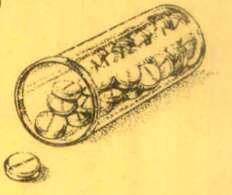
**Contraindications:** To avoid blood pH decreases below 7.20, do not use if arterial $pCO_2$ greater than 63 mm Hg; hepatic insufficiency; renal failure; adrenocortical insufficiency; hyperchloremic acidosis; conditions in which sodium and/or potassium serum levels are depressed. Should not be used in patients with severe pulmonary obstruction who are unable to increase their alveolar ventilation since their acidosis may be increased to the point of narcosis.

**Warning:** Should not be used in women of child-bearing age or in pregnancy, especially during the first trimester, unless the benefits to be expected outweigh potential adverse effects.

**Precautions:** Potassium excretion is increased and hypokalemia may develop with brisk diuresis, when severe cirrhosis is present, or during concomitant use of steroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Hypokalemia may be treated by use of potassium chloride or giving foods with a high potassium content. A close check on electrolyte balance, blood pH, and blood gases should be kept during therapy. Use with caution in severe respiratory acidosis or in the presence of chronic pulmonary infection; discontinue if blood pH falls below 7.20. As with other carbonic anhydrase inhibitors, agranulocytosis, thrombocytopenia, or renal calculi are possible.

**Adverse Reactions:** Side effects (characteristic of carbonic anhydrase inhibitors) may include gastrointestinal disturbances (anorexia, nausea, vomiting), constipation, urinary frequency, mild skin eruptions, pruritus, headache, weakness, nervousness, globus hystericus, sedation, lassitude, depression, confusion, disorientation, dizziness, ataxia, tremor, tinnitus, paresthesias of hands, feet, tongue. If they occur, reduce dosage or discontinue drug temporarily.

**Supplied:** Tablets containing 50 mg dichlorphenamide each, in bottles of 100.



*For more detailed information, consult your MSD representative or see the Direction Circular.*

# *Now* OCUTRON®

## *offers you visual fields*

. . . whenever you want
. . . as often as you want
without your being there

*quickly . . . automatically!*

U.S. Patent Nos. 3,288,546
and 3,421,498

The Ocutron® Visual Field Tester, developed by a leading ophthalmologist, is a highly precise electronic instrument that automatically examines the visual field and records it permanently on the standard chart that you are accustomed to using and interpreting.

Without the presence of doctor or nurse, the patient tests himself by push-button response to stimuli of standard light targets as they appear within the white hemisphere. This response is electrically registered on the chart.

Difficult and time-consuming fields like the above glaucoma field are as easily and quickly tested as a simple normal field.

Background may be lighted or not, as desired, for light or dark adapted fields. Built-in check on patient fixation and patient reliability.

Particularly suitable for high volume performance. Simple enough for screening. Accurate enough for definitive, repeatable field study.

For further information write for new literature
or contact your ophthalmic distributor.

## OCUTRON COMPANY

22500 South Woodland Road
Cleveland, Ohio 44122

# NEVER BEFORE . . . have all these features been included in one Ophthalmoscope.

***Check them:***

- ☐ Better view of macula with less reflection.
- ☐ Stereoscopic observation around opacities in the transparent media.
- ☐ Maximum stereopsis at all times commensurate with the size of the pupil.
- ☐ Now, after many years of research, one instrument[1] affords the best features for routine indirect ophthalmoscopy with the possibility of binocular viewing through pupils as small as 1.5 mm.
- ☐ Better illumination for viewing the fundus periphery.
- ☐ Adjustable diaphragms in the eyepieces insure easy and exact alignment of the ophthalmoscope both vertically and horizontally to prevent diplopia.
- ☐ A special optical system minimizes light loss and conducts most of the available light into the pupil.
- ☐ Built-in infrared filter prevents unnecessary heating of fundus tissues and makes examination far more comfortable for the patient.
- ☐ Eyepieces incorporating any lens corrections to suit the observer's prescription may easily be inserted and removed.
- ☐ Unusually large mirror attachment enables a second observer to view stereoscopically from either side of the primary observer.
- ☐ Headband is designed for comfort. Weight of the instrument is distributed over a large portion of any head to minimize the discomfort of wearing an instrument on the head for a prolonged period.
- ☐ All optical elements are completely enclosed and dust free.
- ☐ Lamp alignment knobs to focus filament are conveniently located outside the instruments.
- ☐ Intensity of illumination is continuously adjustable with a rheostat on the headband.
- ☐ Lamp housing is specifically designed to remain cool. Even after prolonged use it is not hot to the touch; there is a minimum of heat transmitted to the doctor's forehead.
- ☐ Filter is available for fluorescein study.

**Composition:**

**Inflamase**

*Prednisolone Sodium Phosphate .....0.125%
(Equivalent to Prednisolone 0.1%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

**Inflamase Forte**

*Prednisolone Sodium Phosphate 1.0%
(Equivalent to Prednisolone 0.8%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

Prednisolone Sodium Phosphate is a water soluble inorganic ester of prednisolone. It is approximately 2,000 times as soluble in water at 25°C. as is hydrocortisone.

*Licensed under patent #3,134,718.

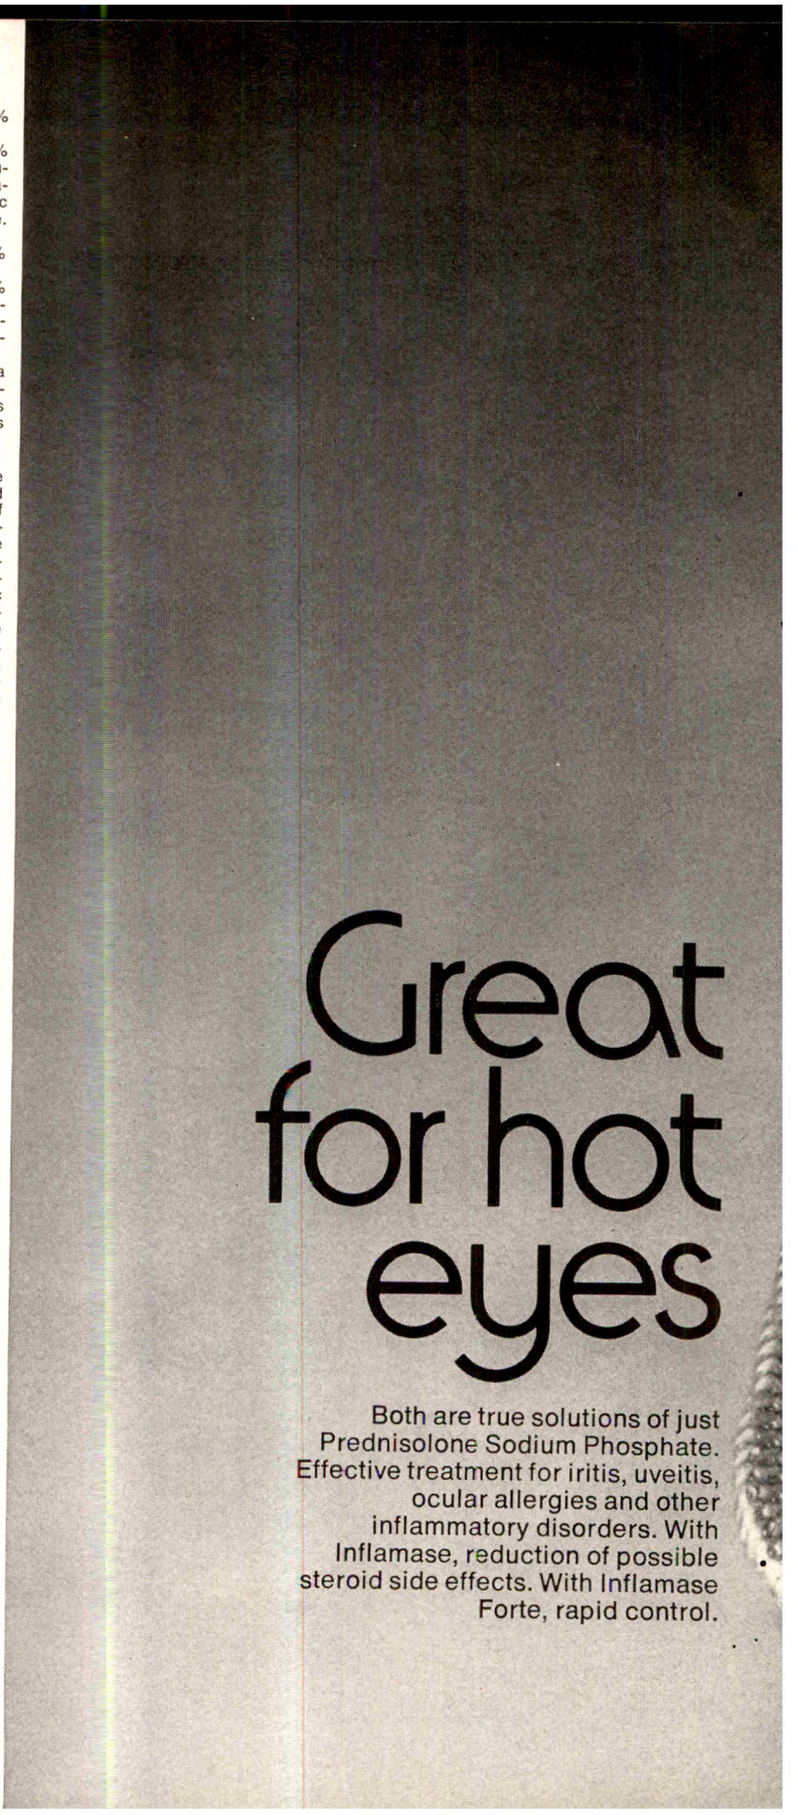
**Indications:** Inflamase and Inflamase Forte ophthalmic solutions may be used effectively in the following conditions of the anterior segment of the eye: superficial keratitis, including punctate epithelial lesions (Thygeson type), phlyctenular keratoconjunctivitis, and Sjogren's keratoconjunctivitis (with systemic steroids); deep keratitis, including interstitial or parenchymatous keratitis, acne rosacea, sclerosing keratitis; herpes zoster opthalmicus (do not use in herpes simplex); non-purulent conjunctivitis, including vernal, allergic, catarrhal; iridocyclitis; acute iritis; recurrent marginal ulceration, whether endogenous or due to atopic or contact allergies, or microbial allergy; corneal injuries, such as aseptic thermal, radiation, or chemical burns and corneal injuries following surgery or the penetration of foreign bodies; lid allergy; and non-purulent blepheritis, including catarrhal and allergic.

Inflamase and Inflamase Forte ophthalmic solutions have their principal effect on the anterior segment of the eye (cornea and the anterior uvea), with acute disorders responding more favorably than chronic disorders. Inflamase Forte 1% solution is recommended for moderate to severe inflammations particularly when rapid control is desired. In stubborn cases of anterior segment eye disease, systemic adrenocortical hormone therapy may be required. When the deeper ocular structures are involved, systemic therapy is necessary.

**Dosage:** Initially, 1 or 2 drops placed in conjunctival sac every hour during day and every 2 hours during night until improvement occurs. Thereafter, 1 or 2 drops 2 to 4 times daily.

**Contraindications:** Contraindicated in acute herpes simplex, ocular tuberculosis, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva; fungal diseases of the eye. Purulent conjunctivitis, purulent blepharitis, and infectious conditions are contraindications to the use of steroids.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.



**Warning:** If irritation persists or develops, patient should be advised to discontinue use and consult prescribing physician.

**How Supplied:** 5 cc plastic squeeze bottle with dropper tip. These products are sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area, or other areas with the dropper tip of the bottle. Keep bottle tightly closed when not in use.

Store in cool place. Protect from light.

**Caution:** Federal law prohibits dispensing without prescription.

**Smith, Miller & Patch, Inc.**
401 Joyce Kilmer Avenue
New Brunswick, N.J. 08902

# Great for hot eyes

Both are true solutions of just Prednisolone Sodium Phosphate. Effective treatment for iritis, uveitis, ocular allergies and other inflammatory disorders. With Inflamase, reduction of possible steroid side effects. With Inflamase Forte, rapid control.

**Inflamase**
for most inflammations.

**Inflamase Forte**
for the tough ones.

**Zoom Optics**—A true zoom unit, the Nikon Slit Lamp Microscope has continuous variable power from 7x to 35x. And yet, the image remains precisely centered and in critical focus throughout the entire range of magnification.

**Simultaneous Photography**—With the Nikon Slit Lamp Photo Attachment, you can view critically and photographically record exactly what you see—at the moment you see it. It is not necessary to remove your examining eye from the microscope to focus or use the camera. If needed you can freeze eye motion completely by use of strobe light.

**Unique Controls**—The slit mechanism is precisely controlled by coaxial vertical and horizontal controls. You can continuously vary the size of the slit with either your right or left hand from one set of controls. And the degree of control is exceptional too. *Both* the width and length of the slit can be precisely adjusted to complete extinction.

**Versatility**—Designed primarily for office practice the Nikon Slit Lamp is equally at home in the research laboratory. Equipped with the teaching head it is highly suitable for the classroom too. And like all Nikon Ophthalmic Instruments, it is guaranteed for 10 years.

We believe that once you examine a Nikon Zoom Photo Slit Lamp Microscope, you'll be well on your way to having the instrument you've always wanted at half the price you thought you couldn't afford.

Write for 8 page detailed brochure or call for a demonstration. Nikon, Inc. Instrument Division Subs. of Ehrenreich Photo-Optical Industries, Inc. Garden City, N.Y. 11530. 516-248-5200. (In Canada: Anglophoto Ltd., Ont.)

Specific for
Herpes Simplex Keratitis

**STOXIL®**
**brand of IDOXURIDINE**

the only brand of IDU
available in two forms:
Solution—Ointment

Both now available in Canada

# The choice is yours

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.

**Description: 'Stoxil' Ophthalmic Solution** contains idoxuridine (5-iodo-2'-deoxyuridine) **0.1% (1 mg./cc.)** in distilled water. Preserved with thimerosal, 1:50,000. **'Stoxil' Ophthalmic Ointment** contains idoxuridine **0.5% (5 mg./Gm.)** in a petrolatum base. (White petrolatum and liquid petrolatum are inactive ingredients.)

**Contraindications:** Contraindicated in patients with known or suspected hypersensitivity to any of its components.

**Precautions:** Some strains of herpes simplex appear to be resistant. If there is no response in *epithelial infections* after 7 or 8 days of treatment, other forms of therapy should be considered.

The recommended frequency and duration of administration should not be exceeded.

'Stoxil' is not effective in corneal inflammations in which the virus is not present.

Corticosteroids are usually contraindicated in herpes simplex keratitis.

Boric acid should not be used during the course of the therapy.

'Stoxil' Ophthalmic Solution should not be mixed with other medications.

**Adverse Reactions:** Occasionally, irritation, pain, pruritus, inflammation, edema of eye or lids and, rarely, allergic reactions have been reported. Photophobia has occurred. Occasionally corneal clouding, stippling and small punctate defects in the corneal epithelium have been observed. The punctate lesions may be a manifestation of the infection.

**How Supplied:** 0.1% Ophthalmic Solution (1 mg./cc.), in 15 cc. bottles with dropper; 0.5% Ophthalmic Ointment (5 mg./Gm.) in 4 Gm. tubes.

**Stability:** The Ophthalmic Solution should be stored in refrigerator until dispensed. 'Stoxil' Ophthalmic Ointment does not require refrigeration.

# !!! AQUALENS T.M !!!

*The All-New Years-ahead Hydrophilic Hard Contact Lens Adds a whole New Dimension to Contact Lenses*

**Developed By and Offered *Exclusively* By MORGAN OPTICS**

## NOW... and NEW...

FOR THE CONTACT LENS WEARER:

- **GREATER COMFORT**
- **LONGER WEARING TIME**
- **INCREASED WETTABILITY**
- **EASIER INSERTION AND REMOVAL**

Developed and tested by Morgan Optics, Dallas, Texas, the hydrophilic hard contact AquaLens, is now available for the greater comfort and wearing time of all who can wear ordinary hard contact lenses . . . **IN COLORS** *as well as clear!*

**Plus, AquaLens now makes contact-lens wear possible for many who previously could not tolerate contact lenses.**

Morgan Optics created AquaLens by changing the molecular structure of methylmethacrylate so that it is now hydrophilic (throughout the entire lens) rather than hydrophobic, and its angle of wettability is in the range of 25 to 30 degrees, in contrast to the 60 or 65-degree wettability angle of ordinary hydrophobic hard contact lenses.

AquaLens plastic has less surface tension than the ordinary hydrophobic hard contact lens, thus allowing tear-flow to adhere more uniformly to the new lens . . . giving greater comfort and longer wearing time.

AquaLens is prescribed and fitted in the same way as hydrophobic hard contact lenses, requires only the normal care and storage prescribed for other hard contact lenses, and is available in colors as well as clear.

AQUALENS *the new hydrophilic hard contact lens, is available ONLY from MORGAN OPTICS, INC.*

*Occupational vision studies*
*(From Study #21, Volume II, Guide to Occupational and Other Visual Needs)*

# Draftsman

In making a space capsule or an electric iron, a nuclear submarine or a TV set, a bridge or a typewriter, intricate detailed plans are needed to guide the people who make the object. These plans are carefully and painstakingly drafted by a technician called a "draftsman".

Working as he does with complicated figures and drawings on a large drafting table, it is needless to point out that the draftsman requires critical vision at many distances and from many angles.

When that draftsman reaches the presbyopic stage, the help he will need to see clearly for his work is available from the more than thirty-two different styles and sizes of multifocals manufactured by The Vision-Ease Corporation. Just check your lab or refer to the Vision-Ease Product Handbook, a copy of which can be obtained for the asking.

Significant new findings
Drug penetration
into the human eye

# for the first time independent research relates ocular drug penetration in humans to your choice of ophthalmic vehicles

## Proof of penetration—new fluorophotometry concentration/duration study[1]

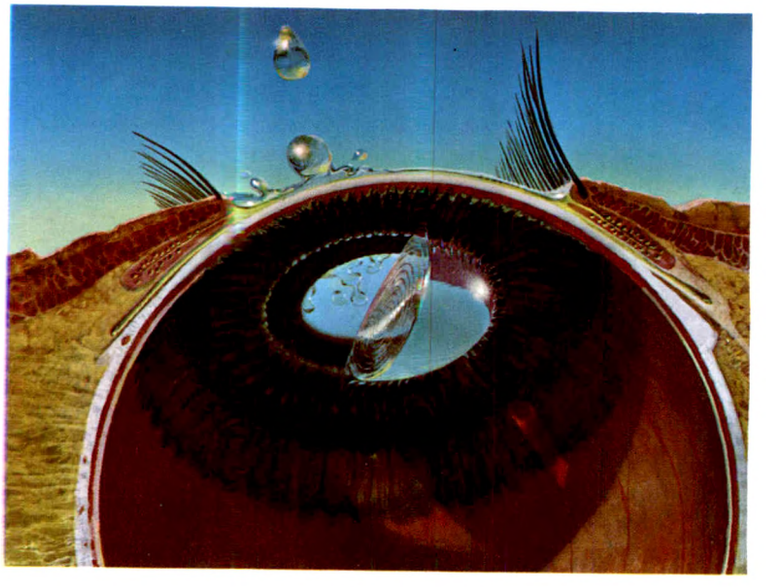
Using a slit lamp fluorophotometer, "the effects of ophthalmic vehicles on the intraocular penetration of topical fluorescein in man" were determined. "Quantitative data on ocular penetration of this drug, in man, in vivo are presented."

### The study

Fluorescein combined with hydroxypropyl methylcellulose 0.5%, polyvinyl alcohol 1.4% and aqueous; each vehicle instilled in the eyes of 20 normal subjects; each subject served as his own control; hourly measurements of attained drug concentration were made quantitatively using a slit lamp fluorophotometer.

### The findings

CORNEA



Over a three hour period, hydroxypropyl methylcellulose produced corneal drug levels 85% higher than polyvinyl alcohol and 43% higher than the aqueous vehicles.‡

AQUEOUS HUMOR

Over a three hour period, hydroxypropyl methylcellulose produced aqueous humor drug levels 93% higher than polyvinyl alcohol and 42% higher than the aqueous vehicle.‡‡

### The authentication

The authors state that their findings may, or may not, be true for drugs other than fluorescein. However, the findings reported above were achieved "consistently and reproducibly"; data were analyzed and tested for significance on a computer.

# when infectious inflammations demand a long-lasting sulfa/steroid

The Isopto® Cetapred vehicle makes for greater concentrations[1] of drug in ocular tissue. Combined with broad, anti-infective range, the high levels of anti-inflammatory action provide rapid and prolonged relief of symptoms—pain/hyperemia/exudation—greater therapeutic efficacy, and maximum patient comfort.

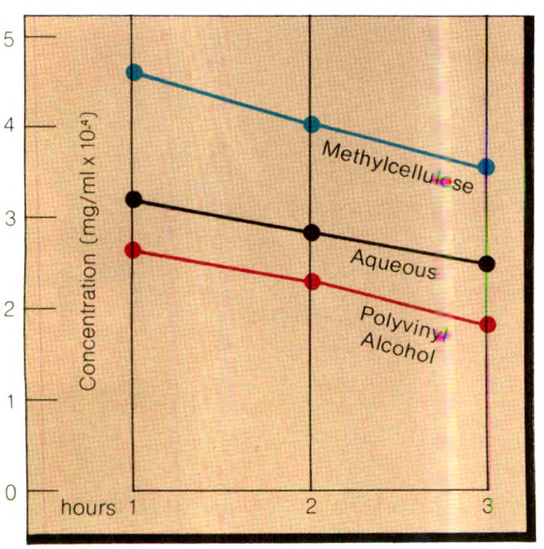
**Cetapred® Ophthalmic Preparations:**

**Description:** *Solution:* Sterile, containing: *Active:* Sodium Sulfacetamide 10%, Prednisolone Acetate 0.25%; *Vehicle:* Hydroxypropyl Methylcellulose 0.5%; *Preservatives:* Thimerosal 0.01%, Sodium Thiosulfate 0.1%; *Inactive:* Sodium Biphosphate, Dried Sodium Phosphate, Hydrochloric Acid (to adjust pH), Purified Water.

**Ointment:** Sterile, containing: *Active:* Sodium Sulfacetamide 10%, Prednisolone Acetate 0.25%; *Preservatives:* Methylparaben 0.05%, Propylparaben 0.01% *Inactive:* White Petrolatum, Anhydrous Liquid Lanolin, Mineral Oil.

**Precautions—Adverse Reactions:** Extended use may cause increased intraocular pressure, which should be checked frequently. Perforation may occur in diseases causing thinning of the cornea. Institute other therapy if favorable response is not obtained within reasonable period. Discontinue if sensitivity occurs.

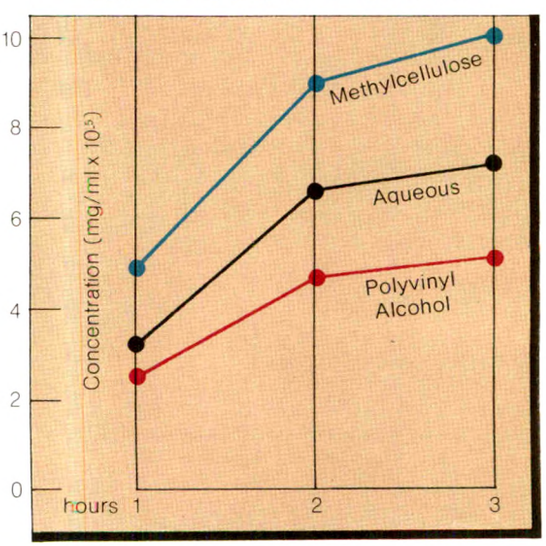
**Contraindications:** tuberculosis, fungal, and most viral lesions of the eye; vaccinia; varicella; acute purulent conjunctivitis, acute purulant blepharitis.



**Supplied:** In 5 cc and 15 cc Drop-Tainer® dispensers; sterile ointment in 1/8 oz. tubes.

**References: 1.** Waltman, S.R. and Patrowicz, T.C.: Invest. Ophthal. 9:966, 1970.
**2.** Linn, M.L. and Jones, L.T.: Amer. J. Ophthal. 65:76, 1968.

Isopto® vehicle (hydroxypropyl methylcellulose 0.5%)
produced significantly higher drug penetration and concentration
compared with 1.4% polyvinyl alcohol or aqueous vehicles.

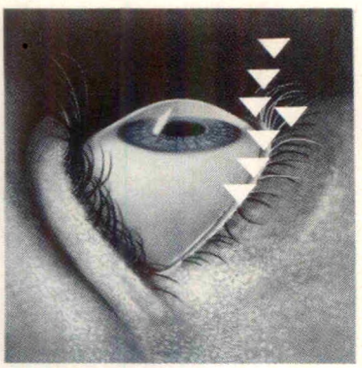


‡Concentration in human cornea

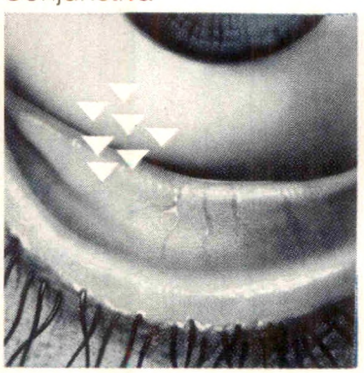
Corneal fluorescein concentration after topical 2% fluorescein in various vehicles.

‡‡Concentration in human aqueous humor

Aqueous humor fluorescein concentration after topical 2% fluorescein in various vehicles.



Adapted from Waltman, S.R. and Patrowicz, T.C.: Effects of hydroxypropyl methylcellulose and polyvinyl alcohol on intraocular penetration of topical fluorescein in man, Invest. Ophthal. 9:966, 1970.



...therefore, when penetration makes the clinical difference

*Licensed under U.S. Patent 3,134,718

Nancy's classmates won't call her names now...

## and her accommodative esotropia no longer affects her grades

Over two years ago, Nancy showed an esophoria of 6 Δ at distance and an intermittent esotropia of 15 Δ at near, with imperfect fusion. She was put on PHOSPHOLINE IODIDE 0.125% O.U., at first once a day. This dosage regimen was reduced gradually to once a week. Orthoptic measures were employed to increase binocular control. Nancy now has an esophoria of 12 Δ at near, no tropia, and excellent stereopsis. Fusion is still variable for near. Vision is 20/20 in each eye. She no longer requires eyedrops.*

## for diagnosis

One drop of PHOSPHOLINE IODIDE 0.125% instilled in both eyes for two or three weeks can help determine if there is an accommodative basis for the esotropia.

## in treatment

If there is a significant accommodative factor present, the continued use of PHOSPHOLINE IODIDE alone is often sufficient for treatment.

If surgery is necessary, postoperative use of PHOSPHOLINE IODIDE may help correct a residual deviation.

*Case history courtesy of Orthoptic Clinic, Department of Ophthalmology, N.Y.U. Medical Center, N.Y. School of Medicine, New York, N.Y. Other children are professional models.

**BRIEF SUMMARY**
**(For full prescribing information, see package circular.)**

**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, browache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local):* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have also been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic):* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

## Tillyer Topics

E. WILLIAM TILLYER

# Modulation Transfer Function

There is a great deal of discussion today about the Modulation Transfer Function, or "M.T.F." M.T.F. refers to what you get out of a lens based on what you put in. Or, how good is the image in relation to the reality? It is used widely today in optics of all types.

All of us are aware of the marginal errors that are present when a lens is not properly designed. As a matter of fact, errors are always present to some degree—even in the best of lens designs. These are usually marginal astigmatic and oblique spherical errors, or vision reductions caused by lateral color blur.

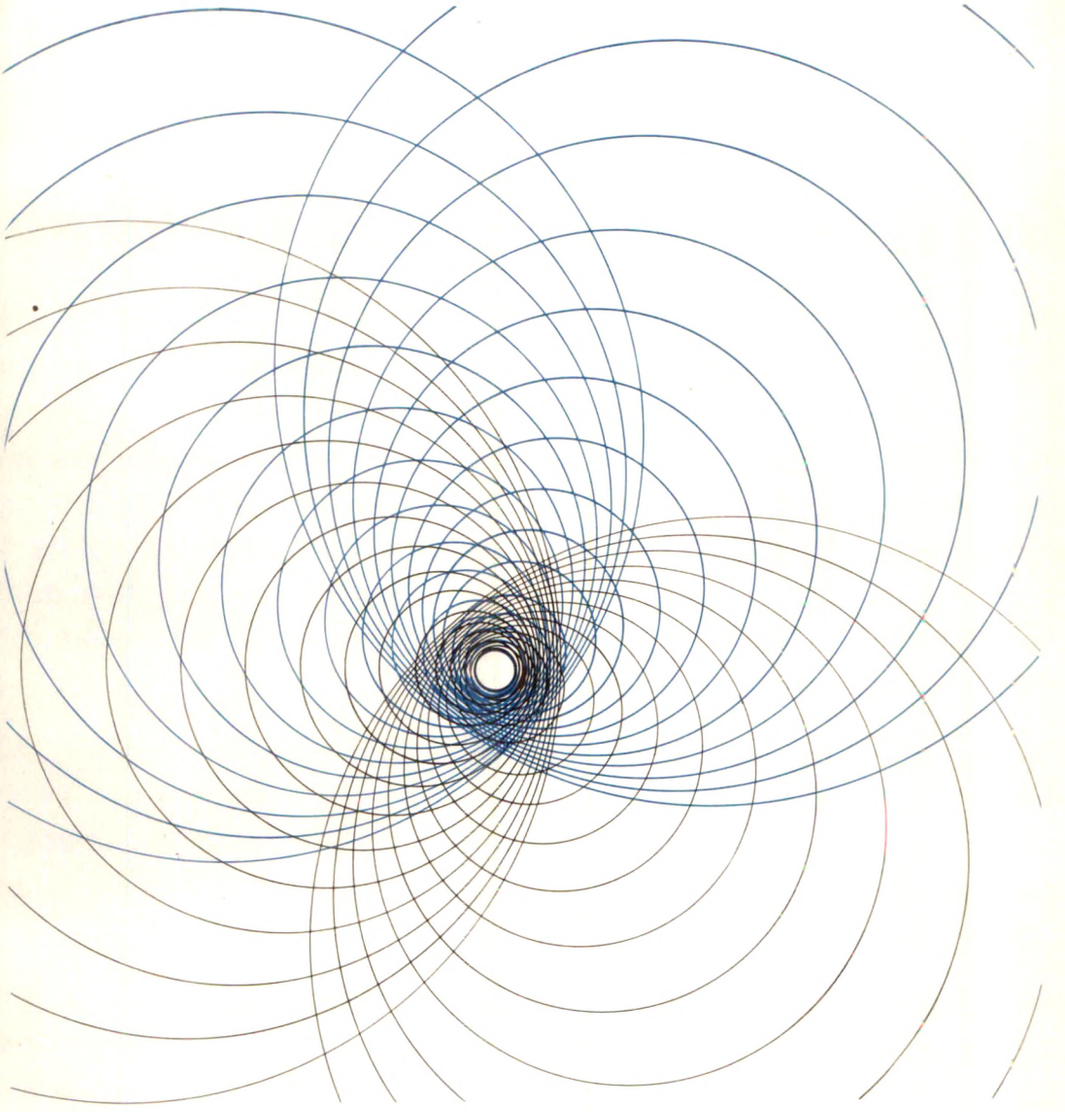
Modulation Transfer Function takes all of these factors into account. Plus any surface defects that might affect resolution. And, in the form of a ratio, M.T.F. says that the lens' ability to create a sharp image is reduced by a factor. The factor is the ratio of the contrast or modulation that enters the eye to that which enters the lens.

Our problem with ophthalmic lenses differs from the problems involved with telescope or total light gathering lenses. Because we never use the whole lens at any given time.

Therefore, we must consider an ophthalmic lens as a series of connected 7mm or 8mm lenses and determine the M.T.F. in each area by analyzing the power, absorption and color errors. Then we can consider what base curves should be used to arrive at the best over-all performance. This will be based on the results from each section of the lens that will be used by the patient.

But design alone is not enough. An M.T.F. measurement would show that without top quality surfaces the resolution is not what it can be.

Therefore, the importance of a fine ophthalmic surface must never be overlooked. If the surface is not the finest—even though the proper curves are used—the patient will not get the image reproduction implied in his Rx.



The deficiencies of the surface aren't usually picked up through the use of the Lensometer. Simply because scanning the entire lens, point for point, for waves, irregular surfaces or poor polish is a long and tedious job.

How, then, can you know which ophthalmic lenses will give your patients the best vision?

The answer is that you must depend upon the reputation of the manufacturer and the Rx laboratory. To duplicate the testing equipment required to determine which is the better lens would be extremely costly. Also to examine every lens would take too much of your valuable time.

So, in the final analysis, only by selecting lenses manufactured to the highest standards can you realize the accuracy of your refraction. And provide the patient with the fine vision to which he is entitled.

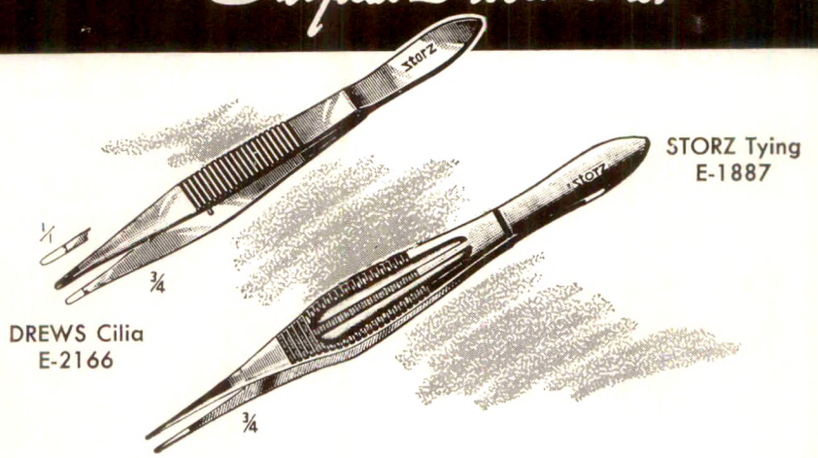
# When a trifocal is indicated... don't prescribe Younger Seamless Lenses!

**It has never been suggested that Younger Lenses were an "all-purpose" replacement for any well-designed, quality multifocal. Youngers are ophthalmically precise, *cosmetic* lenses, offering both distance and near fields invisibly. To the onlooker, they're exactly like single-vision lenses. Youngers are designed solely to bridge the *psychological* change in vision patterns and they don't make the patient look any older, as do the usual age-revealing, visible bifocals.**

**However, if the patient *needs* the three fields of a trifocal for efficient vision, even Younger lenses won't help. So we say . . . by all means prescribe the *finest quality trifocal* you can order. There is no substitute for trifocals when indicated, and your patient is entitled to the best you can provide.**



**NO FITTING PROBLEMS, NO LAB PROBLEMS with Youngers. If your patient has just graduated into the bifocal-wearing class (.75D to 1.75D adds seldom need an intermediate), help her or him (he's vain, too!) with the finest lens of its kind . . . Younger Seamless Lenses. Now available in Younger-Lite Hard Resin as well as glass, from most independent labs and all American Optical branches.**

# Introducing
# SWIRL CLEAN™
## electric contact lens cleaner by Contique™

## the professional way to clean contact lenses

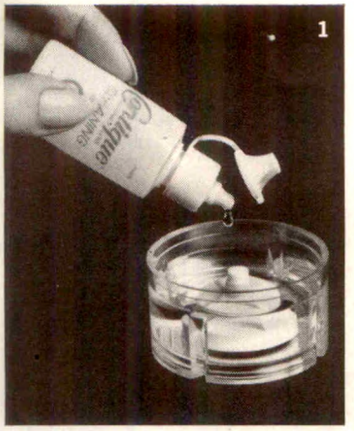
Until now, the most common method cleaning contact lenses has been to rub th between the fingers. As you know, this syst has three serious drawbacks: 1) it doesn't cle properly; 2) it *can* scratch or warp lenses; 3 may not be sanitary.

### A new, more efficient technique

The new Swirl Clean electric contact le cleaner by Contique approaches the problem a totally different manner: It combines t cleaning power of a high-speed agitator w the detergent action of Contique Cleaning So tion. The result is thorough but gentle clea ing—with a minimum of handling and le chance of lens loss.

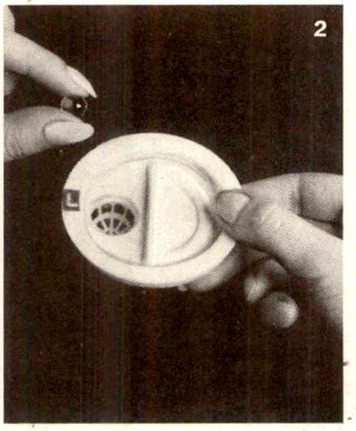
Swirl Clean doesn't stop there. It provid a convenient place to soak and store lenses b tween wearings.

### Perfect for office use



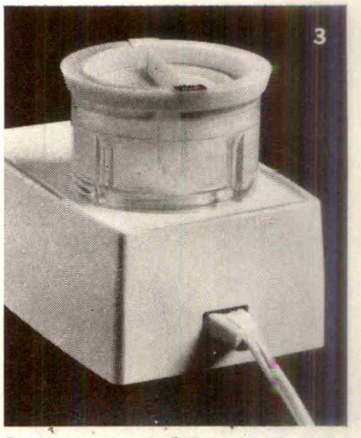
How many times have you wished for ju such an efficient way to clean your patien contacts—when you are delivering a new pa or after making an adjustment?

Swirl Clean fills this long-felt need pe fectly. It's compact. Easy to use. And it *loo* highly professional. Your patients can s you've gone to the expense of securing the mo advanced cleaning device available to mal sure their lenses are clean and comfortable.



And it takes only a few seconds to clea contacts with the Swirl Clean. Once you get in the habit, you'll wonder how you managed wit out it.

### Your patients will want one, too



When they see how effortlessly you clea their contacts with the Swirl Clean, your ne contact lens wearers will want one of their ow to use at home. That's why it makes good bus ness sense to stock a few units to sell or recor mend to your patients. They'll never be mo psychologically receptive than at the mome

**1** *Fill cleaning chamber ¾ full with cold water. Add 6-8 drops of Contique Cleaning Solution and place on base.*

**2** *Place lenses in bottom of clearly marked LEFT and RIGHT baskets of lens holder. Close lid. Place lens holder on cleaning chamber.*

**3** *Flip "ON" switch and run Swirl Clean 30-60 seconds. You can see the lenses being swirled clean before your eyes.*

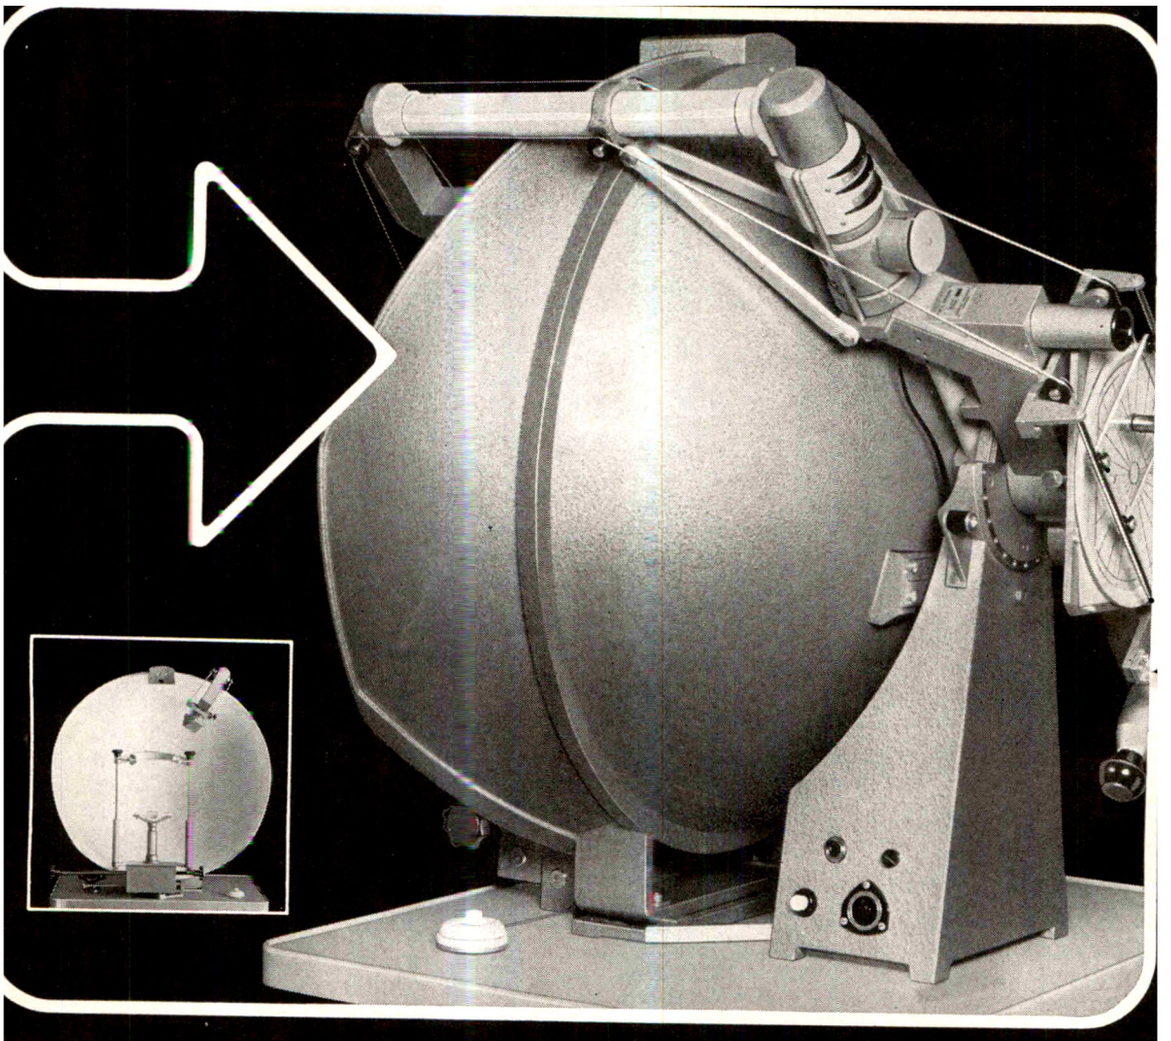
they get their new contacts. It's also a good way of starting them off on a proper lens-care regimen and helping them become satisfied wearers.

### Read what Swirl Clean users say

An O.D. in Knoxville, Tenn. writes: "The compactness of this unit makes its use a pleasure in my office." An M.D. in Bakersfield, Calif. calls Swirl Clean "a very valuable asset to our office." An optician in Long Beach, Calif.: "Excellent method of cleaning lenses after lab adjustment."

Enthusiastic comments have also come in from contact lens wearers all over the country. "My vision is so much better with clean contacts." (Boston, Pa.) "I enjoy its convenience and notice my lenses are more comfortable." (East Point, Ga.) "Cleans lenses 100% better than by hand." (Hyde Park, Mass.) "I wear lenses 16 hours a day and find their comfort greatly increased." (Indianapolis, Ind.)

These comments are on file at Alcon Laboratories and may be examined by anyone interested.



### Complete lens care by Contique

Used with the new Swirl Clean, *Contique Cleaning Solution* dissolves eye-irritating deposits such as mucus, oil and film. Yet it's so gentle you can recommend it with complete confidence. *Contique Soaking Solution* "conditions" lenses by keeping them chemically moist when stored in the special Swirl Clean soaking dish, increasing wettability and wearing comfort. *Contique Wetting Solution* creates a liquid cushion between lens and eyes, makes placement smooth and easy, and can also be used to re-wet lenses during the day.

This family of lens care products from Contique can help your patients become successful, satisfied contact lens wearers. Almost $6 worth of Contique solutions are packed with every Swirl Clean at no additional cost. For more information about the new Swirl Clean and other Contique products, call your optical wholesaler today.

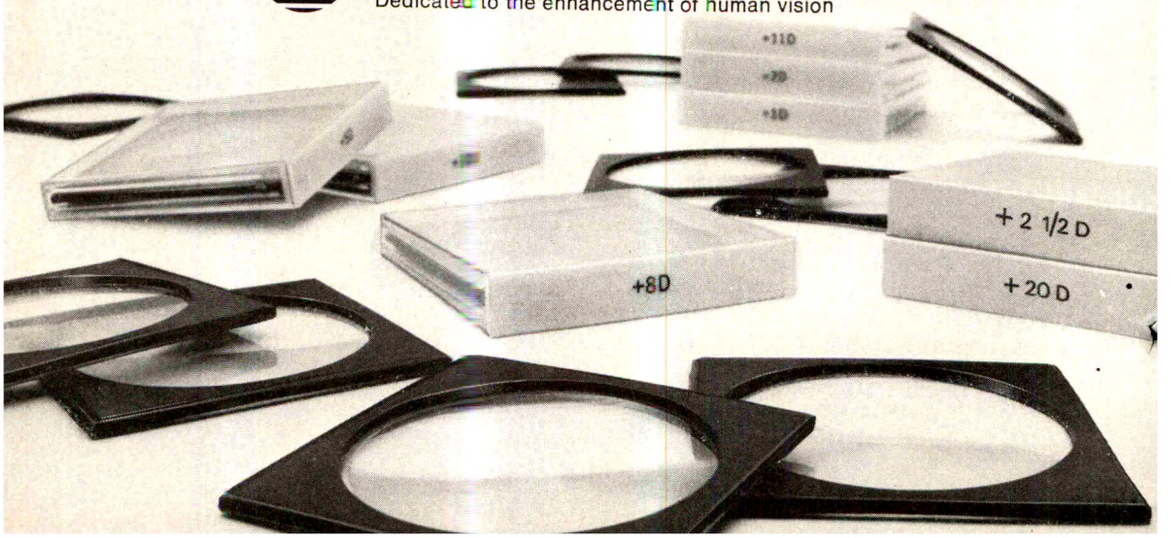
# 18 new ways to treat patients: 18 new Press-On™ Lenses

These eighteen new lens powers dramatically extend the treatment capabilities with Press-On Optics by OSG. The 1mm-thin membranes now range in power from +1D through +20D, including popular fractional diopters. All are lightweight, apply in minutes, are cosmetically attractive and optically outstanding.

With the new powers, Press-On Lenses can now provide help:

**For Post-Operative Cataract Patients . . .**
by permitting immediate post-op wearing of an aphakic correction in their own familiar spectacles . . . by providing aspheric correction with the widest panoramic field of view available

**For Low Vision Patients . . .**
by applying needed power to the ocular surface of even large diameter high fashion frames . . . by providing a large diameter bifocal field not previously available above +3.5D . . . by using as regular bifocal segments up to +6D while providing sufficient decentration to obtain binocular fusion



**For Patients with Vocational Demands . . .**
by meeting unique gaze requirements of librarians, dentists, carpenters, etc. with specially located power segments . . . by providing extra magnification for fine work of jewelers, machinists, inspectors and others . . . by supplying an added safety "laminate" to the ocular surface of a regular spectacle lens . . . by making hyperopic spherical corrections to the inside surface of welders' or machine operators' goggles . . . by adding immediate spherical power to industrial safety glasses for faster on-the-job utilization of new personnel.

**For Patients with Special Hobbies . . .**
by providing out-of-the-way or high-power segments for hobbyists and sportsmen, such as golfers, bowlers, stamp collectors, model builders, fly tyers, etc. . . . by making hyperopic spherical correction to the inside surface of skiers' or skin divers' goggles

**For Bifocal Patients . . .**
by allowing use of higher power segment in various sizes, shapes and positions not previously possible . . . by helping beginning presbyopes establish acceptance of bifocal correction on existing single vision spectacles . . . by creating an intermediate range over existing bifocals for new trifocal wearers before grinding in glass or plastic . . . by converting single-vision sunglasses, including Polaroid and Photochromic, to bifocals . . . by providing segments usable on large size fashion frames

New Press-On Lens plus powers—1D through 8D and 14D through 20D—supplement the 9D through 13D lenses originally introduced by OSG. All are available from an ophthalmic distributor near you. For more information about the Press-On Lens System contact your local distributor or write, Optical Sciences Group, Inc., 24 Tiburon Street, San Rafael, California 94901.

# CONTACT LENS PRACTITIONERS

The next few years promise tremendous changes in the contact lens field. New types of lenses, materials, equipment and fitting techniques will compete for the practitioner's time and attention.

We believe the fitter will look to his laboratory for advice and instruction, as well as for the latest and best lenses. Thus, the need for dependable laboratories with research facilities, knowledgeable personnel and adequate resources, will be evident as never before.

Recognizing this need, we have formed UNION OPTICS CORPORATION, comprising a select group of established laboratories under the leadership of respected contact lens authorities. This organization is now the second largest contact lens manufacturing entity in the U.S.A. We expect it to play a major part in research, development and improvement of contact lenses in the future.

If you are not yet acquainted with our laboratories, we invite you to get in touch with the one nearest you.

available as sterile ophthalmic drops and sterile ointment...

Alcon *dedicated to advances in ophthalmic therapy*

DESCRIPTION: *DROPS*—Sterile suspension containing: *Active:* Dexamethasone 0.1%, Neomycin (present as sulfate) 3.5mg/cc, Polymyxin B Sulfate 6000 units/cc; Vehicle: Hydroxypropyl Methylcellulose 0.5%; *Inactive:* Sodium Chloride, Polysorbate 20, Hydrochloric Acid and/or Sodium Hydroxide (to adjust pH), Purified Water; Preservative: Benzalkonium Chloride 0.004%. *OINTMENT—Active:* Dexamethasone 0.1%, Neomycin Sulfate equivalent to 3.5mg/gm Neomycin; Polymyxin B Sulfate 6000 units/gm; *Inactive:* White Petrolatum, Anhydrous Liquid Lanolin; Preservatives: Methylparaben 0.05%, Propylparaben 0.01%. CONTRAINDICATIONS: This drug is contraindicated in tuberculous, fungal, and most viral lesions of the eye (herpes simplex/dendritic keratitis); vaccinia, varicella; acute purulent conjunctivitis and acute purulent blepharitis, and in those persons who have shown hypersensitivity to any of its components. PRECAUTIONS: Extended use may cause increased intraocular pressure which should be checked frequently and may result in overgrowth of nonsusceptible organisms. Perforation can occur in diseases causing thinning of the cornea. Discontinue use if sensitivity occurs. Not recommended for long-term use in pregnant patients.

# MANAGEMENT OF CORNEAL PROBLEMS WITH HYDROPHILIC CONTACT LENSES

## A REPORT OF 30 CASES

JOHN W. ESPY, M.D.

*New York, New York*

Several earlier reports[1-6] describe the use of hydrophilic contact lenses for various therapeutic and optical indications. This paper reports the results in 30 consecutive patients with corneal diseases fitted with Griffin hydrophilic lenses at the Presbyterian Hospital during the past year.

### MATERIALS AND METHODS

*The lens*—The material used in the manufacture of the Griffin lenses is a combination of 2-hydroxyethyl methacrylate (HEMA), a hydrophilic polymer, mixed with other plastics. The chemical structure and characteristics of the HEMA polymer were described initially by Wichterle and Lim[7] in Czechoslovakia, and more recently by Gasset and Kaufman.[2] Because of the differences in the material and purification methods, the Griffin lens varies considerably from the other hydrophilic lens manufactured in this country (Soflens, Bausch and Lomb, Inc.). At the time of this study, the Griffin lens had not yet received FDA approval, and therefore, it was only available to investigators.

The main virtues of the Griffin lens are its index of refraction, softness, and ability to equilibrate with human tears. When fully hydrated, it is approximately 55% water by weight. In the hydrated state, the lens cannot fracture, but when it is dehydrated, it is quite brittle.

There is recent evidence that, unlike the original Czechoslovakian lenses, fluid and nutrients are exchanged through the Griffin lens in significant amounts. Whether this is adequate or not to maintain normal corneal metabolism is uncertain, but if this proves to be correct, tear flow and tear interchange would cease to be important considerations.

The Griffin lens is cut in the hard form, ground, and polished. The lenses are available in the following base curves: 7.2, 7.5, 7.8, 8.1, and 8.4 mm. The diameters of the lenses are 12.5, 13.0, 13.5, 14.0, 14.5, and 15.0 mm. Both surfaces are spherical. The inside surface of the edge has a bevel varying from 0.3 to 0.5 mm. The edge is thin but well rounded. The front edge has a lenticular cut to reduce thickness.

In fitting the lens, the curve–diameter relationship is the critical factor. A keratometer reading is useful as a starting point to get the base curve, and the lens should approximate the base curve of the flattest corneal meridian. The lens touches the central cornea and sclera arching the limbus. The diameter of the lens should be 2.0 mm larger than the cornea, thereby covering 1.0 mm of sclera around the limbus. The lens should center on the cornea with no restriction of eye movements, no movement with blinking, and no lens lag with rapid shift of gaze.

The Griffin lens is sterilized by soaking it in 3% hydrogen peroxide for five minutes,

From the Institute of Ophthalmology, Columbia-Presbyterian Medical Center, New York, New York.

Reprint requests to John W. Espy, M.D., 945 Lexington Avenue, New York, New York 10021.

followed by shaking the lens in normal saline buffered with 0.65% sodium bicarbonate for one minute. The lens is then shaken in normal saline for one minute, and placed in fresh saline for 45 minutes. Boiling the Griffin lens will cause deterioration. Eye medications cannot be used when the lenses are being worn, as the lenses will absorb the medication and concentrate the preservative, thus damaging the corneal epithelium.[2]

*The patients*—Without preselection, 30 consecutive patients with corneal diseases were fitted with Griffin hydrophilic contact lenses by following the curve–diameter relationship described above. All were outpatients. Initially, each was seen daily, the lenses were removed, and the cornea examined for any evidence of irritation by the lens. The lens was then sterilized and re-inserted. The time between examinations was gradually lengthened, depending on each patient's condition. Some patients were able to wear the lenses 24 hours a day from the start, and some removed the lenses at night. Several elderly patients with irritated eyes found it impossible to insert and remove the lenses themselves. No topical medications were used. To keep the lenses well hydrated, the patients were instructed to use a drop of saline every hour, but with adaptation the drops were used less frequently. The result was considered good if the condition was controlled or improved with the lens.

## Results

*Bullous keratopathy*—The largest group of patients treated were those with bullous keratopathy (Table 1). Their eyes became white and quiet. Although fitted primarily to relieve the symptoms of pain and irritation, there was an unpredictable improvement in vision. In some cases this was dramatic (in one case, 20/200 to 20/50). The improvement in the visual acuity appears to be due to a flattening of the large epithelial bullae, and not due to any significant change in stromal thickness or decrease of folds in Descemet's membrane. The use of 5% sodium chloride[2] appeared to have no effect, although it was well tolerated by all patients.

As in the eight cases reported by Lerman and Sapp,[4] all except one patient tolerated the lenses well. After a few weeks, these patients were seen only every two to three months for examination and sterilization of the lenses. One patient removed her lenses at night, but all others wore their lenses 24 hours a day. Some of the 11 successful patients have now been wearing their lenses constantly for over six months. The cause of the single failure is not clear, but the eye became red and irritated and the lens was discontinued after one week. No complications occurred in the remainder of this group.

*Neurotrophic and neuroparalytic keratitis*—The three patients with neuroparalytic keratitis from seventh nerve paresis (Table 2) had tarsorrhaphies, but the corneas continued to stain. The eyelid adhesions were released and they were fitted with lenses. They had immediate subjective improvement and the corneal staining cleared. The vision with the lenses in place was satisfactory. These patients remove the lenses at night, and taped their eyelids shut.

The two patients with fifth nerve lesions and neurotrophic keratitis had complete clearing of the epithelial irregularities and improvement in vision. One of these patients had previously worn a scleral lens, but it proved unsuccessful because of irritation and mucous problems. He had no difficulty with the hydrophilic lens, which he removes at night. The other patient had marked epithelial irregularity after an automobile accident. He wears the lens 24 hours a day for protection from the scarred and roughened upper eyelid.

*Corneal ulcers*—This group of patients (Table 3) was the most challenging because of the acute nature of the problems. All the patients had been treated for varying lengths of time with topical corticosteroids or antibiotics, or both, plus pressure dressings, without improvement. In each case, the bacterial culture was negative. The corneal ulcers in

the two patients with disciform keratitis (metaherpetic), the indolent ulcer in the patient with thyroid ophthalmopathy, and the case of radiation keratitis all involved the deep stroma. The other two involved the anterior stroma.

The patients were fitted with the lenses and followed daily. The two cases of disciform keratitis did not improve. The eyes became red and more irritated. The lenses were discontinued, and the patients were hospitalized, where one responded to topical corticosteroids and microthermy with the ulcer filling in. The other patient did not respond to similar treatment and the cornea perforated several months later.

The only complication in this study occurred in a patient who received extensive radiation to the right antrum for carcinoma of the antrum. The skin around the right eyelids was severely affected, and the cornea broke down. She was extremely uncomfortable, and had marked subjective improvement for several weeks after being fitted with a lens. However, over a weekend, she developed a severe superficial infection under the lens, and a 4 mm sterile hypopyon developed. She was admitted to the hospital and initially she responded to conservative treatment. Two months later the cornea dissolved and perforated. This was followed by an expulsive choroidal hemorrhage, and the eye was enucleated.

The patient with thyroid ophthalmopathy had a deep indolent ulcer near the limbus at approximately five o'clock. After wearing the lens continuously for five weeks, there was minimal vascularization from the limbus and the ulcer filled in with fibrous tissue. In the two patients with superficial ulcers, in one case due to a degenerating graft and the other to herpes zoster, the epithelium regenerated while wearing the lenses. These patients wore the lenses 24 hours per day. The staining completely cleared and the vision improved dramatically. When their eyes had healed, the lenses were removed, and there have been no recurrences.

*Keratitis*—Five patients were treated for keratitis (Table 4). One patient with keratitis sicca did not do well, because the vision was poor due to a high corneal astigmatism. The other patient with keratitis sicca, and the three patients with superficial punctate keratitis following cataract extraction, tolerated the lenses well; vision was good, and

* Superficial punctate keratitis.

the corneas did not stain. One has macular changes resulting in poor vision.

*Essential conjunctival shrinkage*—These two patients (Table 5) had dry eyes, scarred eyelids, and trichiasis due to pemphigus and Stevens-Johnson disease. Because damage occurs at night as well as during the day, the patients wear the lenses 24 hours a day. One of these patients did poorly because it was impossible to follow him adequately.

## DISCUSSION

Of the 30 patients fitted with the Griffin hydrophilic contact lens, 24, or 80%, responded favorably, indicating that these lenses are a useful adjunct in the management of some difficult corneal diseases. They act as a protective shield and prevent drying much as a tarsorrhaphy or conjunctival flap in neurotrophic keratitis, neuroparalytic keratitis, and corneal ulcers; but the results are often more satisfactory and the vision can be maintained. Furthermore, in cases where cautery of Bowman's membrane is indicated, as in bullous keratopathy, a hydrophilic lens gives adequate relief of the irritating symptoms and often some improvement in vision, as well. In cases of keratitis sicca and superficial punctate keratitis, where hard contact lenses are contraindicated, the hydrophilic lenses supply a precorneal source of fluid and prevent evaporation. For protection against scarred eyelids and trichiasis, as in pemphigus and Stevens-Johnson disease, they can be worn 24 hours a day without complications.

The poorest results in this study were with corneal ulcers involving the deep cor-

TABLE 5

ESSENTIAL SHRINKAGE OF CONJUNCTIVA
(2 Cases)

| Age in Years | Etiology | Visual Acuity | | Hours Daily Wear | Weeks of Wear | Result |
|---|---|---|---|---|---|---|
| | | With Lens | Without Lens | | | |
| 71 | Pemphigus | 20/70± | 20/30 | 24 | 16+ | Good |
| 12 | Stevens-Johnson disease | 20/100 | 20/50± | 16 | 6 | Poor |

neal stroma. Liebowitz and Rosenthal[5] reported a higher percentage of success, but in their cases the ulcers were mostly superficial, the epithelium was removed before fitting the lenses, and chloromycetin drops were used. The only serious complication occurred in the patient with severe radiation keratitis. In all other indications, a high success rate is predictable.

The mechanism by which the lenses produce their therapeutic effect may not only be due to the protective bandage shielding the eye and the fact that they supply a constant precorneal source of fluid. In addition, Liebowitz and Rosenthal suggest that the hydrophilic contact lens also provides a structural framework upon which the regenerating epithelium may grow.

Because a few patients experience some irritation initially, a gradual buildup in wearing time is preferable, when this is compatible with the disease being treated. However, there is no gross epithelial edema, as seen initially with hard lenses, and the lenses do not cause corneal staining. There is minimal conjunctival injection and the eyes are white and quiet. Except for one patient successfully treated for corneal ulcer, there has been no vascularization noted in patients wearing the lenses continuously for as long as nine months.

A small percentage of patients do not tolerate the lenses, although the reason is not apparent. Occasionally, even in a patient in whom the lens is successful, the eye will become red and irritated for no evident reason. If the lens is removed for a few days, usually it can be re-inserted and again well tolerated. Extremely careful follow-up is essential. Although the patients in this study were followed as outpatients, initial hospitalization for acute problems should be considered.

This study substantiates the results of others that hydrophilic lenses offer a valuable alternative in the management of difficult corneal problems. Because of the semirigid nature of the Griffin lens, it may offer certain advantages in some indications over a more flexible hydrophilic lens.

## Summary

Thirty unselected patients with bullous keratopathy, neurotrophic and neuroparalytic keratitis, corneal ulcers, keratitis sicca and superficial punctate keratitis, and essential shrinkage of the conjunctiva from ocular pemphigus and Stevens-Johnson disease were fitted with Griffin hydrophilic contact lenses. For acute problems, the lens was worn until the corneal lesion healed, and in chronic conditions the lens is worn permanently to control the disease and alleviate symptoms. Eighty percent of the patients reported responded favorably.

The lens is available in base curves ranging from 7.2 to 8.4 mm, and in diameters 12.5 to 15.0 mm. The curve–diameter relationship is critical in fitting the lens. The lens should touch the central cornea and sclera arching the limbus and extend 1 mm beyond the limbus. It should center on the cornea with minimal movement and cause no restriction of eye movements.

Sterilization of the lens requires approximately 50 minutes, during which time the lens is successively placed in solutions of hydrogen peroxide, buffered saline, and normal saline.

# BIONITE HYDROPHILIC CONTACT LENSES USED AS COSMETIC DEVICES

JAMES V. AQUAVELLA, M.D., G. KEEFE JACKSON, M.D., AND L. FRASER GUY, M.D.
*Rochester, New York*

In evaluating reports of experience with the various hydrophilic contact lenses, it is important to bear in mind that each is a specific entity, having its own distinct physical and chemical characteristics.

Despite the warnings of certain investigators (Gasset and Kaufman[1,2]), the increasing number of published reports has tended to obscure this fact. These differences necessitate the development of specific techniques for use with a particular hydrophilic material. Many of the methods which have been developed for use with standard methyl-methacrylate lenses must be discarded or modified before being applied to lenses of another material.

This paper reports the results obtained in fitting 89 cosmetic cases with the Bionite* hydrophilic contact lens, employing a standard technique.

## MATERIALS

In general, the Bionite lens is available in powers ranging from plus 20 to minus 20 diopters. Four standard diameters are currently being manufactured (13, 13.5, 14, and 14.5 mm). In addition, each lens is available in any one of several radii of curvature (8.7, 8.4, 8.1, 7.8, 7.5, and 7.2 mm). Isotonic saline solution is supplied by the manufacturer in plastic bags containing 400 ml; Bionite capsules containing sodium bicarbonate are also offered. A 3% hydrogen peroxide solution may be purchased by the patient without prescription in any pharmacy.

## SELECTION OF CASES

Preliminary investigation with the Bionite lenses revealed that moderate to high degrees of corneal astigmatism cannot be corrected consistently (Kaufman and Gasset,[2] and Gasset[3]). Therefore, patients were excluded if their astigmatic error was greater than 1.50 diopters. In addition, all patients included in this series were free of active ocular disease, each had expressed a desire to wear cosmetic contact lenses, and each was willing to participate in the investigational program.

Although eventually all powers of lens will be available, at present plus powers are in short supply, and therefore this series includes only one patient with hyperopia.

## CALIBRATION OF LENSES

The trial lens set employed for this series consisted of only 10 lenses; these varied in radii of curvature from 8.4 to 7.5 mm and in diameter from 14.5 to 13.0 mm. The average power of the trial lenses employed was minus 3.00 diopters.

Although the lenses are delivered in individual containers marked with the various parameters, each lens was re-checked for accuracy of power, diameter, and radius of curvature. The power of the lens is ascertained by blotting both surfaces to remove excess moisture and then reading the power on a lensometer. The effectiveness of the Bionite lens is related to its state of hydration, so that one should read the power of this lens within a few seconds after blotting.

The radius of curvature (base curve) is measured with the optical gauger. This device is made up of a series of plastic studs whose distal extremities have been ground to the standard radii. By placing a lens over the various studs one can quickly ascertain the base curve of the lens.

The diameter of the lens was confirmed by placing it on a magnifying reticle.

### Fitting procedure

Gasset[3] has recommended employing the keratometer reading as the starting point for the fitting procedure. In our hands this proved both cumbersome and misleading. We soon developed our own method of fitting, however, and can suggest the following standard procedure: The ideal lens diameter is 1.2 mm greater than the corneal diameter, so we suggest starting with a lens 14.0 to 14.5 mm in diameter. In addition, experience has demonstrated that the long-term results are far superior with a lens that has a relatively flat radius of curvature. Therefore, initially we always select a lens with an 8.4 mm radius of curvature and a diameter of 14.0 or 14.5 mm. We make no attempt to correlate the power of this first lens to the patient's actual refraction. After insertion of the lens, patients invariably experience a mild foreign-body sensation which lasts approximately 30 seconds. As soon as the patient is comfortable the lens is inspected. First, we ascertain that the diameter is approximately correct and second, we check the stability of the lens on the cornea. The lens should move readily with each blink and there should be some small degree of displacement with lateral or downward gaze. At this stage, corrections may be indicated: The diameter may be altered if necessary, a steeper lens may be employed if the adherence is grossly inadequate, or a flatter curve may be necessary in cases where the motion is obviously inadequate. After the fitting is satisfactory, the trial lens is then worn for 20 minutes to allow for stabilization. When 20 minutes have elapsed, the lens is re-inspected to ascertain that the lens is not adhering excessively to the cornea; if not, the over-refraction may be performed. In performing the over-refraction, the retinoscopic image often provides an excellent clue as to the resultant visual acuity—the aim is to obtain a consistently clear 20/20 acuity which does not seem to vary with blinking. Theoretically, we anticipate that the spherical equivalent of the manifest refraction will be within one-half diopter of the power of the prescribed Bionite lens. The algebraic sum of the over-refraction and power of the trial lens equals the power of lens to be ordered.

Fig. 1 (Aquavella, Jackson, and Guy). Diagram showing the lens-cornea interface area in a proper fit relationship.

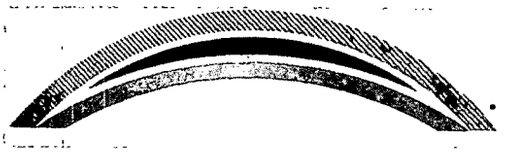

Fig. 2 (Aquavella, Jackson, and Guy). Diagram showing the lens-cornea interface area when the lens is too steep.

A cross section of the interface area in a case of proper fit (Fig. 1) reveals only a very thin tear film layer interposed between the lens and the cornea. If the lens is too steep, the interface area will have a plus lens effect (Fig. 2) and in the process of over-refraction the patient will accept an unusually high amount of minus correction. In addition, if the patient blinks, the interface area will tend to collapse, temporarily eliminating the plus tear film, and producing a variability both in the subjective acuity and in the objective retinoscopic reflex.

With the completion of the over-refraction, the specific lenses may be ordered with the correct diameter, radius of curvature, and power.

### Insertion and removal

We advocate that the patient receive preliminary instruction on insertion and removal at the first visit. In addition, we supply a sample lens so insertion and removal may be practiced at home. In this way, the patient quickly becomes adept and the initial experience is with an expendable lens rather than with the specially ordered material.

The recommended technique is as follows:

*Insertion*—The patient places the lens on

the index finger, looks up and holds the eyelid down with the other hand. He then places the lens on the inferior sclera, presses gently, and closes the eyelids.

*Removal*—The patient looks up and pulls the lower eyelid down, exposing the inferior bulbar conjunctiva. With the tip of the index finger the lens is moved down and pinched against the thumb. This permits air to pass under the lens, facilitating removal.

### Sterilization and storage

The recommended daily procedure was developed specifically for Bionite lenses by Gasset, Kaufman, and Morrison[4]; it is effective against bacteria, fungi, and herpes simplex virus. Furthermore, its routine use adds durability and strength to the new lenses. The procedure requires only a few minutes at bedtime.

On retiring, the lenses are placed in the case and the case is filled with hydrogen peroxide 3%. After five minutes the peroxide is discarded. The case is then filled with normal saline solution and the contents of a Bionite capsule, containing a pre-measured amount of sodium bicarbonate USP. After a one-minute soak in this solution, the solution is discarded and the lenses are rinsed four or five times with sterile normal saline. The case is then refilled with sterile saline and the lenses are allowed to soak overnight. Before insertion in the morning, the lenses are soaked again in a fresh change of sterile normal saline solution.

### Delivery

Prior to their delivery to the patient, the lenses are rechecked as to the accuracy of the power, diameter, and radius of curvature. Following this, they are sterilized. At the time of delivery, the lenses are inserted and after 20 minutes visual acuity and accuracy of fit is rechecked. Patients are instructed to wear their lenses during essentially all their waking hours. With properly fitted Bionite lenses no gradual increase in the wearing time is necessary.

### Results

Of 89 cases (178 eyes), there were 82 successes (92%); 78% achieved 20/20 vision, 11.2% had 20/25, and 3.4% had 20/30.

There were seven cases (8%) termed as failures. Final visual acuity in 7.4% of the 178 eyes was 20/40-20/60. Cases considered failures are as follows:

Case 1 is a young attorney who was unable to wear standard methylmethacrylate lenses. He reported variable acuity with the Bionite lenses, and complained of difficulty with insertion and removal.

Case 2 was termed a failure because the patient could not achieve good acuity, although she demonstrated no significant residual astigmatism.

Case 3 did well and reported good stable acuity without adverse effects, but this patient was advised by her allergist not to wear contact lenses.

Cases 4 and 5 were patients who were very apprehensive and nervous individuals who could not master the insertion and removal technique. They both have narrow interpalpebral fissures. Case 4 developed blepharospasm and a tendency to over accommodate when wearing the lenses.

Case 6 was unable to achieve satisfactory acuity due primarily to residual astigmatism.

Case 7 demonstrated good acuity but could not master insertion and removal.

Three of the successful cases deserve further comment. One has high myopia (−9.50) with two and one-half diopters of astigmatism in one eye. She has a significant amount of residual astigmatism in this eye and her acuity with the lens is only 20/60. The fellow eye has less astigmatic error and adequate acuity. The patient is happy and comfortable.

Another is a 14-year-old student with a personality problem who absolutely refuses to wear spectacles, despite a significant refractive error.

A third patient is a 16-year-old high school athlete who has difficulty participating in sports while wearing spectacles. Despite a

significant degree of residual astigmatism resulting in 20/40 vision, he is comfortable and enjoys his lenses for this purpose.

## Discussion

Fluorescein and other dyes must not be used with hydrophilic lenses as the dye will become incorporated within the lens. The lenses should be removed before instilling eye medications. If a disease develops which requires the wearing of a "bandage" hydrophilic lens and the instillation of medication, a special lens should be provided for wear during the treatment period in order to prevent the incorporation of the medication into the cosmetic lens.*

If the patient is having difficulty in wearing the lenses comfortably, or if he reports corneal injection or slight irritability with varying visual acuity, it is important to recheck the lenses for changes in diameter or radius of curvature. Most of these difficulties are caused by lenses that are "too tight." If that is the case, the patient will invariably be more comfortable with a lens of increased radius of curvature. Some of the earlier Bionite lenses had a tendency to become steeper when the fitting was "too tight." With improved manufacturing technique, this is no longer a common occurrence.

Isolated epithelial edema was rarely observed and always responded to selection of a flatter or thinner lens; restriction of wearing time did not become necessary. One recurring problem was the splitting of the lenses by the patient. Women patients with long fingernails, who had not completely mastered the removal technique, often scratched or nicked their lenses during the process of removal, and a lens so damaged tended to split either then or later. In addition, if the there were small nicks or defects in the lens periphery that had escaped the scrutiny of the manufacturer's quality control inspection, such lenses would be predisposed towards splitting when, on wearing, they were flexed in the appropriate axis.

Splitting has been satisfactorily controlled by a combination of several measures. Because of improved quality control by the manufacturer, all lenses are now free from peripheral defects on delivery. Patients are now given full instructions on insertion and removal, and this, combined with the policy of lending the patient an expendable lens on which to practice these techniques, has lessened the risk of such damage. In addition, our technicians now routinely instruct all women patients to trim the fingernails of the thumb and index finger of both hands prior to manipulation of their lenses.

If the patient notices a foreign-body sensation after insertion of the lens, he is instructed to remove the lens and clean it between the thumb and forefinger with saline to remove lint or other small dust-like particles.

On occasion some of the patients have reported falling asleep with the Bionite lenses in place. These episodes have not resulted any problems. Bandage lens wearers (not included in the present series) are often able to wear their lenses 24 hours a day for several months without discomfort or adverse effects. It is possible for cosmetic lens wearers to report on their progress by telephone, although office visits are advisable after the first and second week.

Because of the degree of adherence between the cornea and the lens, it is extremely difficult for a Bionite lens to loosen enough to fall out. Several patients said they were able to wear their lenses while swimming.

The Bionite lenses may be worn comfortably all waking hours from the first day of wear. No gradual increase in wearing time is necessary to achieve maximum comfort. All of our cases have demonstrated a lack of spectacle blur, and patients have been able to change from their spectacles to their contact lenses and back to their spectacles without

---

* When the Bionite hydrophilic material is used as a bandage in the treatment of corneal disease,[1,3] the technique employed in fitting such a bandage lens differs considerably from that advocated in the present communication.

the usual difficulties encountered by methylmethacrylate lens wearers.

The fact that the Bionite lenses can be worn comfortably for long periods of time is undoubtably due to their inherent fluid and oxygen permeability. This factor probably accounts also for the low incidence of epithelial edema. Gruber[5] reports a comparative lack of permeability to oxygen in his experience with another hydrophilic material (Soflens). He also found that it was necessary to increase the wearing time slowly, despite the fact that the lens used in his study possessed a flexibility similar to the Bionite lens. This suggests that oxygen and fluid permeability may be critical factors in this respect as well.

Although a comparatively elaborate trial set is supplied, the great majority of patients can be fitted quickly and easily with one or two lenses. Certain factors may alter this situation, however. The patient with a narrow palpebral fissure, or one who has difficulty in learning insertion technique, might best be fitted with a lens of a relatively smaller diameter. An individual who is interested in wearing his lenses primarily for sports such as football or swimming might be better served with a larger diameter lens to lessen the possibility of loss. Although the overwhelming majority of patients are quite happy with the acuity that they obtain with the Bionite lenses, many individuals do demonstrate a small degree of residual astigmatic error. The manufacturers plan to produce a toric lens in the near future. This should prove very helpful in correcting moderate to high degrees of astigmatism.

Currently, a much more simplified system for storage and sterilization is under investigation which will eliminate the necessity of the hydrogen peroxide, bicarbonate, and saline solutions.

In its present form the Bionite lens offers immediate comfort combined with increased safety and a simplified fitting procedure.

## Summary

Bionite hydrophilic contact lenses were fitted in 89 cosmetic cases, according to a standardized routine. There were 82 wearers who were successful, representing 92% of those fitted. The new lens material offers the advantages of safety, comfort, and comparatively simple fitting procedure in individuals with less than one and one-half diopters of astigmatism.

# A THERAPEUTIC EVALUATION OF HYDROPHILIC CONTACT LENSES

JORGE N. BUXTON, M.D., AND CLYDE R. LOCKE, M.D.
*New York, New York*

Early experience with the use of hydrophilic contact lenses in selected corneal disorders has been encouraging, particularly in patients with corneal ulcers, neuroparalytic keratitis, Stevens-Johnson syndrome, and ocular pemphigoid disease. This report describes the findings in 45 patients (54 eyes) with corneal diseases who were hospitalized at the New York Eye and Ear Infirmary and treated with hydrophilic lenses.

## MATERIALS AND METHODS

Since hydrophilic lenses had not yet been approved by the Food and Drug Administration when this study took place, all patients were advised of the experimental nature of the lens trial and all were admitted to the New York Eye and Ear Infirmary. Routine blood work, smear, culture, sensitivity, and photographic studies were made and each patient was examined twice daily with the Haag-Streit slit lamp.

Lenses were inserted on the morning of admission and patients were allowed to wear them for four to eight hours the first day, when they were then removed, sterilized, and reinserted the following morning for a full day's wear.

The lenses used in the study (Soflens) are manufactured by Bausch and Lomb Company. They are composed of a polymeric hydrophilic gel, 2-hydroxy-ethyl methacrylate (HEMA) which absorbs approximately 40% of its weight in water or normal saline. When hydrated, the lenses are soft, pliant, transparent, and elastic. When allowed to dehydrate, they become brittle and crenated, and can be broken easily. Although the lens is hydrophilic in nature, tear exchange is still necessary for corneal oxygenation and nutrient transfer.

*Fitting the lens*—The lenses are pliant enough when wet so that keratometry readings for central posterior curvature is not essential. Instead, the lens power is determined by using the spherical equivalent of the basic refraction plus the vertex distance compensation; the lenses can then be adjusted by refraction over a trial lens.

*Sterilization*—Conventional contact lens wetting and cleaning solutions cannot be used with the soft lenses, nor can standard topical eye medications, because of the absorptive nature of the lenses which allows retention of the preservatives of the solutions, thus creating the possibility of damage to corneal epithelium. Daily sterilization is accomplished by boiling the lens for 15 minutes in a normal saline (0.9% NaCl) solution.

The lens should be stored and sterilized in isotonic saline. If the lens is stored in hypotonic solution or plain water, it will stick tightly to the cornea causing discomfort until the lens loses its tackiness by absorbing enough tears to approach isotonicity. Hypertonic saline will also cause discomfort, stinging, hyperemia, and lacrimation.

## RESULTS

The lenses were used for treatment of basically four problems: (1) corneal edema, (2) dry eyes, (3) corneal ulcers, and (4) a miscellaneous category that included mainly keratoconus, interstitial keratitis with corneal scarring, and post-keratoplasty dryness. The results of treatment are as follows:

*Corneal edema*—Six patients (six eyes) with advanced bullous keratopathy were treated with uniformly poor results. Although all the patients could tolerate the lens comfortably, in no case was there evident re-

From the New York Eye and Ear Infirmary, New York, New York.

duction of corneal edema. Visual acuity, compared to spectacle correction, was unchanged in five cases, slightly worse in one. The instillation of normal saline or hypertonic saline (5%) drops did not significantly affect vision. Wearing time was also modified in an attempt to improve visual acuity, but neither all-day wear, part-time daily wear, or continuous wear provided any significant improvement in vision—in fact, 24-hour wear produced a slight increase in corneal edema, with no change in comfort. Patients did not report any improvement or change in vision during the late afternoon or evening hours as might have been expected in non-lens wearers with similar corneal pathology.

CASE REPORT

The only eye of this 55-year-old white man was affected with aphakia, bullous keratopathy, and glaucoma for many years; phospholine iodide and acetazolamide (Diamox) were required for control. His best visual acuity was 20/200 with aphakic correction. The cornea showed superficial blotch staining with microcystic and stromal edema and prominent corneal guttata. The pupil was irregular because of posterior synechiae and lens capsule remnants. A trial with the hydrophilic lens provided no change in vision or edema, even when hypertonic (5%) NaCl solution was instilled every two hours.

In all advanced cases in this category no change was noted in vision or edema, even when hypertonic sodium chloride solution was instilled every two hours. In all cases of bullous keratopathy treated with a hydrophilic soflens, the only tangible improvement noted was a variable increase in comfort in the majority of patients.

*Dry eyes*—Thirteen patients (18 eyes) were treated in this category, which includes keratitis sicca, Stevens-Johnson syndrome, ocular pemphigoid with symblepharon, and exposure keratitis. Patients in this category generally responded favorably to hydrophilic lens wear. Nine of the 13 patients were able to tolerate the lens with no discomfort, even on the first insertion. Wearing time varied; some wore the lens only during waking hours, and others wore the lens around the clock, but in all cases, sterilization was performed daily. Stipple staining and blotch staining, reflecting corneal dryness, was seen both before and after lens wear.

CASE REPORT

This 26-year-old mechanical engineer had a history of Stevens-Johnson syndrome from the age of 11 years, resulting in cicatricial entropion, symblepharon, and trichiasis in both eyes. By the age of 21 years, the patient had undergone four mucous membrane graft operations and at least three procedures for stenosis of the right nasolacrimal apparatus. The patient was unable to tolerate flush-fitting scleral lenses, but maintained 20/20 vision in both eyes, with frequent instillation of lubricant drops. During the trial with hydrophilic lenses, the patient was able to tolerate all-day wear comfortably. The cornea showed no edema but punctate stain was still present. He was troubled initially by flare and glare and significant peripheral distortion, particularly for reading and near work. His best visual acuity was 20/20 in both eyes.

Eyelid tonus, mechanics, and scarring proved to be very important factors in determining the success or failure of hydrophilic lens wear, as the following case demonstrated.

CASE REPORT

In 1955, this 23-year-old man developed Stevens-Johnson syndrome with marked symblepharon, cicatricial entropion, trichiasis, and subsequent corneal pannus. Both eyes were treated with a tarsorrhaphy from 1957-1964, and the patient has worn scleral lenses continually since 1965. A trial with hydrophilic lenses was unsuccessful despite frequent normal saline application because of the lens edges and extrusion by the scarred, thickened eyelids. Despite the use of normal saline drops applied every five minutes, the lenses could not be retained.

This case demonstrates that in severe drying conditions, as the lens loses its flexibility, it is easily displaced by thickened and scarred eyelids, especially when eyelid retraction and cicatricial entropion co-exist. Two other retention factors are the shape of the cornea and the presence of symblepharon bands. In the most advanced cases of corneal ectasia, secondary to advanced drying conditions, the lens is often expelled. Of great significance, however, in a case of ocular pemphigoid, following the lysis of symblepharon bands, a hydrophilic lens was tolerated and retained with improvement of corneal appearance and no symblepharon formation.

*Corneal ulcers*—The most dramatic results were seen in this category. A total of 11 patients (11 eyes) were treated, three with neuroparalytic keratitis and central ulcer, two with deep metaherpetic ulcers with stromal scarring, and six with deep chronic indolent ulcers that had not responded to other forms of treatment. Smears and cultures taken in all cases failed to reveal significant pathogens. In all 11 cases the lenses were tolerated without any discomfort, understandable since corneal sensitivity was reduced. Importantly, the lenses provided rapid epithelial healing of ulcers and slow restitution of corneal thickness. No scraping of the lesion was performed prior to the wearing of the lens.

### Case reports

This 55-year-old white man had a history of herpes simplex keratitis of 12 years duration and was treated initially with iodine scrub. The patient had recurrences over the next 18 months with stromal scarring. A fourth recurrence in 1960 healed quickly with IDU therapy and the condition was quiescent until September, 1968, when a central geographic ulcer developed and smoldered for six months, despite various treatment regimens. Visual acuity was 3/200. A trial with the hydrophilic lens provided significant and immediate comfort. The lens was worn continuously for 72 hours, with marked improvement in the appearance of the ulcer and complete healing within three weeks. Full corneal thickness is present 12 months later.

A 35-year-old white woman with atopic dermatitis, eczema, and severe eyelid and conjunctival involvement, developed a sterile indolent corneal ulcer in her right eye and secondary keratoconus in her left eye while wearing conventional methacrylate lenses. She was hospitalized for one month, but despite intensive local and systemic treatment and two epithelial debridements and ether cauterizations, the ulcer failed to respond. A hydrophilic lens was applied and the ulcer healed within 48 hours.

The ability of corneal ulcers to fill in under soft contact lens was demonstrated both in phakic and aphakic eyes. In the two aphakic cases, the ulcer was associated with interstitial keratitis in one, and a very soft eye secondary to retinal detachment in the other. In both cases the healing was complete, but required four to six days, somewhat longer than in the phakic group. Only one corneal ulcer failed to heal in this group. This case was a 25-year-old man who developed an indolent ulcer at the margin of a penetrating keratoplasty done for a chemical burn. However, under the lens, the progression of the ulcer was halted, allowing time to secure good donor material for subsequent keratoplasty.

*Miscellaneous group*—Fifteen patients (18 eyes) were treated in this group, which comprised mainly keratoconus, interstitial keratitis, and post-keratoplasty problems. In keratoconus of moderate degree (below 52 D in both meridians in the visual axis), remarkably good visual results were obtained despite the degree of corneal astigmatism. Of course, in these cases better vision can be obtained with hard lenses. Disappointing visual results were seen in cases of advanced keratoconus. In two of the 15 cases affected with interstitial keratitis, the patient experienced improved vision that was not possible with other lenses. Post-keratoplasty fittings are indicated when dryness is a factor. The advantage of hydrophilic lenses over conventional methacrylate lenses is that they can be fitted within a month or sooner, postoperatively. Nonetheless, care should be exercised in observing for edema and increasing vascularization. Vascularization appears to be less stimulated by the soft than the hard lens.

### Discussion

There is little doubt that the present hydrophilic lenses function efficiently as a protective patch and reduce eyelid and external irritative factors to allow healing and epithelialization. Unlike glued-on lenses, hydrophilic lenses provide a flexible treatment modality that can be altered as necessary. In general, the lenses are well tolerated by both normal and some diseased corneas, although in some cases prolonged wear produced edema, indicating some effect on oxygenation and tear exchange, not unlike hard lenses.

In this series, the lenses proved most useful in the treatment of indolent, noninfectious corneal ulcers. Visible improvement of-

ten came within 24 hours, and all patients were comfortable. Visual acuity was improved secondarily as tissue healing progressed.

Dry eyes also responded well to hydrophilic lenses, with immediate improvement of comfort, even though the fluorescein staining pattern often showed no change. Visual acuity was as good or only slightly poorer than that obtained with spectacles or hard lenses. However, in severe cases with extensive scarring of the eyelids, the lenses were frequently pushed off the cornea by eyelid action. Normal eyelid tonus was essential to the maintenance of good lens centration and motility. In these cases, flush-fitting, hard scleral lenses still appear to be the most useful treatment aid, although hydrophilic lenses can be tried if symblepharon formation can be severed and normal eyelid position re-established.

There are several reports[1,2] of significant improvement of corneal edema and visual acuity in cases of bullous keratopathy, using other hydrophilic lenses. Our experience with the use of hydrophilic lenses in the treatment of advanced bullous keratopathy showed uniformly poor results in improving vision or reducing edema. Nonetheless, comfort and visual fields were improved to various degrees. It is important to differentiate between epithelial and stromal edema. The former responds well to both topical hygroscopic solutions and hydrophilic lenses, whereas in stromal edema comfort is improved but the edema is not affected.

## Summary

Therapeutic indications for hydrophilic lens treatment of corneal diseases were evaluated in 45 patients (54 eyes) whose disease could be categorized in four basic groups: corneal edema (six eyes), dry eyes (18 eyes), corneal ulcers (11 eyes), and a miscellaneous group (18 eyes). Six patients (six eyes) with advanced bullous keratopathy were treated. Poor results were seen when stromal edema was present. Neither visual acuity nor edema was improved; comfort and visual field were variably improved. The group with dry eyes consisted of 13 patients (18 eyes) with keratitis sicca, Stevens-Johnson syndrome, ocular pemphigoid, and exposure keratitis. These were treated with significant improvement of comfort and maintenance of good vision. Hydrophilic lenses proved most useful in the treatment of 11 patients (11 eyes) with indolent, noninfectious corneal ulcers of varying depth. Fifteen patients (18 eyes) were treated with hydrophilic lenses which were well tolerated postoperatively in keratoplasty where dryness was a problem. In moderate keratoconus, and occasionally in interstitial keratitis, good visual results were obtained using hydrophilic lenses.

Hydrophilic lenses in this series provided the best results in the treatment of corneal ulcers and dry eyes and the poorest results in cases of advanced bullous keratopathy.

### Acknowledgment

We thank our chief resident, C. Frank Chambers, M.D., for significant help in following the patients reported herein.

# BLEPHAROPTOSIS AS A COMPLICATION OF CONTACT LENS MIGRATION

JOHN G. YASSIN, M.D., ROBERT H. WHITE, M.D., AND GERARD M. SHANNON, M.D.
*Philadelphia, Pennsylvania*

Contact lenses have been lost in the eyelid for periods of 12 days to 69 months.[1-6] One report[6] described mild blepharoptosis of the eyelid involved. Blepharoptosis in an adult who wears contact lenses should suggest the possibility that a lost lens may be embedded in the tissues of the upper fornix.

## CASE REPORT

A 29-year-old man was seen at Wills Eye Hospital on June 22, 1970. His chief complaint was that for the past three months, coincident with the period in which he resumed wearing contact lenses, he had experienced a white, mucous-like discharge from both eyes during the daytime, and his eyelids were stuck together each morning when he arose. Secretion was significantly worse in his right eye, and in the week prior to admission, his right upper eyelid had become slightly swollen. He had noted drooping of his right eyelid for 18 months.

The patient reported that he had worn glasses since childhood for moderate myopia. Contact lenses were fitted initially in August, 1967. Although his right eye was always a bit sore compared to the left, he wore his lenses 14 to 16 hours daily, removing them twice daily for cleaning and always removing them before retiring. He had lost his right lens two years earlier, and it was immediately replaced, but some months later, he discontinued wearing these lenses for an eight-month period. He resumed daily wear in May, 1970.

Past medical and ocular histories were not otherwise significant.

At the time of his first evaluation, visual acuity was RE:20/25, and LE:20/20 with his contact lenses in place. Vision in his right eye improved to 20/20 with the use of a pin-hole. External examination revealed about 2 mm of right blepharoptosis in the primary position. A bilobular clear cyst was present in the upper fornix medially. Applanation pressures were 15 mm Hg in each eye. The remainder of the ocular examination was normal. The patient was treated with 15% sulfacetamide drops four times daily.

On re-examination August 7, 1970, the blepharoptosis was worse and the cyst contained blood. He was admitted August 30, 1970. There was tumefaction of the right upper eyelid and 3 mm of right blepharoptosis (Fig. 1). The eyelid mass had two distinctly different, palpable areas. Centrally, at the upper margin of the tarsus, there was a firm, round mass approximately 1 cm in diameter. On eversion of the eyelid this mass was seen to be connected to a cystic lesion in the nasal third of the eyelid at the level of the superior border of the tarsus.

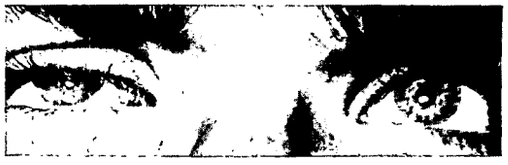

Fig. 1 (Yassin, White, and Shannon). Preoperative photograph showing blepharoptosis and thickening of right upper eyelid.

Systemic examination was within normal limits. Routine hemogram, urinalysis, and blood chemistries were unremarkable. Serology was non-reactive. Chest x-ray films and electrocardiograms were within normal limits.

On August 31, 1970, under general anesthesia, the right upper eyelid was everted with an Erhardt clamp. The superior aspect of the firm tarsus mass was incised and the edge of a contact lens immediately became visible. The incision was enlarged and the lens was delivered. The cystic area was simply incised and drained. A biopsy specimen of surrounding tissue was taken and later showed chronic inflammatory changes.

The patient made an uneventful recovery, and has returned to the use of spectacles with safety lenses on a permanent basis.

## COMMENT

This case indicates the need to examine carefully the superior cul-de-sac in any patient who demonstrates blepharoptosis and reports a history of contact lens loss. The need for such examination was stressed in similar case reports by Green[1] in 1963 and by Shenken[6] in 1969 of eyelid tumors containing a "lost" contact lens. Acquired blepharoptosis in patients who have lost a contact lens should arouse suspicion that the lens may be embedded in the soft tissues.

## SUMMARY

A lost corneal contact lens was found to have become embedded above the tarsal plate in a 29-year-old man who presented with ac-

quired blepharoptosis of 18 months' duration and a mucous discharge over the most recent three months. Surgical removal of the contact lens was followed by prompt resolution of all signs and symptoms in this patient and restoration of an essentially normal eyelid. It is suggested that acquired blepharoptosis, particularly with tumefaction, in a contact lens wearer should indicate careful questioning as to the possibility of the earlier loss of a contact lens.

ACKNOWLEDGMENT

We thank Arthur H. Keeney, M. D., Ophthalmologist-in-Chief, Wills Eye Hospital and Research Institute, for his help in the preparation of this case report.

# GRANULOMATOUS KERATITIS RESULTING FROM USE OF CYANOACRYLATE ADHESIVE FOR CLOSURE OF PERFORATED CORNEAL ULCER

ANDREW P. FERRY, M.D., AND ALAN H. BARNERT, M.D.
*New York, New York*

In recent years use of cyanoacrylate adhesive monomers has been advocated for a variety of ocular disorders. Because of the potential value of this technique in sealing certain types of corneal perforations, many laboratory investigations have been carried out to evaluate the efficacy of cyanoacrylate adhesives in this regard and their possible side effects upon the cornea. Although several clinical reports describe the successful use of cyanoacrylate monomers in sealing corneal perforations, we believe this is the first reported case in which a human cornea, treated with cyanoacrylate adhesive for a perforation, subsequently became available for pathologic study.

## CASE REPORT

In 1965, a 51-year-old white man underwent a penetrating keratoplasty of the right eye. Recurrent herpes simplex keratitis had caused extensive scarring of his right cornea. His left eye was blind following an accident in 1953. The graft in the right eye remained clear for six months, but the next 18 months were marked by episodes of graft edema with subsequent vascularization. This required treatment with topical and systemic corticosteroids. On July 26, 1968, the right cornea was treated by cryotherapy. Several days later the ulcer extended to the level of mid-stroma, and within four weeks a descemetocele was present at the corneal apex. On August 26, 1968, a 5.5 mm tectonic lamellar keratoplasty was done. The graft became cloudy and vascularized.

On October 9, 1968, the patient developed severe pain in the right eye and was found to have a corneal perforation with uveal prolapse. The host cornea and graft were opaque and vascularized. The corneal perforation was situated at two o'clock, about midway between the corneal apex and the limbus (Fig. 1). The uveal tissue prolapsed through

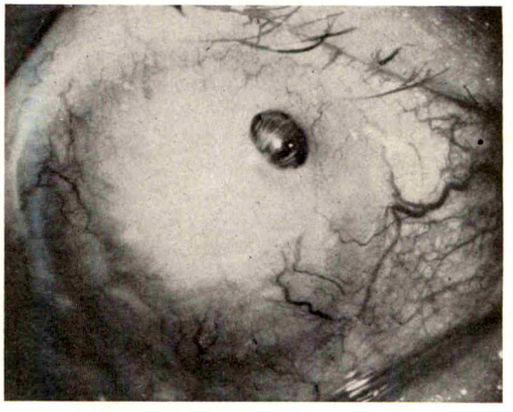

Fig. 1 (Ferry and Barnert). Right eye. Corneal perforation with prolapse of uveal tissue.

the defect was about 1 × 2 mm in diameter. Several hours later the prolapsed uvea was excised and the corneal perforation was repaired using isobutyl-2 cyanoacrylate monomer adhesive. This was done as follows: A cotton applicator was attached to one side of a polyethylene plastic disk, after which a small amount of the fluid cyanoacrylate adhesive was applied to the other surface. Using the applicator stick for manipulation of the polyethylene disk, the fluid cyanoacrylate adhesive was then apposed to the corneal perforation and held in place for 15 seconds. The applicator stick was then removed, after which the polyethylene disk was lifted away from the perforation site with forceps. It was seen that a satisfactory film of the adhesive material was in place, closing the corneal perforation. No leakage of aqueous humor was evident upon application of slight pressure to the eye. On the first postoperative day the adhesive patch was observed to be in place. There was no leakage from the wound. On the second postoperative day the adhesive patch was found in the superior fornix. The perforated area of cornea was closed over but a deep ulceration was still present. Because of diffuse corneal opacity, the patient's iris and anterior chamber could not be visualized satisfactorily.

On May 3, 1969, the patient was admitted for a second penetrating keratoplasty of the right eye. The host and donor cornea were extensively vascularized, chiefly peripherally (Fig. 2). The anterior chamber and iris were not satisfactorily visualized over much of their extent because of corneal scarring. Two days after admission, a 9 mm penetrating keratoplasty was performed and a mature cataract was concurrently extracted. Postoperatively, visual acuity in the right eye improved to 20/50, but subse-

quently bouts of graft edema again developed despite intensive immunosuppressive therapy.

### Pathologic examination

Examination of the corneal button revealed a marked irregularity in thickness of the corneal stroma (Fig. 3). Over about one-half of the corneal button, the stroma was reduced to about one-third of its normal thickness and disorganized iris adhered to its posterior surface. In the remaining half of the corneal button, the stromal thickness appeared slightly increased, Descemet's membrane was interrupted but better preserved than in the other half, and only a small fragment of iris adhered to its posterior surface. Throughout the entire corneal button there was prominent stromal vascularization and a heavy infiltrate of inflammatory cells, chiefly plasma cells and lymphocytes. Particularly in the thicker half of the corneal button, many epithelioid and giant cells were scattered throughout the corneal stroma (Fig. 4). Examination of this area under higher magnification revealed the presence of innumerable "clear" areas occupied by the plastic material used to seal the corneal perforation. Foreign body giant cells enveloped many of these particles (Fig. 5). No other foreign material was present. Special stains for bacteria and fungi revealed no organisms. No inclusion bodies of the type seen in herpes simplex keratitis were observed in the epithelium, nor was there a granulomatous reaction to Descemet's membrane.

### Comment

The use of cyanoacrylate adhesives for surgical purposes was first reported in 1960.[1] The various cyanoacrylate adhesives produce tissue reaction, it generally being held that the shorter-chain homologues (methyl and ethyl) tend to produce more acute reactions,[2-7] while those with longer chains produce a foreign-body reaction, often with giant cells.[4-7] The inciting factor has been thought to be liberation of cyanide and formaldehyde as the material is degraded,[7] the actual heat liberated by the monomer as it polymerizes,[6] and the mechanical presence of the polymer.[3,8] In the eye, reactions have not been as severe as in some other tissues.[8-12] Among the reasons suggested for this[13] is that the amount of material used in ocular procedures is so small (large amounts cause considerable reaction).

Fig. 2 (Ferry and Barnert). Corneal vascularization and scarring immediately before the second penetrating keratoplasty (seven months after closure of corneal perforation with cyanoacrylate adhesive).

More rapid polymerization and lower tissue toxicity have been regarded as two advantages of the higher homologues over the lower homologues. But recently laboratory studies have been published in which the investigators were unable to demonstrate a difference in tolerance to various cyanoacrylates.[8,14]

Aronson and associates[14] have emphasized the biphasic character of the corneal inflammatory response to the various monomers.

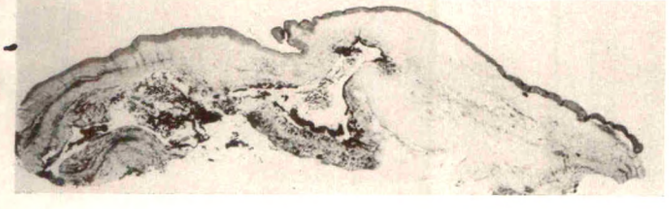

Fig. 3 (Ferry and Barnert). The corneal button removed at time of second penetrating keratoplasty. Stroma is of irregular thickness, vascularized, scarred, and heavily infiltrated by inflammatory cells. A large fragment of iris adheres to posterior corneal surface (hematoxylin and eosin, ×15).

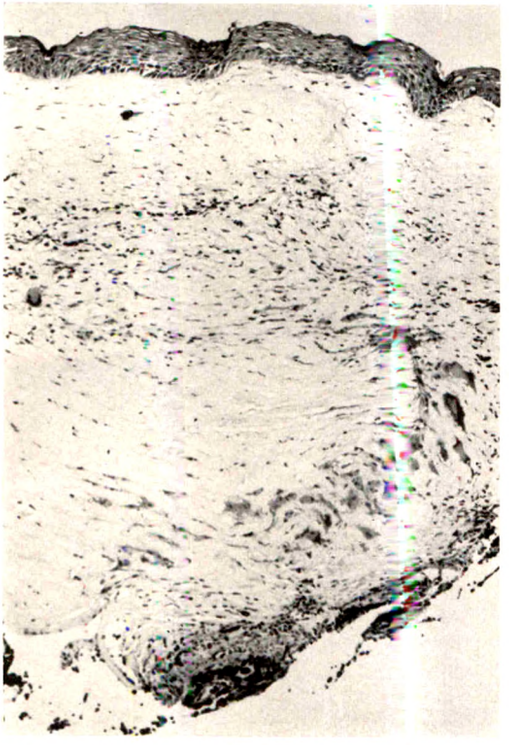

Fig. 4 (Ferry and Barnert). The right-hand side of corneal button shown in Figure 3. Stroma (mid- and deep) contains a prominent infiltrate of epithelioid and giant cells (hematoxylin and eosin, ×76).

These authors comment that "The initial acute response, characterized by PMN proliferation, probably represents activation of the acute inflammatory pathway, while the late granulomatous reaction indicates inflammation produced by a particulate stimulus."

The corneal tissue became available for study seven months after isobutyl-2-cyanoacrylate had been applied to the corneal perforation in the patient we have reported. A granulomatous response to the cyanoacrylate was a striking feature (foreign-body giant cells had enveloped the fragments of plastic). No other foreign bodies were present, nor was any other cause for a granulomatous reaction demonstrable.

Another aspect of corneal tissue reaction to the different cyanoacrylates is the dose-related nature of the response observed by various investigators. In our laboratory we created lamellar pockets in six rabbit corneas and immediately thereafter injected a small amount of isobutyl-2-cyanoacrylate monomer into the tract. Pathologic examination seven weeks later showed the corneal incisions to be well healed, without undue scarring. Only a few giant cells surrounding scattered fragments of the plastic were observed. This is in contrast to the striking granulomatous response to innumerable fragments of cyanoacrylate in the presently reported patient. We believe the extensive necrosis in our patient's cornea permitted relatively large amounts of the cyanoacrylate to enter the stroma adjacent to the perforation tract. This resulted in a massive granulomatous response to the plastic, in contrast to the limited reaction observed in clean, surgically created wounds in animals, where necrosis away from the perforation site itself

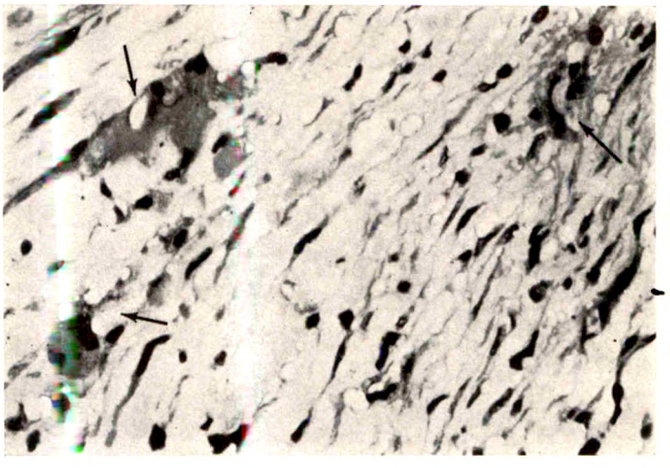

Fig. 5 (Ferry and Barnert). Giant cells and epithelioid cells envelop many of the "clear" spaces representing sites of adhesive deposition (arrows) (hematoxylin and eosin, ×480).

was minimal. Perhaps a more vigorous curettage and removal of necrotic corneal tissue before application of the adhesive to our patient's perforation site would have resulted in a less extensive deposition of cyanoacrylate in his cornea.

Sealing certain corneal perforations with tissue adhesive is a therapeutic method of considerable promise. Webster and associates,[15] and Malaev,[16] have reviewed some advantages inherent in this technique. In the presently reported patient there was widespread corneal necrosis and softening in addition to the localized perforation. Under these circumstances we were most reluctant to perform an immediate keratoplasty and elected to attempt closing the perforation with cyanoacrylate adhesive. The successful sealing of the perforation permitted subsequent penetrating keratoplasty at a time when the cornea was no longer as soft and necrotic. Another major feature of this technique is that if the corneal perforation is located peripherally, scarring consequent to wound healing may not interfere with corneal transparency along the visual axis, and the patient may be spared a surgical procedure.

## Summary

When isobutyl-2-cyanoacrylate adhesive was used to close an area of perforation in an extensively necrotic cornea, the plastic produced a marked granulomatous keratitis. This was not the response observed in animal experiments; seven weeks after the same material was injected in six rabbit corneas, pathologic examination showed the corneal incisions in these animals to be well healed and without undue scarring. In the patient reported, it is probable that extensive necrosis permitted relatively large amounts of the cyanoacrylate to enter the stroma. Despite this patient's reaction to the adhesive, the use of the cyanoacrylate permitted the successful sealing of the perforation and allowed subsequent penetrating keratoplasty to be performed when the cornea was no longer as soft and necrotic. This technique of using cyanoacrylate adhesive is of potential value in sealing certain types of corneal perforations.

# UNUSUAL EPITHELIAL CHANGES IN A CASE OF COMBINED CORNEAL DYSTROPHY OF FUCHS

GEORGE T. SCHROEDER, M.D., AND CALVIN HANNA, PH.D.
*Little Rock, Arkansas*

In 1910, Fuchs described a degenerative disease of the cornea involving first the endothelium and then the epithelium.[1] This combined endothelial–epithelial dystrophy of Fuchs (Fuchs' dystrophy) is characterized by early endothelial guttata and later by stromal edema and epithelial vesicles.[2] The degenerative changes are progressive and lead to corneal opacity. Since corneal homografts may be used to correct the opacity, fresh corneal specimens are thus available postoperatively for light and electron microscopic observations. Ultrastructural studies are helpful in understanding the degenerative changes; however, these studies have concentrated on presenting details of fibrillar changes in Descemet's membrane and stroma.[3,4] The present study describes unusual changes in the epithelium in a case of Fuchs' dystrophy.

The intracellular and intercellular edema of the deepest layer of the epithelium and the structure of the vesicles were described by earlier investigators.[2] In 1958, Chi noted subepithelial fibrillar material in several cases studied by light microscopy.[5] In 1967, McTigue reported a case with delicate fibrillar material containing "invading cells" which he considered to migrate from the superficial corneal stroma to lie beneath the basement membrane of the epithelium.[6] The fibrillar layer in the present case is shown to lie above the epithelial basement membrane and the epithelial cell layers are traversed and encapsulated by septa of fibrillar material which is continuous with the subepithelial fibrillar material.

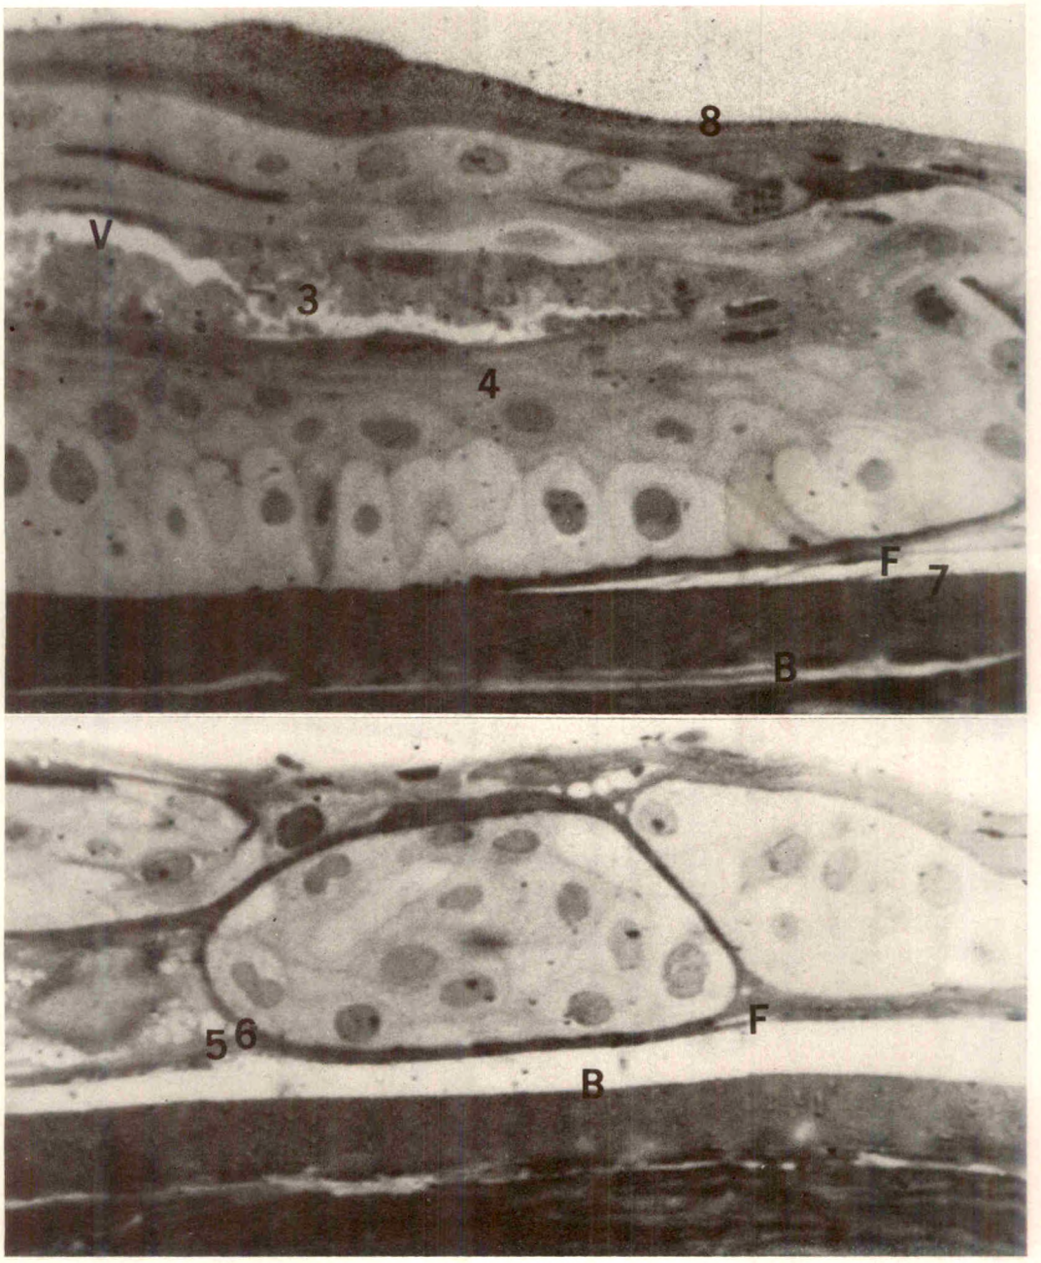
## CASE REPORT

A 56-year-old white man gave a history of blurring of vision and intermittent pain in the right eye for one year. He had had an uneventful cataract extraction in the right eye three years previously. On initial examination, the visual acuity was 20/100 in the right eye and 20/30 in the left eye with correction. There were guttate changes involving at least 40% of the endothelial surface of the right eye with the vitreous face touching the endothelium. Corneal edema was present but no vesicles or bullae were observed. The left eye showed central guttata and an early senile cataract. Applanation tonometry was 17 mm Hg in each eye. Pain in the right eye increased and the visual acuity decreased to 20/400 at which time a 7.5 mm penetrating homograft with vitrectomy was performed with good visual result.



## MATERIAL AND METHODS

The removed corneal button was fixed in freshly prepared 4% formaldehyde, then dehydrated through increasing concentrations of methanol and propylene oxide and embedded in Araldite. The tissues were cut through the center of the cornea into four equal parts. Thick sections were stained with 0.1% toluidine blue in 1% borax solution. Thin sections were stained with uranyl acetate and lead citrate for electron microscopic studies.

## RESULTS

The epithelial vesicles in this case gave the appearance of being blood vessels under light microscopy (Figs. 1, 2). At higher magnifications the vesicles were found to contain degenerating epithelial cells and cellular debris (Figs. 3, 4). The individual epithelial cells are attached to each other by desmosomes (Fig. 4). The vesicles appear to result from the encapsulation of groups of epithelial cells by the fibrous sheets (Fig. 2).

The fibrillar layer covering groups of epithelial cells morphologically resembles Bowman's layer in structure (Figs. 5-8). Fine fibrils and short collagen fibers are intermingled and randomly oriented (Fig. 7). However, this fibrillar layer does not appear to be an extension of Bowman's layer since it is

Figs. 1 and 2 (Schroeder and Hanna). Photomicrographs of the epithelium (a central and a peripheral area) in Fuchs' dystrophy. The epithelium is divided into numerous groups of cells by a fibrillar layer (F) that lies above Bowman's membrane (B). A portion of an intraepithelial vesicle (V) is seen in Figure 1 (top), while the numbers in both illustrations correspond to the figure numbers of subsequent illustrations showing these same sites as they appear on electron microscopy (toluidine blue, ×600).

well above and separated from this layer by the basement membrane of the epithelial cells (Fig. 5). The epithelial cells are attached to the fibrillar layer by hemidesmosomes, while in no case were the epithelial cells observed to be attached to Bowman's layer by cell junctions. Cells resembling keratocytes are occasionally found in the fibrillar layer sur-

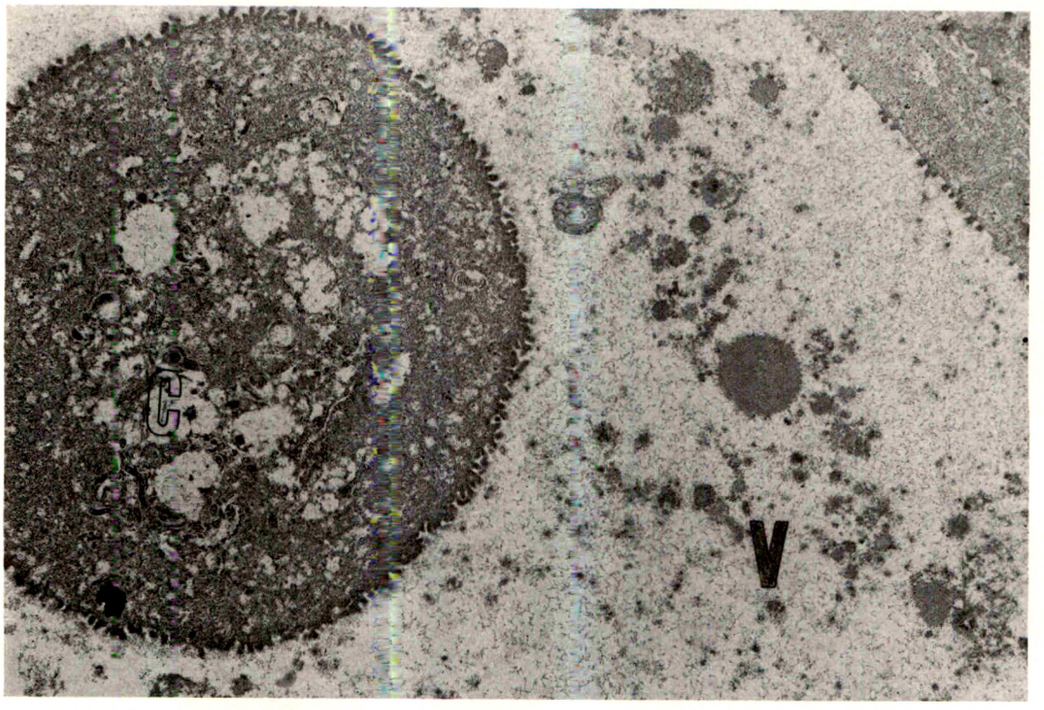


Fig. 3 (Schroeder and Hanna). Electronmicrograph of a cross-section of the vesicle (V) containing a degenerating cell (C) and other cellular debris (×9000).

rounding the epithelium (Figs. 5, 7). The fibrillar layer is continuous with the anterior surface of the cornea (Figs. 1, 2). The surface fibrillar layer is shown being exfoliated from the corneal surface (Fig. 8). Neovascularization and evidence of inflammatory processes are absent from the corneal button.

When four other corneal buttons (surgical specimens from additional cases of Fuchs' dystrophy) were examined in this laboratory, each demonstrated corneal changes that were typical of those previously reported. In each case, a collagen-like fibrillar layer was found between Bowman's layer and the basal epithelial cells. Occasionally, the fibrillar layer extended between basal epithelial cells. The fibrillar layer generally resembled Bowman's layer in structure rather than fibers of the stroma.

## Discussion

Previous reports of the pathologic changes at the ultrastructural level in Fuchs' dystrophy have stressed the stromal and endothelial changes. A few reports have described the presence of subepithelial fibrillar material located below the basal epithelial cells.[3,5,6] The present report describes the complete encasement of the epithelium by a collagen fibrillar layer containing fibroblasts. The keratocytes were surrounded by short collagen-like fibrils which are arranged randomly in a structure morphologically identical to Bowman's layer. Since the changes of Fuchs' dystrophy occur in adults, this leaves little doubt that keratocytes are capable of producing a Bowman-like layer under this pathologic condition in the adult eye. Previous studies have indicated that Bowman's layer is formed only during embryonic life. In the case of Fuchs' dystrophy a new Bowman's layer may form.

## Summary

In a case of Fuchs' combined corneal dystrophy, an unusual epithelial change was seen upon microscopic examination of the diseased corneal button after surgery. The

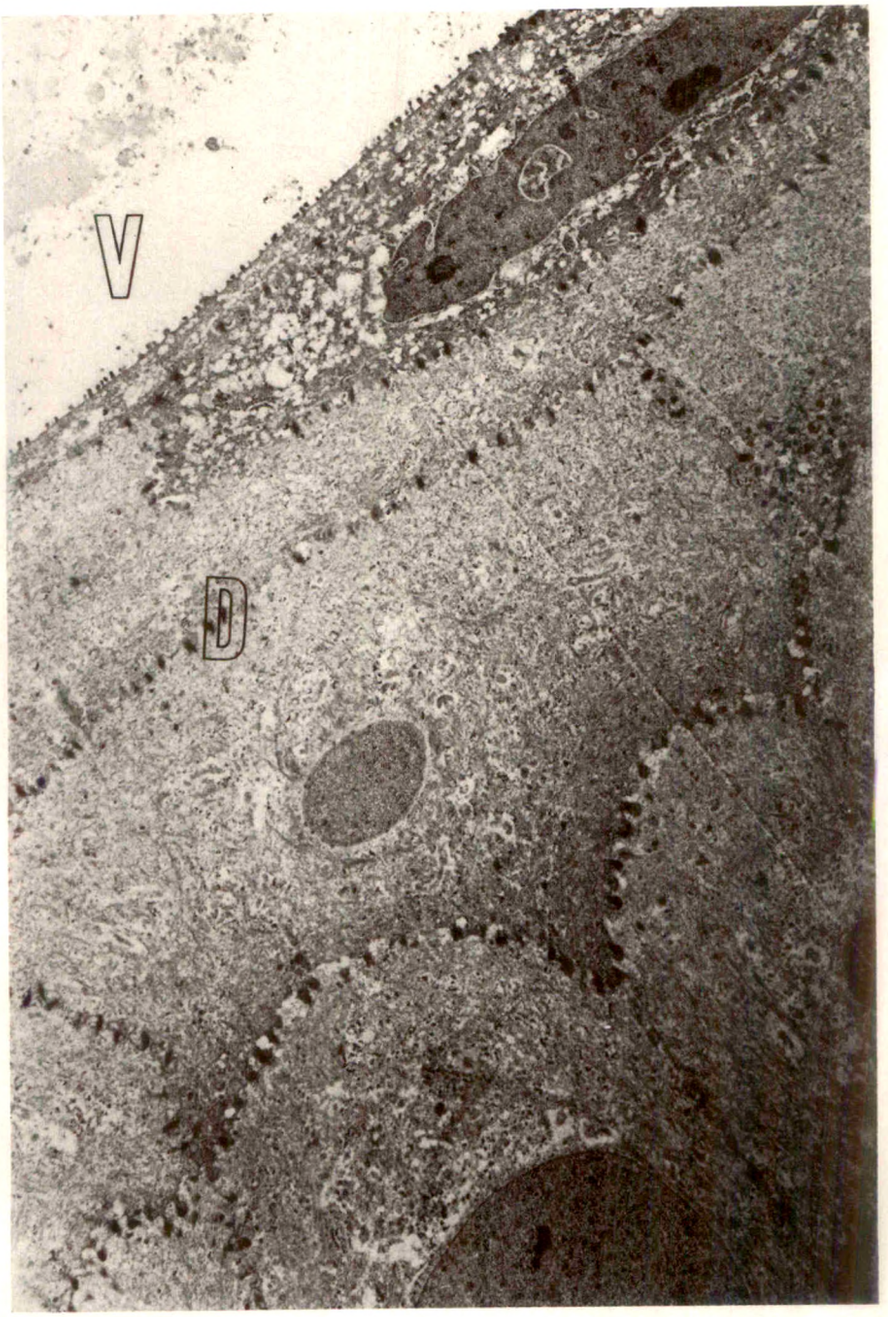

Fig. 4 (Schroeder and Hanna). View of the cells lying deep to the vesicle (V). Desmosome junctions are demonstrated (D). Note the relative lack of intracellular organelles in these epithelial cells (×9000).

epithelium was separated into encapsulated islands by a collagen fibrillar layer that resembled Bowman's layer in structure. These fibrils were apparently produced by keratocytes located above Bowman's layer and this suggests that under certain conditions a new Bowman-like layer may be produced in adults, despite the fact that it is presently accepted to be formed only during embryonic life.

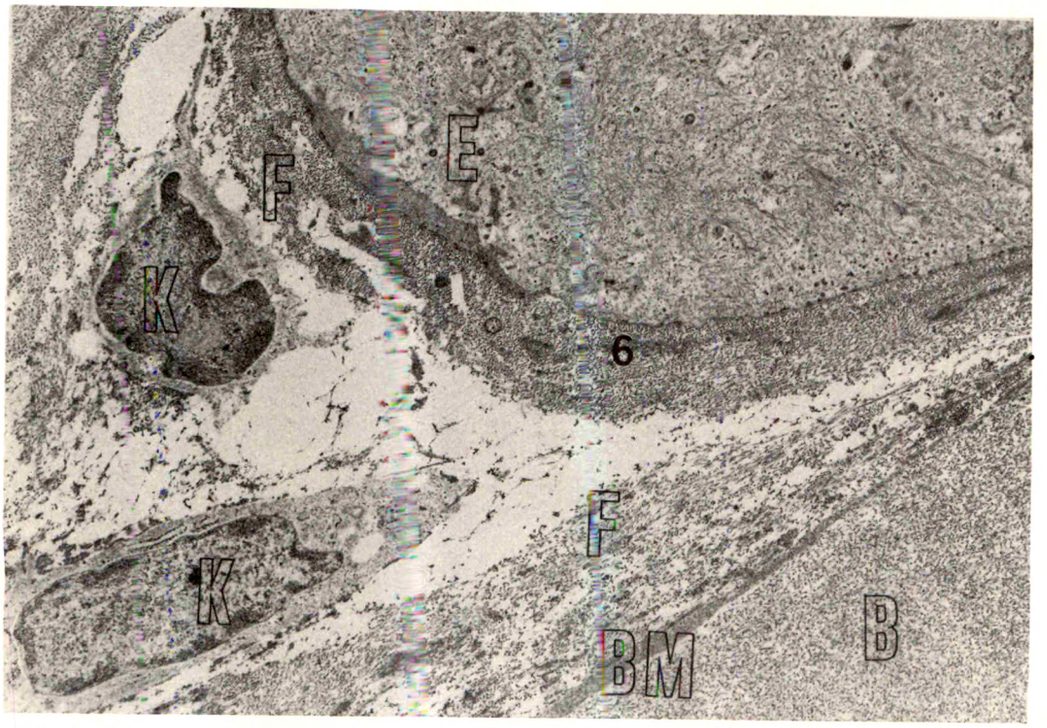

Fig. 5 (Schroeder and Hanna). The fibrillar layer (F) surrounding the epithelial cells (E) is generally attached to the epithelial cells by hemidesmosomes. The fibrillar layer resembles Bowman's layer, based on the appearance of the macroperiod of collagen in closely packed bundles. This resemblance is especially apparent in Figure 7. At the junction between the groups of epithelial cells (E) are found cells (K) surrounded by the fibrillar layer which is generally separated from Bowman's layer (B) by a basement membrane (BM). The 6 refers to the area enlarged for Figure 6 (×6000).

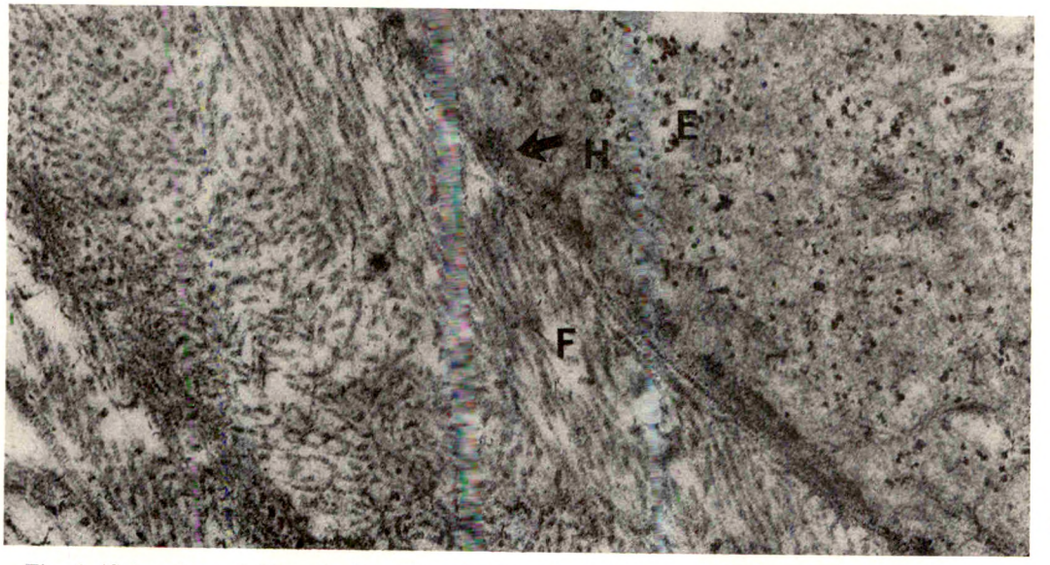

Fig. 6 (Schroeder and Hanna). An enlarged view of area 6 shown in Figure 5 showing the collagenous nature of the fibrillar layer and the hemidesmosomes (H) of an adjacent epithelial (E) cell (×25,000).

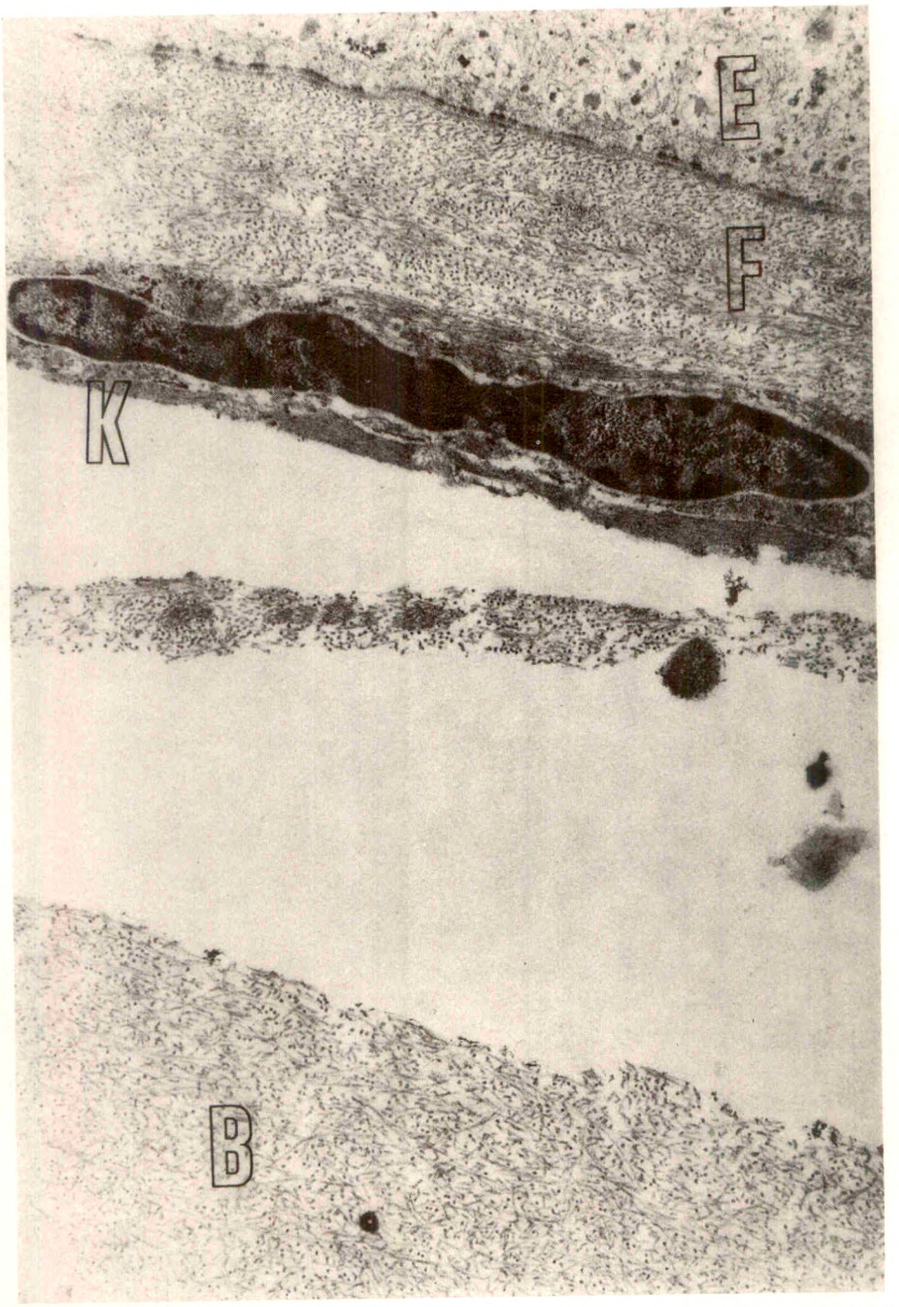

Fig. 7 (Schroeder and Hanna). In many areas, the fibrillar layer is separated from Bowman's layer (B). Occasionally, the fibrillar layer contains cells that closely resemble keratocytes (K) in structure (×30,000).

Fig. 8 (Schroeder and Hanna). The fibrillar layer extends to the anterior surface of the cornea where, in association with cellular debris, it defoliates (×10,000).

ACKNOWLEDGMENTS

We thank Catherine Dodd for her considerable assistance in the electron microscopic observations and F. T. Fraunfelder and D. Van Horn, who supplied the corneal buttons.

# THE ULTRASTRUCTURE OF REIS-BÜCKLERS' DYSTROPHY

SHINOBU AKIYA, M.D., AND STUART I. BROWN, M.D.
*New York, New York*

In 1949, Bücklers[1] described a corneal dystrophy affecting four successive generations of a German family, some members of which had already been reported by Reis[2] (1917). These authors stated that this condition is characterized clinically by a diffuse opacification in the region of Bowman's membrane and recurrent epithelial erosions. Since then, various studies have described the clinical and histopathologic features of this dystrophy. The first electron microscopical study was reported by Griffith and Fine[3] (1967). They studied the scrapings from the superficial portion of a cornea with the clinical appearance of the dystrophy. The specimen showed normal appearing epithelial cells, but the basement membrane of the epithelium appeared poorly defined or absent. Bowman's layer was almost replaced by collagen fibrils. Masses of closely packed, delicate fibrils were found in the junctional areas between Bowman's membrane and the adjacent stroma and were thought to be fibrillar degeneration. There was insufficient stroma for a definitive description. Later, Rice and associates[4] (1968) described the clinical, genetic, histological, and electron microscopic appearances of two corneas with Reis-Bücklers' dystrophy. Electron microscopy amplified the report of Griffith and Fine, and in addition showed that the epithelium was degenerated, particularly in the basal layer where there were also clusters of extremely electron-dense cells ("dark cells"). This study was almost identical to that of Griffith and Fine—i.e., Bowman's membrane was replaced by a fibrous tissue consisting of disoriented collagen fibrils of varying electron density interspersed with electron dense fibrils of smaller caliber (about 8.0 nm) which were occasionally grouped in irregular masses. In addition, the anterior stroma was examined and showed active fibroblasts. This indicated that the changes in Bowman's layer were regenerative rather than degenerative.

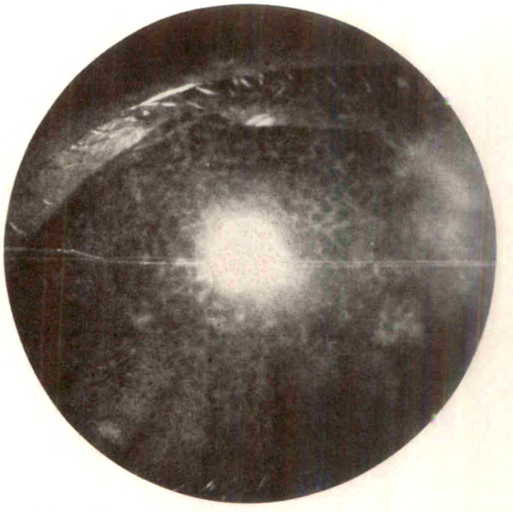

Fig. 1 (Akiya and Brown). Preoperative appearance of right cornea is typical for Reis-Bücklers' dystrophy.

This paper is the third of the electron microscopy of Reis-Bücklers' dystrophy and the second of a full-thickness corneal button.

## MATERIALS AND METHODS

The material for this study consisted of a corneal disk removed during keratoplasty. The patient was an 18-year-old woman with a history of recurrent erosions in both eyes for more than 10 years. The visual acuity was reduced to RE: 20/80 and LE: 20/30. Slit lamp examination showed a ground glass appearing opacification of the subepithelial area of both corneas (Fig. 1). The peripheral cornea was spared. The patient's mother had a similar history and had similar

From the Department of Ophthalmology, Cornea Research Laboratory, New York Hospital-Cornell University Medical College, New York, New York.
Reprint requests to Stuart I. Brown, M.D., Department of Ophthalmology, Cornea Research Laboratory, Cornell University Medical College, 525 East 68th Street, New York, New York 10021.

corneal opacifications which were more dense.

The corneal disk removed at surgery was bisected immediately after removal from the patient. One-half was fixed in 10% neutral formalin, embedded in paraffin, and stained with hematoxylin and eosin, periodic acid Schiff reagent, toluidin blue, colloidal iron, and Congo red. The other half was fixed in 3% glutaraldehyde in 0.2% sodium cacodylate buffer (pH 7.4) and postfixed 2% osmium tetroxide in 0.2M sodium cacodylate and embedded in Epon.

Thin sections were cut on a LKB-3 microtome with a diamond knife, mounted on uncoated copper grids, stained with uranyl acetate and lead citrate, and examined with a Siemans Elimiscop 1A at 80 kv. Thicker sections (5μ) of the epoxy-embedded tissue were stained with either toluidin blue or basic fuschin and alkalinized methylene blue[5] and examined with the light microscope.

### Histology

The epithelium was irregular in thickness. The basal layer of the epithelium had many pale swollen cells, many darkly staining cells, and intercellular vacuoles. The nuclei of the pale cells had irregular outlines and were degenerative. Bowman's membrane was almost entirely replaced by a material or deposit which stained bright red with basic fuschin and alkalinized methylene blue (Fig. 2). Similar material could be seen in the superficial stroma (Fig. 2). These areas did not stain with PAS, colloidal iron, or Congo red, but was faintly red with Masson's stain.

### Ultrastructure

The cellular degenerative changes—i.e., swollen mitochondria, large vacuoles, swelling and disruption of the endoplasmic reticulum—were evident through all layers of the epithelium. There was distention of the intercellular spaces and the desmosomes were

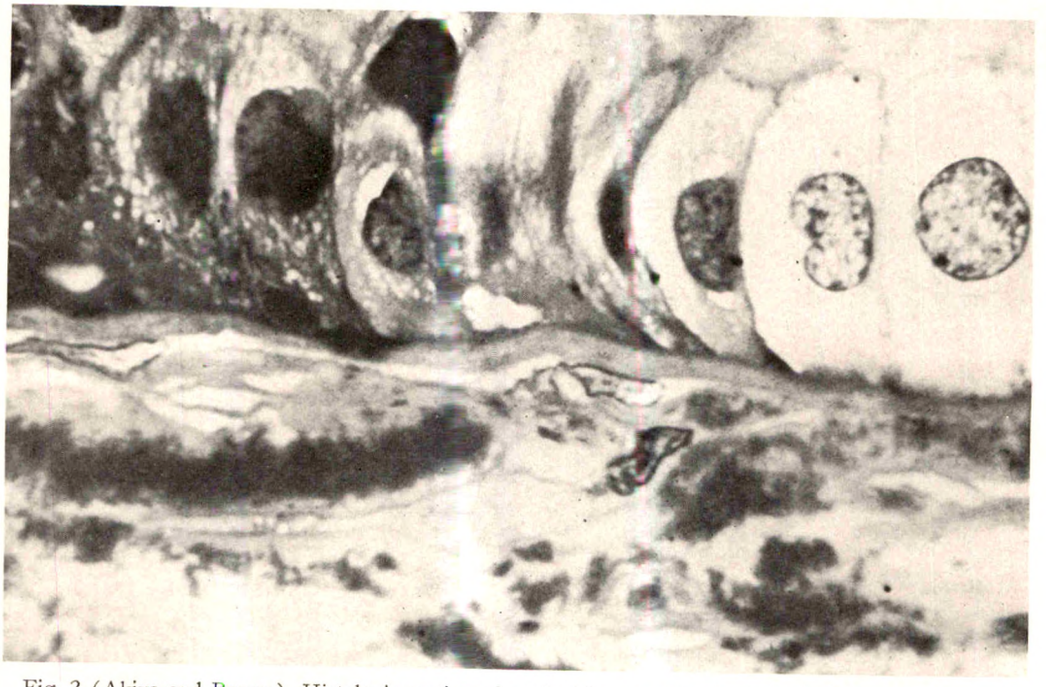

Fig. 2 (Akiya and Brown). Histologic section of excised host cornea shows both dark and pale swollen basal epithelial cells. Superficial stroma has stained darkly and it shows somewhat amorphous deposits (basic fuschin and alkalinized methylene blue, ×400).

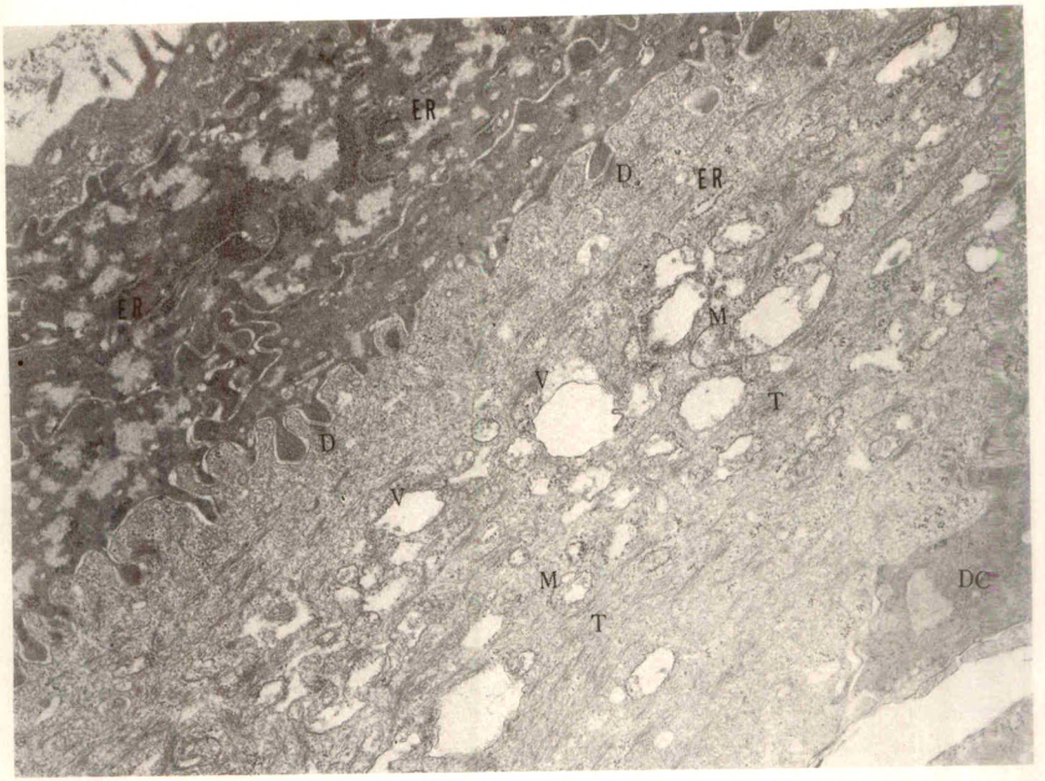

Fig. 3 (Akiya and Brown). Electron micrograph of basal epithelial cells. Both the electron-dense cell (DC) and the adjacent lighter cells have few recognizable organelles except for swollen mitochondria (D = desmosome, M = mitochondria). In the intercellular space, there is an extension of another dark cell (×17,000).

normal. Prominent in the basal layer were groups of cells which were extremely electron dense and flat or polymorphous in shape. These "dark cells" also showed degenerative changes and in some the internal structures were indiscernable. The basement membrane was irregularly present and where it was absent, the epithelium was usually detached from the underlying stroma.

Under low magnification, Bowman's membrane appeared to be replaced by an unorganized fibrous tissue containing collagen fibrils and electron-dense, finely granulated deposits. Under higher magnification these deposits were seen to be made up of fibrils with diameters of 5.0-8.0 nm (Figs. 4-6).

There were many keratocytes in this abnormal Bowman's layer. They appeared to be either degenerating, grossly degenerated with cell membrane breakdown, or active, as suggested by the increase in number and size of the rough-surfaced endoplasmic reticulum (Fig. 6). The endoplasmic reticulum in these active appearing cells contained fine filaments or finely granulated substances in their cisternae.

## Comments

The electron microscopic examinations of the specimen of Reis-Bücklers' dystrophy reported in this paper are almost identical to those of Rice and associates.[4] There were two main alterations. The first was degenerative changes of almost every epithelial cell, but especially the basal cells. The second was that Bowman's membrane was completely absent and replaced by masses of disoriented collagen fibrils and smaller electron-dense

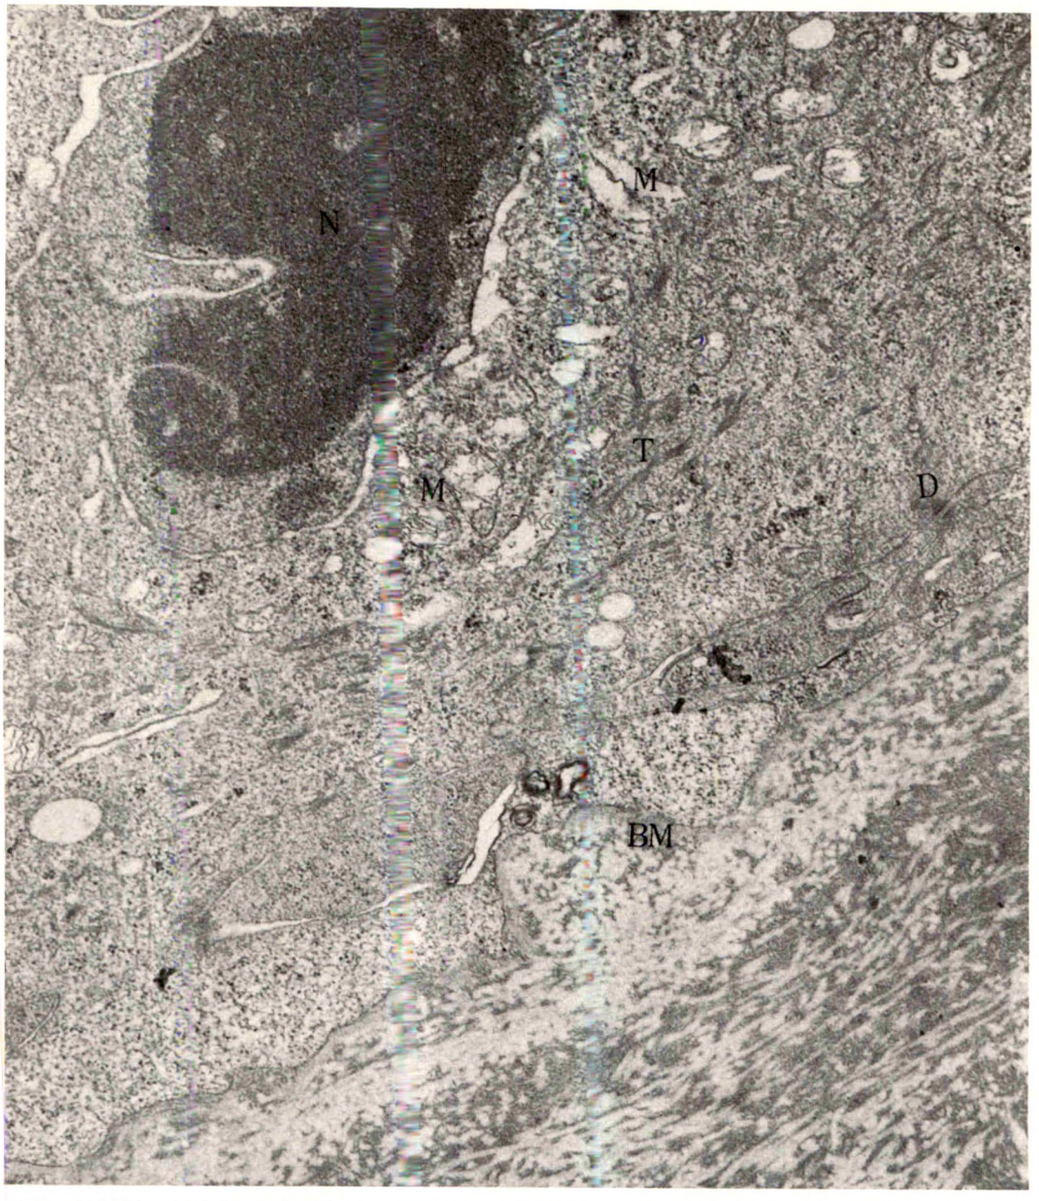

Fig. 4 (Akiya and Brown). The basal cell membrane is very irregular, and portions of the basement membrane (BM) are present. Bowman's membrane is replaced by the electron-dense fibrous materials (M = mitochondria, N = nucleus, D = desmosome, T = intracytoplasmic fibril) (×17,000).

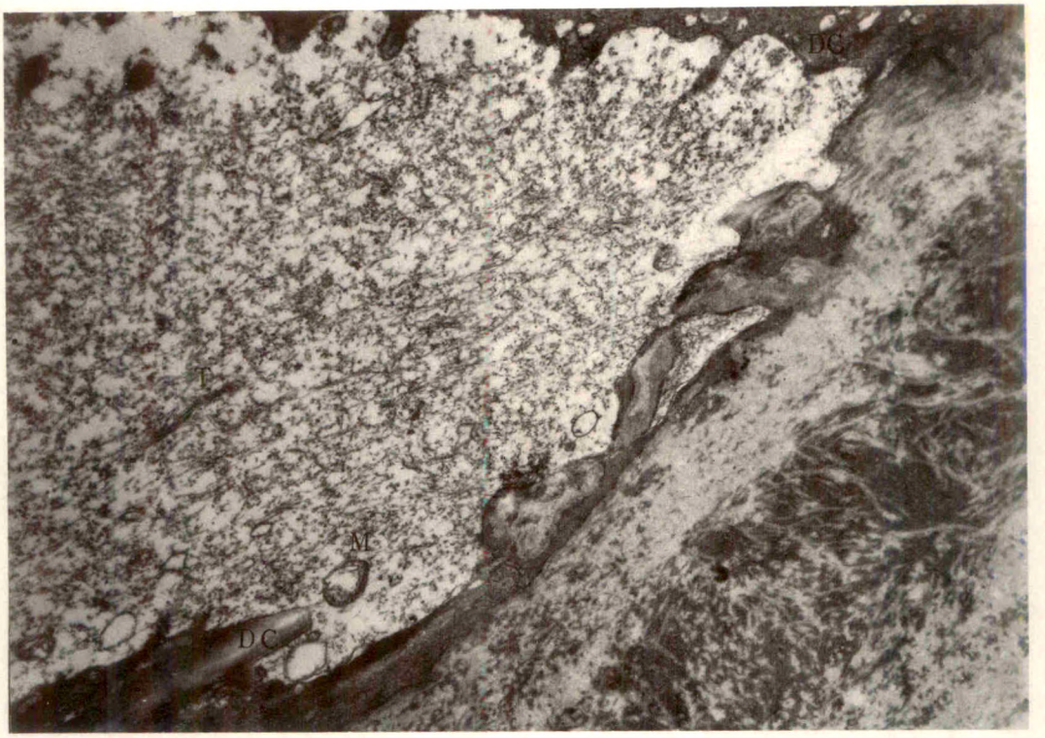

Fig. 5 (Akiya and Brown). This micrograph shows two basal epithelial cells and the anterior stroma. The basal membrane is absent. Bowman's membrane is replaced by disorganized tissues containing electron-dense masses which surround irregular extensions of one of the basal cells (×17,000).

fibrils whose composition and origin have not been determined. Similar material was unevenly dispersed in the anterior stroma near active fibroblasts.

The most likely origin of the new fibrous tissue is the corneal stromal fibroblast. A less obvious origin is the epithelial cell which under normal conditions produces tropocollagen or a collagen-like protein which is incorporated into the epithelial basement membrane. The consistently intimate relationship between the predominantly collagenous tissue which replaced Bowman's layer and the epithelium suggests that the new tissue could be a product of altered epithelial metabolism.

The abnormal stromal deposits in the specimen of Reis-Bücklers' dystrophy stain bright red with basic fuschin and alkalinized methylene blue. Generally, these deposits do not stain with other methods and it may be that this stain will be useful in the localization and identification of the deposits of Reis-Bücklers' dystrophy.

## Summary

The ultrastructural changes of Reis-Bücklers' dystrophy were mainly epithelial cell degeneration and replacement of Bowman's membrane by masses of collagen fibrils. Because these changes are identical to those reported previously, it is probable that they are specific for the dystrophy. The anterior stromal deposits may be visualized histologically after staining with basic fuschin and alkalinized methylene blue.

# OCCURRENCE OF HERPES ZOSTER OPHTHALMICUS IN A CHILD WITH ABSENT IMMUNOGLOBULIN A AND DEFICIENCY OF DELAYED HYPERSENSITIVITY

RICHARD A. KIELAR, M.D., GUY C. CUNNINGHAM, M.D., AND KENNETH L. GERSON, M.D.
*Lexington, Kentucky*

The following case is reported to present the uncommon finding of herpes zoster ophthalmicus in a child, and to show its possible relationship to an immunologic deficiency.

## CASE REPORT

A seven-year-old white boy was seen in the ophthalmology clinic on January 12, 1970, with a three-day history of a rash on his left forehead. Examination at that time revealed a skin eruption typical of herpes zoster ophthalmicus. It was noted that there was involvement of the skin of the inner canthus and the tip of the nose. Except for mild conjunctival injection, there was no evidence of any ocular involvement. Uncorrected visual acuity was 20/25 in each eye. Neosporin ophthalmic solution was instilled and examination the following day showed a small amount of edema of the lower eyelid.

Three days later, the uncorrected visual acuity in the left eye had decreased to 20/60. There was epithelial edema of the cornea and an irregular fluorescein staining pattern near the limbus. The stroma was not involved. There was a moderate aqueous flare and a few small, nonpigmented keratic precipitates (KPs) present. Atropine ophthalmic solution was begun. The following day the patient was febrile and dehydrated, and he was admitted to the hospital. Topical atropine and neosporin were continued, but five days later the aqueous flare in the anterior chamber was more severe, many more KPs were present, and there were folds in Descemet's membrane. Topical prednisone 1% was added to the local medications. Two days later, the aqueous flare was much less severe and there were fewer KPs. The central portion of the cornea revealed a superficial irregular stain measuring approximately 5.0 mm in diameter. At this time, the corticosteroid drops were decreased to twice a day. Three days later, the stain of the corneal epithelium was the same; however, the signs of anterior uveitis were less and the topical corticosteroids were then discontinued.

Three weeks later, an irregular central punctate stain of the corneal epithelium remained, several mid-peripheral, subepithelial corneal opacities were present, and corneal sensation was decreased. The patient was then put on methylcellulose drops four times a day. Two months later a tarsorrhaphy was performed due to persistent, diffuse corneal staining associated with decreased corneal sensation. It is also notable that there was an absence of lymphoid follicles in the conjunctival cul-de-sac, a finding described in immunoglobulin deficiencies by Little and Schulkind.[1]

FIG. 1 (Kielar, Cunningham, and Gerson). Cutaneous eruption seen on initial examination.

This child has had generalized candidiasis involving the mucous membranes of his mouth, skin, and nails since early infancy. The total leukocyte count and differential have been normal. His serum immunoglobulins were normal at the age of 18 months, but the serum, tear, and salivary IgA gradually diminished and have not been detectable since the age of six years. The serum IgG and IgM are normal for his age. The boy has consistently had a negative response to candida skin tests as well as to a variety of other tests for delayed hypersensitivity. It is of note that this patient had varicella at two

and one-half years of age and other illnesses with a usual course.

## Discussion

It is known that herpes zoster may be associated with gamma globulin deficiency. In a large pediatric hospital, Keidan and Mainwaring[2] observed 17 cases of herpes zoster involving various cutaneous sensory nerves during a 14-year period, and several of these patients had decreased serum gamma globulin levels when the rash appeared. Unfortunately, serum IgA levels were not reported on these patients.

There is a frequent association of herpes zoster and chronic lymphatic leukemia and Hodgkin's disease, and these lymphomatous diseases may have associated decreased gamma globulin levels. Shanbrum, Miller, and Haar[3] postulated that the decreased gamma globulin antibodies make these patients more susceptible to virus infection, and this decrease may also explain the tendency for herpes zoster to become generalized in these patients. Miller[4] has shown that patients with lymphomas have decreased tuberculin-type sensitivity, and decreased circulating antibodies. In a similar manner, Sokal and Firat[5] have shown that a number of patients with Hodgkin's disease and herpes zoster have a negative delayed type skin test to numerous and various antigens.

There is evidence that IgA deficiency is associated with several diseases. It is known that IgA antibodies have viral neutralizing activity.[6] Chilgren, Meuwissen, Quie, and Hong[7] have described several cases of chronic mucocutaneous candidiasis with inability of these patients to manifest delayed hypersensitivity, and also demonstrated in these patients the presence of a defect in parotid fluid IgA antibody against C. albicans. Patients with ataxia-telangiectasia have been shown to have low IgA levels, absent delayed hypersensitivity reactions, and progressive sinobronchial pulmonary infections.[8] Tokumaru[9] also demonstrated decreased herpes simplex IgA antibody titers in the serum of patients with recurrent herpetic stomatitis.

Although there is no direct evidence for the association of herpes zoster in chiddren with IgA deficiency, the occurrence of these two uncommon findings in a child may be more than a fortuitous association. Herpes zoster occurs in lymphomatous neoplasias where there is evidence of an altered immune mechanism, including absent delayed hypersensitivity. IgA deficiency also occurs in disease states where there are defects in delayed hypersensitivity. There is an association of lymphoid tumors in patients with ataxia-telangiectasia, which manifests IgA deficiency and absent delayed hypersensitivity as its immunologic defects.[10] The prolonged and severe course of herpes zoster ophthalmicus in this child is likely to be related to the absence of secretory and serum IgA together with a deficiency of delayed hypersensitivity.

## Summary

In a seven-year-old boy with an IgA deficiency, the course of herpes zoster was prolonged and severe. This child's history showed that serum immunoglobulins were normal at the age of 18 months; however, the serum, lacrimal, and salivary IgA were no longer detectable after the age of six years. Normal conjunctival lymph follicles were absent. It is postulated that the IgA deficiency and absent delayed hypersensitivity increased the susceptibility to, and prolonged the clinical course of the viral illness in this child.

OPHTHALMIC MINIATURE

Once we were hunting under the isolated rocks of La Cassidaigne. Twenty fathoms down Did shot an eight-pound liche. The harpoon entered behind the head but missed the spinal column. . . . Dumas hauled in the last feet of cord and got a grip on the harpoon shaft. He flashed his belt dagger and plunged it into the heart of the big fish. A thick puff of blood stained the water.

The *blood was green!* Stupefied by the sight, I swam close and stared at the mortal stream pumping from the heart. It was the colour of emeralds. We had swum among the liches as aqualungers, and taken them on goggle-dives, but we never knew there was a type with green blood. Flourishing his astounding trophy on the harpoon Did led the way to the surface. At 55 feet the blood turned dark brown. At 20 feet it was pink. On the surface it flowed red.

Once I cut may own hand seriously 150 feet down and saw my own blood flow green . . . I thought of the liche and managed to convince myself that my blood was really red.

# IMMUNOGLOBULIN E IN HUMAN TEARS

G. E. BRAUNINGER, M.D., AND Y. M. CENTIFANTO, PH.D.
*Gainesville, Florida*

Immunoglobulin E (IgE) is a distinct immunoglobulin class present in serum in extremely low concentrations ranging from 100 to 700 ng/ml.[1,2] It is composed of two light and two heavy chains,[3] possesses antibody activity, and is specifically characterized by the presence of the epsilon antigenic focus on the heavy chains.[1,2]

IgE is of unique importance, as it is the only immunoglobulin that has been isolated and demonstrated to be capable of mediating atopic (reaginic) type hypersensitivity reactions in man. The term reagin was originally applied to the serum factor which on passive transfer to healthy individuals caused allergic symptoms and positive skin reactions (wheal and erythema) to develop. Recent studies demonstrated that a very small amount of IgE antibodies isolated from ragweed-sensitive patients' sera passively sensitizes the skin of normal individuals on intracutaneous injection.[2,4] On challenging the same skin site by the intracutaneous injection of ragweed antigen, a wheal and erythema reaction (Prausnitz-Küstner reaction) occurs.[2,4] The minimum amount of IgE antibody necessary to passively sensitize the skin has been estimated to be on the order of $10^{-6}$ to $10^{-5}$ microgram protein nitrogen.[5]

Extensive studies have shown that the ability of serum immunoglobulin fractions to produce the wheal and erythema reaction is related to the IgE content of the serum fractions studied, and is not associated with the four other known immunoglobulins, IgG, IgA, IgM, and IgD.[4] The IgE fraction of patients' sera which did not contain detectable IgG, IgA, IgM, or IgD demonstrated very high reaginic activity which was removed by anti-IgE but not by specific antibody to the other immunoglobulins.[2,4]

Lymphoid cells producing IgE have been located in the respiratory and gastrointestinal mucosa, and in lymph nodes draining the respiratory tract and gut, but only infrequently in subcutaneous lymph nodes, spleen, buffy coat cells, and marrow.[6] This demonstration of an anatomical association of cells that produce IgE with mucous membranes, combined with the finding of higher ratios of IgE/IgG in sputum and nasal washings compared to the sera of the same individuals, supports the possibility that IgE is produced locally near the mucous membrane surfaces.[7]

It is apparent that IgE, if present in tears, might represent a local immune system participating in atopic phenomena in the eye. Therefore, it was considered important to initially determine the presence of IgE in the tears of normal individuals and patients with presumed atopic disorders (vernal conjunctivitis and hay fever conjunctivitis), using a semiquantitative radioimmunodiffusion technique[8] capable of detecting IgE at levels on the order of $10^{-8}$ g/ml.

## MATERIALS AND METHODS

*Subjects*—Tear samples were obtained from 15 individuals, ages 18 to 40 years, whose ocular histories and external eye examinations were normal. Additional samples were obtained from five patients with untreated, clinically diagnosed, typical vernal conjunctivitis; four patients with untreated active ragweed conjunctivitis (seen during ragweed season); one patient with chronic untreated, bilateral Mooren's ulcer, and one patient with bullous keratopathy two days following penetrating keratoplasty.

From the Department of Ophthalmology, College of Medicine, University of Florida. This study supported in part by Public Health Service Grants EY-00007, EY-00446, and EY-00033 from the National Eye Institute.

Reprint request to Y. M. Centifanto, Ph.D., Department of Ophthalmology, College of Medicine, University of Florida, Gainesville, Florida 32601.

Tear flow was not stimulated by contact with the eye, but the subjects were asked to stare at a point without blinking. When tears began to flow, the first 50 λ were collected in a capillary tube and stored in vials at −4°C for less than one month.

*Radioiodination*—Using rabbit antisheep globulin serum, a pure IgG fraction of such serum was obtained by DEAE chromatography according to the method of Levy and Sober.[9] This preparation was then labeled with $^{131}I$, according to the method of McConahey and Dixon.[10]

*Measurement of IgE*—Sheep antihuman IgE and IgE reference standards were obtained from D. Rowe of the World Health Organization. The IgE reference standard contained 10148 ng/ml. This antiserum is specific for the Fc fragment of IgE. Such specificity precludes any cross-reaction with light-chain determinants of other immunoglobulins present in tears. The immunodiffusion plates containing sheep antihuman IgE were prepared according to the method of Rowe.[8] A series of 3 mm holes were cut in the agar and the individual wells were filled with IgE reference standards, tear samples under test, and phosphate-buffered saline (PBS) controls. The plates were then incubated in a moist chamber at 37°C for 48 hours, washed in the cold with PBS for 48 hours, overlaid with the $^{131}I$ rabbit antisheep globulin for 30 minutes, and allowed to stand at room temperature overnight. The excess unreacted $^{131}I$ label was removed by washing with PBS for 48 hours. The plate was dried and exposed to x-ray film for several hours. The diameter of the diffusion ring around the well indicated the relative IgE concentrations (Fig. 1).

*Measurement of IgA*—The IgA content of tear samples was measured by radial immunodiffusion in Hyland plates as previously described.[11]

## Results

IgE was determined in a semiquantitative manner and found in small, detectable amounts in the tears of all patients studied. The IgE determined was total tear IgE and does not selectively demonstrate IgE antibody.

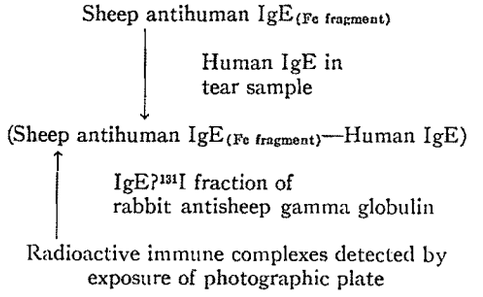

Fig. 1 (Braunninger and Centifanto). Schematic diagram of IgE determination by radioimmunodiffusion method.

It was possible, using a double-blind method, to separate two populations of samples on the basis of relative IgE content. One group demonstrated large immune rings which extended more than 1 mm beyond the rim of the well on the exposed photographic plates, while the other group showed smaller but still definite rings compared to controls. The group of patients whose specimens demonstrated large immune rings had measurable IgE in tears ranging from 1650 to 2600 ng/ml. Specimens from the other group demonstrated smaller but still definite rings that were not quantitatively resolved by our method.

The group demonstrating relatively high IgE levels included seven patients with diseases generally accepted as being caused by atopy and included all five cases of vernal conjunctivitis, two of the four cases of ragweed conjunctivities, and only one of the 15 normal subjects. The group demonstrating minimal IgE included the patient with Mooren's ulcer, the post-keratoplasty patient, the two remaining patients with ragweed conjunctivitis, and 14 of the 15 normal subjects (Table 1).

Simultaneous quantitative IgA determinations on all the tear samples studied were within the range of normality and no corre-

TABLE 1

RELATIVE IgE DETERMINATIONS IN TEARS

| Diagnosis | Age (in years) | Relative IgE Content | Range IgA (mg/100 ml) |
|---|---|---|---|
| Vernal conjunctivitis | 14–29 | Elevated in 5 of 5 | 24–33 |
| Ragweed conjunctivitis | 23–42 | Elevated in 2, trace amount in 2 of 4 | 11.5–20 |
| Penetrating keratoplasty | 46 | Trace amount in 1 of 1 | — |
| Mooren's ulcer | 72 | Trace amount in 1 of 1 | 36 |
| Normal individuals | 16–40 | Elevated in 1 of 15<br>Trace amount in 14 of 15 | 8.8–50 |

lation between IgE and IgA tear content was found. Furthermore, there was no correlation between the clinical inflammatory state of the eye from which the tears were obtained and the relative IgE levels measured. The data indicated that IgE is present in human tears in detectable amounts and strongly suggest an association of higher IgE tear content with atopic disease of the external eye. However, a relatively low tear IgE level does not exclude allergy and elevated IgE in tears may occur without apparent allergic disease. Relatively small amounts of tear IgE were present in two of the four patients with ragweed conjunctivitis, while one of the 15 apparently normal individuals had elevated tear IgE.

## DISCUSSION

The detection of IgE in normal human tears and the strong suggestion that it is present at relatively increased levels in cases of ragweed and vernal conjunctivitis is a matter of potential importance. Increased levels of IgE in the serum of allergic asthmatic,[12] ragweed sensitive,[13] and eczematous patients,[14] combined with the finding of cells producing IgE near mucous membranes[6] suggest that this immunoglobulin is the mediator of atopic hypersensitivity at the surface of eye.

Immunochemical investigations have indicated the possibility that two IgE antibody molecules on the target-cell surface are bridged together by a single antigen molecule to initiate the production of inflammation.[2] Indeed, extremely small amounts of soluble IgE antibody-ragweed antigen complexes formed in vitro are maximally active at a two: one ratio ($Ab_2$ Ag) directly causing the wheal and erythema reaction on intracutaneous injection in normal subjects.[2] This information, combined with the findings of relatively increased IgE in the tears of patients with vernal conjunctivitis and ragweed conjunctivitis, suggests that such antigen-antibody complexes fixed to target cells near the conjunctival mucous membrane could produce inflammation and result in clinical disease.

Over 40 years have elapsed between the demonstration of the Pausnitz- Küstner reaction and the recent understanding that IgE is the mediating antibody present in serum in amounts previously too small to detect. As better methods of quantitatively measuring total IgE are improved over the present laborious procedures, elevated IgE may be found in a variety of diseases in which elevated immunoglobulin has not been detected.

With the increased understanding of IgE that will result from the quantitative determination of this immunoglobulin in tears and sera of normal individuals and patients with eye disease, IgE determination may become of value to the clinician faced with the problem of defining the presence of a hypersensitivity component in patients whose inflammation of the external eye may be of infectious, allergic, toxic, or combined etiology.

## Summary

IgE was demonstrated by a specific radioimmunodiffusion procedure and was found in detectable amounts in all tear samples studied and in increased amounts in seven out of nine patients suffering from presumed allergic disorders of the external eye, including all five cases of vernal conjunctivitis.

IgE may represent a local immune system at the mucous membrane surfaces of the eye mediating allergic phenomena in man and causally related to certain allergic disorders.

A further definition of the IgE system in man may be of clinical importance. IgE levels in tears might someday serve as a test for the presence of an atopic component in inflammatory states and in the diagnosis of inflammations of the cornea and conjunctiva.

# CLASSIFICATION OF THE CHOROIDAL ATROPHIES

ALEX E. KRILL, M.D., AND DESMOND ARCHER, F.R.C.S.
*Chicago, Illinois*

A number of diseases of the ocular fundus are characterized by abnormalities of the choroidal vasculature. These conditions vary in severity with changes ranging from atrophy of the choriocapillaris only in the posterior eyegrounds to an almost complete absence of all choroidal vascular elements throughout most of the eyegrounds.

Heretofore, most descriptions of these clinical entities have been based on direct ophthalmoscopic observations, and as a result, the literature abounds with vague, erroneous, and misleading terms. The recent introduction of electrophysiologic methods of analysis and angiographic techniques, coupled with accumulated histologic data, have given fresh insight into the nature of many of these conditions.

It is the purpose of this paper to describe and classify those choroidal atrophies believed to be primary in nature, progressive, and not associated with obvious toxic or inflammatory factors.

## METHODS

Thirty patients with choroidal atrophy were selected for study. These patients could be conveniently grouped according to the position of the lesion and the extent of the involvement of the fundus, and by the degree of involvement of the different layers of the choroidal vasculature.

*Group 1—Regional choroidal atrophies*—This group included patients in whom the involved area was limited to the posterior pole of the eye. This group was subdivided into (a) patients with choriocapillaris atrophy alone, and (b) patients with total choroidal vascular atrophy.

*Group 2—Diffuse choroidal atrophies*—This group consisted of patients with extensive involvement of the eyegrounds, and it was subdivided into (a) patients with choriocapillaris atrophy alone, and (b) patients with total choroidal vascular atrophy. The latter subgroup (b) was further divided on the basis of inheritance into (1) patients with autosomal inheritance, and (2) patients with X-linked inheritance.

All patients received routine ophthalmoscopic evaluation, visual field studies with the Goldmann perimeter, color vision testing, dark adaptation, electroretinogram (ERG), and frequently, electro-oculogram (EOG) studies. The techniques used for these tests have been described.[1-3]

A modified Zeiss fundus camera was used for fluorescein angiography. This permitted rapid sequence photography and automatic recording of the time of photography. The apparatus and technique are described elsewhere.[4]

## CLASSIFICATIONS

### REGIONAL CHOROIDAL ATROPHIES

#### CHORIOCAPILLARIS ATROPHY INVOLVING THE POSTERIOR EYEGROUNDS

There are three topographical patterns that the disease may follow: (1) involvement of the macula alone, (2) involvement of the peripapillary area, and (3) involvement of the paramacular area.

1. Involvement of the macula alone. Disease at this site was previously called central choroidal sclerosis, central choroidal vascular atrophy, central areolar choroidal sclerosis, central progressive areolar choroidal dystrophy, and central choroidal angiosclerosis.[5-8]

2. Involvement of the peripapillary area. Disease involving this area was previously

From the Eye Research Laboratories, the University of Chicago. This study was supported in part by Public Health Service Grants EY-0523, EY-00277, and RR-55.

Reprint requests to Alex E. Krill, M.D., Eye Research Laboratories, 950 East 59th Street, Chicago, Illinois 60637.

termed peripapillary choroidal sclerosis. This form may be associated with angioid streaks, and on occasion may precede them. Occasionally, this type is characterized by finger-like extensions of choriocapillaris atrophy from the primary area of involvement around the disk.

3. Involvement of the paramacular area. This is also referred to as circinate choroidal sclerosis.[9] This form may expand to occupy most of the posterior eyegrounds.

*Clinical features*—The age of onset is thought to range from about 20 to 40 years. Vision may not be significantly affected unless the macula is involved. In familial cases, the inheritance has been either autosomal recessive or dominant.[5-11]

In our patients the earliest fundus change was atrophy of the retinal pigment epithelium. This was characterized by pigment stippling and mottling, with occasional formation of clumps. These areas demonstrated hyperfluorescence on fluorescein angiography, typical of a pigment epithelial abnormality.[12] According to Sorsby and Crick,[6] the earliest changes are nonspecific edematous-exudative reactions in the macular and perimacular areas, or an atrophic reaction—pigment mottling with exudative reaction around it. We have not seen such changes in what we thought were early cases, or at the borders of lesions which later showed progression.

Choriocapillaris atrophy probably closely follows initial changes in the pigment epithelium. As a result of both choriocapillaris atrophy and pigment epithelium disease, the larger choroidal vessels become visible, and are seen as tortuous, yellow-white cords, often with white deposits along their borders. These vessels are vividly outlined through all stages of fluorescein angiography.*

As the disease progresses, the area of choriocapillaris atrophy slowly expands centrifugally, revealing the underlying intermediate-sized and larger choroidal vessels.

The appearance and evolution of the disease is usually symmetrical; however, occasionally one eye may show advanced disease with the fellow eye only minimally involved.

The retinal vasculature may be attenuated in some cases, with the optic disk assuming the waxy appearance typical of retinitis pigmentosa.

*Retinal function*—Visual acuity and color vision are moderately to severely abnormal (except in cases where the fovea has been spared). Peripheral visual fields are normal. Central and paracentral scotomas reflect macular involvement by the disease process.

Subjective dark-adaptation studies, which measure retinal function away from the area of obvious ophthalmoscopic involvement, are frequently mildly to moderately abnormal. The ERG and EOG, which reflect functional integrity of large retinal areas, are also frequently abnormal. Thus, from a functional standpoint, the abnormality is more widespread than would be expected from ophthalmoscopic examination.

*Histology*—Histologic studies of involved areas have shown atrophy of the choriocapillaris, pigment epithelium, and neuroepithelium.[13-15] Bruch's membrane was relatively normal in two of these eyes studied,[13,14] but definitely abnormal in the third.[15]

## Case reports

Case 1 illustrates the following points: (1) progression of eyeground changes, (2) asymmetry, and (3) impairment of peripheral retinal function.

*Case* 1—This 64-year-old man has a sharply defined area of choriocapillaris atrophy in the macula (Fig. 1). He gave a history of experiencing some visual loss in his left eye 10 years earlier. He also reported that his maternal grandmother had grossly impaired eyesight when she was middle-aged but the cause of her blindness is uncertain. An autosomal dominant inheritance, with lack of penetrance of the gene in the patient's mother, is possible, but unsubstantiated.

*Progression of eyeground changes*—A slight in-

* Normally, the larger choroidal vessels are not seen beyond the early or midretinal venous phase of angiography because of the dense homogeneous background formed by the normal choriocapillaris which is completely filled by this stage.[4]

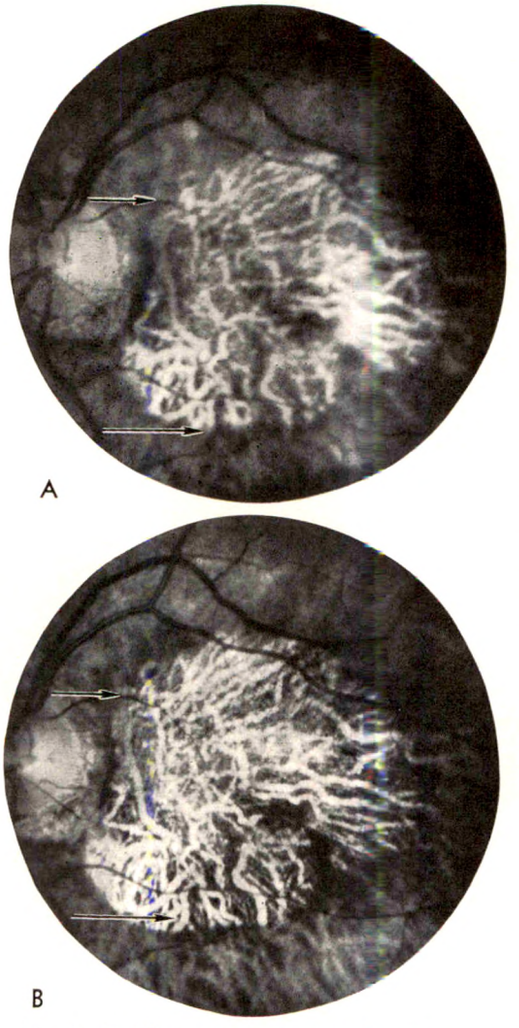

Fig. 1. (Krill and Archer). Case 1. Left posterior eyegrounds of a 64-year-old man with choriocapillaris atrophy at the macula. (A) Increased visibility of the larger choroidal vessels is seen in July, 1967. These vessels are tortuous, and of variable color and caliber. The area of pigment epithelial and choriocapillaris atrophy has a sharply defined border. Fine pigment clumps are scattered throughout the area of involvement. (B) In August, 1969, there is an expansion of the involved area (compare arrows in A and B), and there is better definition of the large and intermediate-sized choroidal vessels.

crease in the total area of choriocapillaris atrophy occurred from July of 1967 to August of 1969 (compare arrow sites in Figs. 1-A and B). The larger choroidal vessels have not altered during this time, although some appear to be more sharply defined. The small branches of the larger choroidal vessels are more obvious.

*Asymmetry*—The fovea is minimally affected in the right eye, but is directly involved in the left. Right vision has remained 20/25, whereas left vision has deteriorated to 20/300.

*Peripheral retinal function impairment*—Peripheral visual fields are normal. Dark adaptation beyond the posterior eyegrounds is normal. A subnormal ERG (Fig. 2) and an abnormal EOG (Fig. 3) were obtained from both eyes.

Cases 2 and 3 illustrate the following points: (1) progression of eyeground changes, (2) sparing of the fovea, and (3) impairment of peripheral retinal function.

*Case 2*—This 58-year-old man has choriocapillaris atrophy throughout most of the posterior eyegrounds (Fig. 4). Visual symptoms began about the age of 35 years. A 65-year-old sister with the same condition had severe visual impairment (Fig. 5). Autosomal recessive inheritance is presumed.

*Progression of eyeground changes*—A considerable extension of the total area of choriocapillaris atrophy occurred from 1963 to 1969 (compare arrow site in Fig. 6-A with that in 6-B). No edema or exudates were seen at sites of progression. Pigment stippling, depigmentation, and increased visibility of the underlying larger choroidal vessels were the earliest changes in such areas.

There was no significant atrophy of the large choroidal vessels during the six-year follow-up period. However, the large choroidal vessels became more easily visualized (compare Figs. 6-A and B), and a lacy intertwining network of fine branches from these vessels was eventually seen. In both 1963 and 1969 the retinal arterioles were slightly attenuated and the optic disk showed a waxy pallor.

*Sparing of fovea*—Visual acuity in 1963 and 1969 was 20/25 in the right and 20/40 in the left eye. The patient's sister, with the same disease, has been severely blind for many years, indicating that the site of this disease may vary among affected members of the same family.

*Peripheral retinal function*—Peripheral visual fields were normal, but large paracentral scotomas, corresponding to the areas of ophthalmoscopic involvement, were evident in Case 2. Dark adaptation, mildly abnormal in 1963, was markedly abnormal in 1969. (The final threshold was one-half log unit above the normal mean plus two standard deviations in 1963, but in 1969 was 2.5 log units above this value.) The ERG, subnormal in 1963, was considerably smaller on retesting in 1969 (Fig. 7).

Case 3 illustrates parapapillary choriocapillaris atrophy.

*Case 3*—This 45-year-old man had normal vision and choriocapillaris atrophy around the disk (Fig. 8). There were four finger-like extensions of the area of involvement. There were a few angioid streaks in the upper temporal atrophic area. Visual

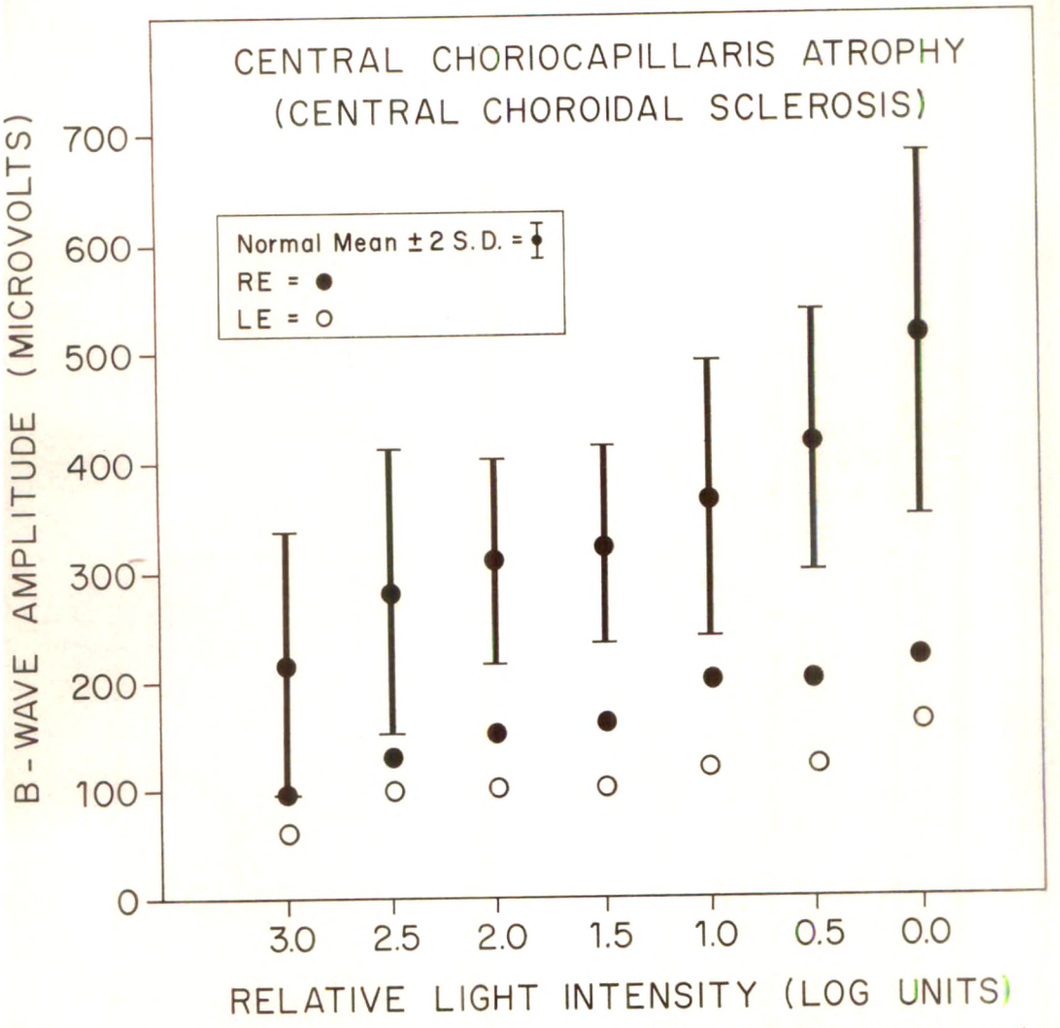

Fig. 2 (Krill and Archer). B-wave amplitudes from a normal control population (normal mean plus or minus two standard deviations) and from Case 1. Note that b-wave amplitudes are subnormal at all intensities of stimulation used.

fields demonstrated enlarged blind spots; all other visual function tests were normal.

TOTAL CHOROIDAL VASCULAR ATROPHY INVOLVING THE POSTERIOR EYEGROUNDS

This condition is characterized by atrophy of the large choroidal vessels, as well as the choriocapillaris. The atrophy often has a serpiginous-like configuration. There are four sites of involvement: (1) the macula alone, (2) the posterior eyegrounds, (3) nasal and temporal foci, and (4) the disk.

When confined to the macula or throughout most of the posterior eyegrounds, the disease has been called choroidal vascular abiotrophy helicoid, serpiginous degeneration of the choroid,[16] or central gyrate atrophy.[8]

When the foci is nasal or temporal, the disease has been termed progressive bifocal chorioretinal atrophy.[17] It begins as a discrete temporal focus of semilunar configurations and feathery edges. A similar nasal focus develops later in life.

When the site is the disk, names include

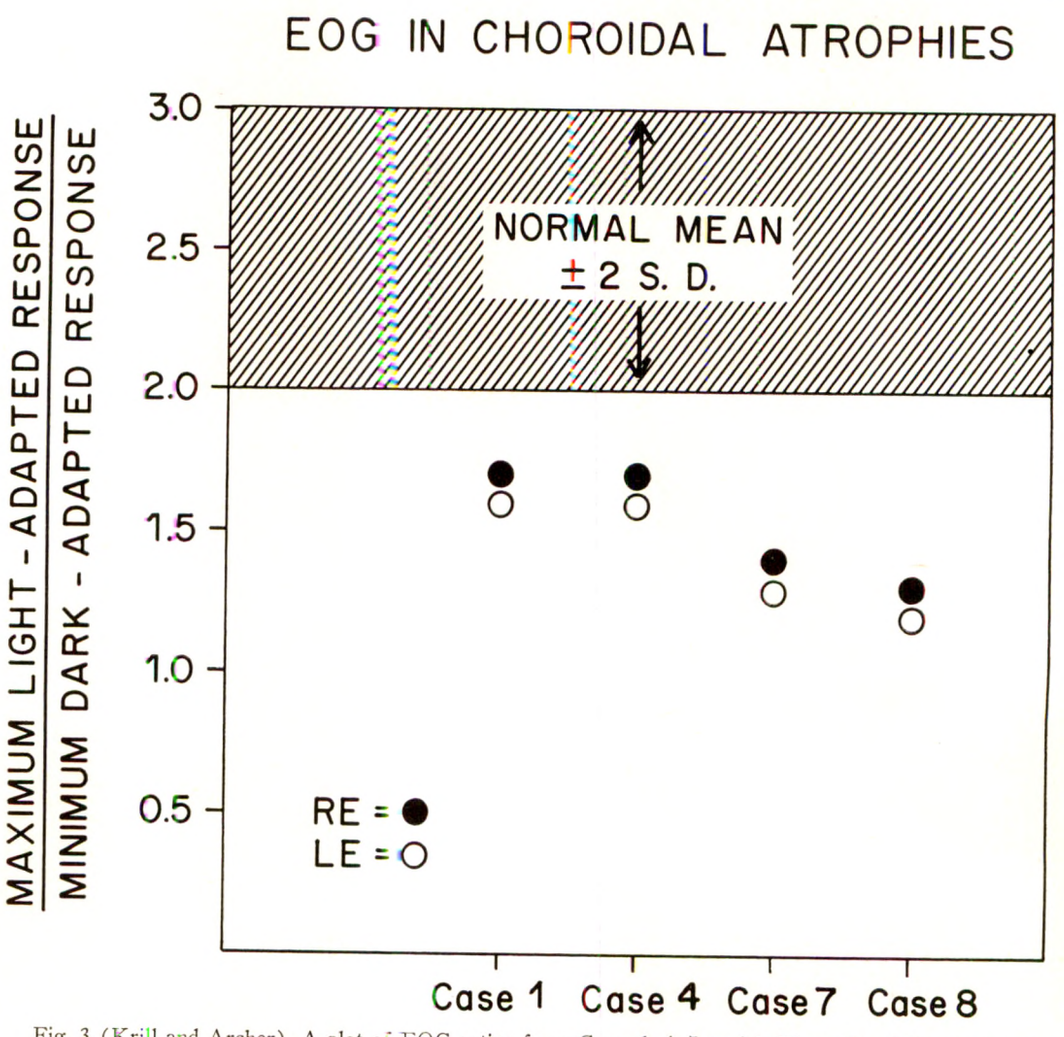

Fig. 3 (Krill and Archer). A plot of EOG ratios from Cases 1, 4, 7, and 8. The ratio of the maximum light adapted response to the minimum dark adapted response for each patient is plotted and compared with a standard control group (normal mean plus or minus two standard deviations). These patients all had abnormal values.

helicoid peripapillary chorioretinal atrophy,[18,19] choroiditis areata,[20] circumpapillary dysgenesis of the pigment epithelium,[21] and chorioretinitis striata.[22] In such cases, wing-like radial extensions are characteristic.

*Clinical features*—There is no uniform age of onset for the conditions discussed here. Progressive bifocal chorioretinal atrophy may begin in infancy. Total choroidal vascular atrophy around the disk has been observed to develop between the ages of four to 43 years, with the majority of cases developing in the first 25 years of life.[7] The serpiginous form of atrophy involving the macula or posterior eyegrounds probably begins somewhere between the ages of 35 to 55 years.

The inheritance is clearly autosomal dominant in progressive bifocal chorioretinal atrophy.[17] Involvement of both a mother and son with a peripapillary atrophy suggests that this type of inheritance may be operant in some of these patients.[7,23] However, almost all the other cases are sporadic, sug-

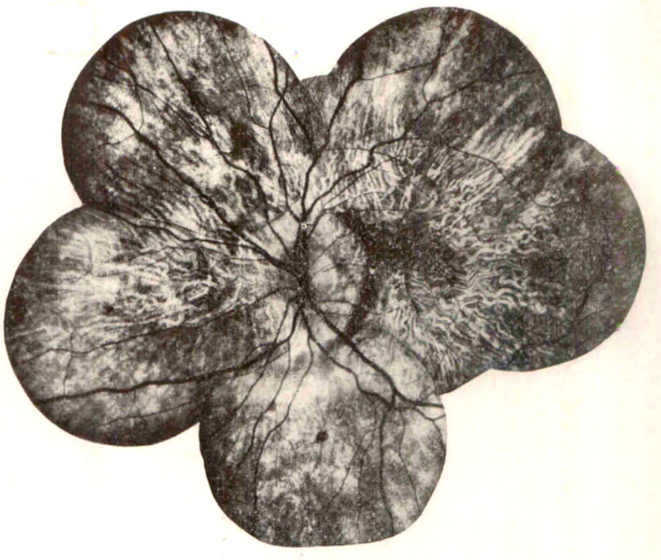

Fig. 4 (Krill and Archer). Case 2. Composite photograph of the left posterior eyegrounds. The choriocapillaris atrophy involves much of the posterior eyegrounds.

gesting either an environmental origin or autosomal recessive inheritance for cases which are genetic in origin.

The earliest change consists of a homogeneous gray, edema-like appearance of the involved retina, probably representing a change in the pigment epithelium. This type of lesion is frequently surrounded by a zone of pigment stippling and atrophy indicative of further deterioration of the pigment epithelium. These areas show hyperfluorescence on fluorescein angiography typical of abnormal pigment epithelium.[24] This early lesion advances to a stage of total choroidal vascular atrophy in which there are only a few large choroidal vascular remnants. There does not appear to be an intermediate stage during which only the choriocapillaris atrophies.

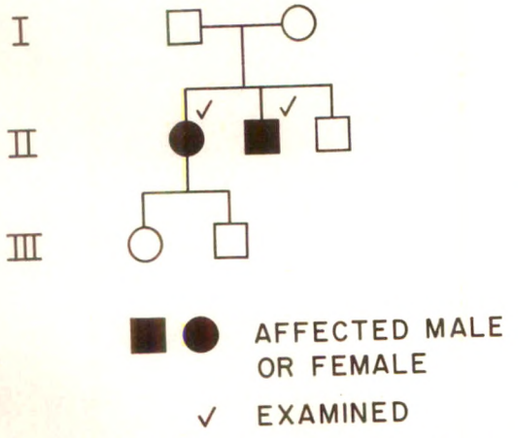

Fig. 5 (Krill and Archer). Pedigree of Case 2.

*Retinal function*—The unusual geographic configuration often causes asymmetrical impairment of central visual acuity. Although the atrophy appears limited to the posterior eyegrounds, retinal function tests (dark adaptation, ERG, EOG) usually show abnormal response beyond the obviously involved area. Visual fields are usually normal except for central and paracentral scotomas corresponding to obviously involved areas.

## Case reports

Case 4 illustrates the following points: (1) early eyeground changes, (2) progression of eyeground changes, and (3) central and peripheral visual function impairment.

*Case* 4—This 65-year-old man had serpiginous-like areas of total choroidal vascular atrophy at both maculas (Fig. 9). He complained that his vision had been "failing" in both eyes for at least six months. There was no family history.

*Early eyeground changes*—A homogeneous grayish area was evident at the superior portions of the lesions in 1963 (see A in Fig. 9-A and B).

*Progression in eyeground changes*—Considerable progression occurred between 1963 and 1969 (compare Fig. 9-A and B with Fig. 9-C and D). Almost

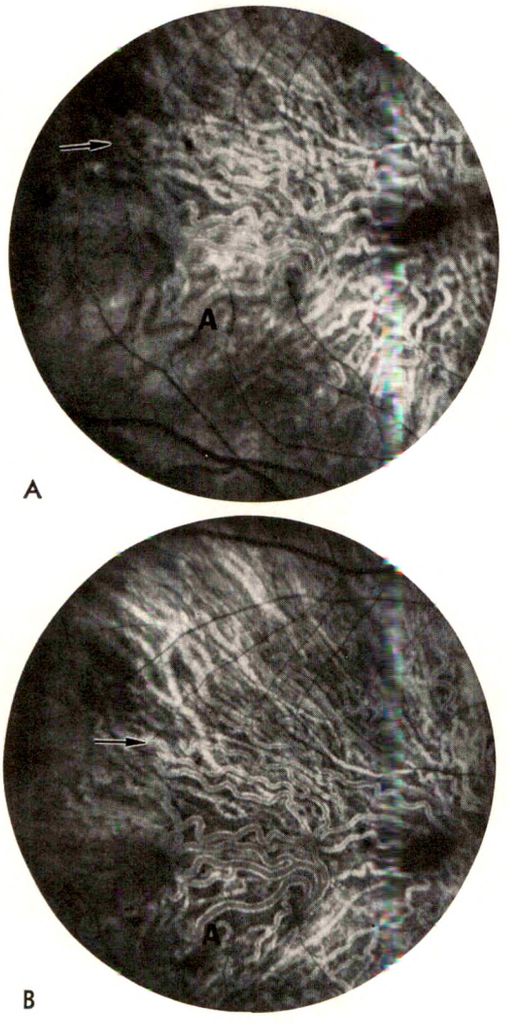

Fig. 6 (Krill and Archer). Case 2, posterior eyegrounds. (A) The right macula in 1963 and (B) the right macula in 1969. During the period of time between 1963-69, no atrophy of the larger choroidal vessels occurred; however, these vessels are more obvious in the recent photographs (compare sites marked A). There has been an expansion of the area of pigment epithelium and choroidal atrophy (compare arrow sites).

the entire macular area of both eyes was involved in 1969. In addition, the atrophy extended inferior to the optic disk and temporal to the macula (Fig. 9-C and D). The temporal retinal arterioles had become slightly attenuated by 1969.

*Central and peripheral visual function impairment*—Visual acuity was 20/30 in both eyes in 1963, but had deteriorated to 20/200 in both eyes by 1969. Complete retinal function studies were done only in 1969. Visual fields were normal apart from large central scotomas. Dark adaptation was normal beyond the involved areas. An EOG was abnormal (Fig. 3) and the ERG subnormal (Fig. 10).

Case 5 illustrates the following points: (1) early eyeground changes, (2) progression of eyeground changes, and (3) asymmetry, with (4) normal peripheral visual function.

*Case* 5—A 52-year-old man with a five-year history of left visual loss shows atrophy of the choroidal vasculature throughout most of the posterior eyegrounds (Fig. 11). The right eye had slight visual loss of recent onset. There was no family history of similar ocular disease.

*Early eyeground changes*—The temporal portion of the left macula showed a homogeneous grayish edema-like opacification (letter A in Fig. 12-A). There appeared to be no intraretinal edema at this site on slit lamp examination. Nasal to this area there is pigment epithelial atrophy with pigment stippling (Fig. 12-A). A fluorescein angiogram showed hypofluorescence in the area of gray opacification (see arrow in Fig. 12-B) and a spotty hyperfluorescence in the adjacent depigmented region.

*Progression of eyeground changes*—Both eyes showed marked progression of choroidal atrophy. Note changes in the right eye over a one-year period (compare arrow sites in Figs. 12-C in 1968 and 12-D in 1969).

*Asymmetry*—On initial examination in 1966, right vision was 20/25 and left vision was 20/200. On last evaluation in 1969, right vision was still 20/25, but 10/200 in the left eye.

*Peripheral visual function*—There was a large left central scotoma and bilateral irregular paracentral scotomas coincident with the areas of ophthalmoscopic abnormalities. Peripheral fields were normal; an ERG in 1969 revealed responses at the lower limit of normal (Fig. 10).

## Malignant myopia

We consider cases of malignant myopia to belong to the group of regional choroidal atrophies, and as most of these cases eventually show atrophy of both large and small choroidal vessels, they fit into the subgroup of total choroidal vascular atrophies.

These patients usually have at least six diopters of myopia. Discrete areas of atrophy, eventually involving small and large choroidal vessels, the retinal pigment epithelium, and possibly a portion of the external retina, are seen in the posterior eyegrounds of such patients.[25]

Focal areas of atrophic choriocapillaris and pigment epithelium are seen initially. They often have pigment clumps around

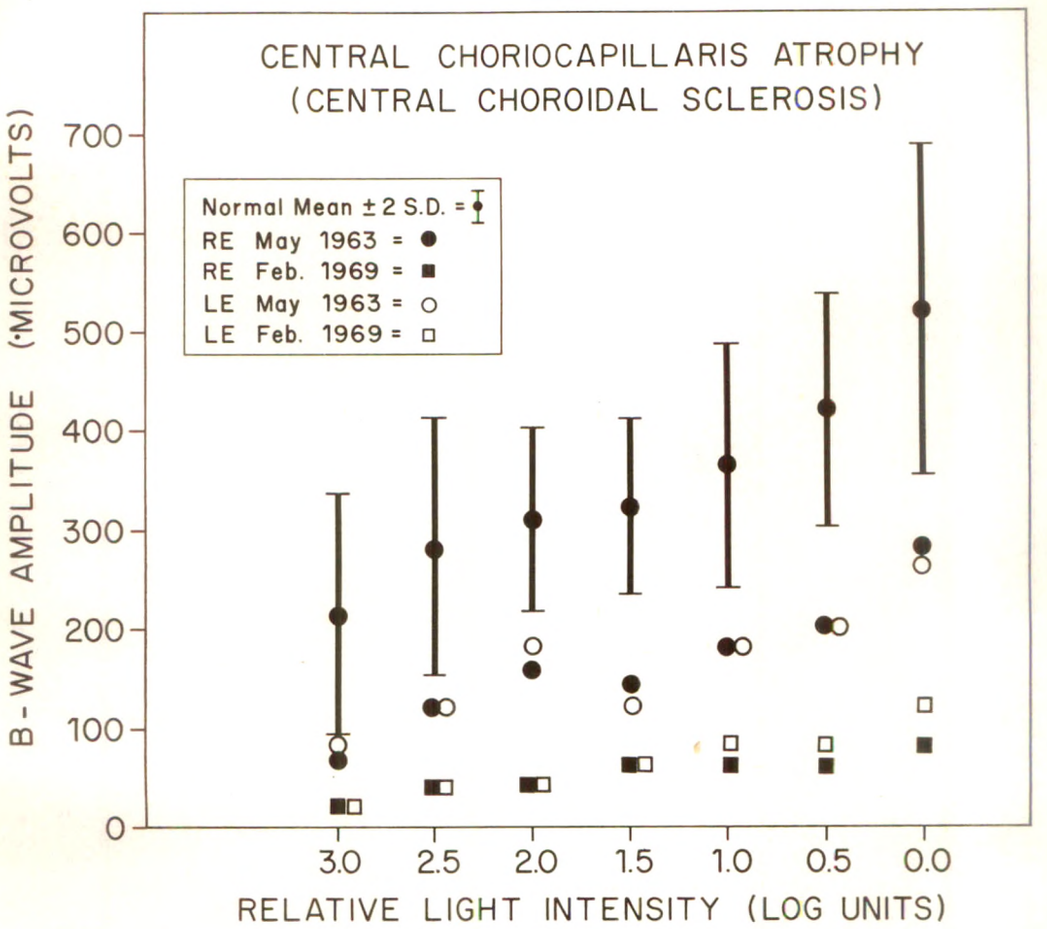

Fig. 7 (Krill and Archer). Case 3. B-wave amplitudes plotted from both eyes in 1963 and from both eyes in 1969 at seven different intensities of light stimulation. The data from this patient are compared with a normal control group. Note that subnormal b-wave amplitudes were obtained on initial evaluation and that a marked decrease in these amplitudes occurred over the six-year period.

their borders. These focal areas may coalesce and form large geographic areas of choroidal vascular atrophy, often merging with an enlarged peripapillary degenerative area.

Changes at the optic disk are common. A border of chorioretinal atrophy and pigmentation may appear on the temporal side of the disk (temporal or myopic crescent), or it may surround the entire disk. Commonly, an oblique entry of the optic nerve into the eyeball may cause an extension of the retina over the nasal portion of the optic disk (supertraction crescent or supertraction of the retina).

A posterior ectasia or staphyloma, usually nasal to the optic disk, is common in eyes with very high myopia (e.g., over 12 diopters). The ectatic area appears as an abrupt out-pouching in which the fundus is pale and the choroidal pattern more prominent than in the surrounding eyegrounds.

Fine ruptures in Bruch's membrane may be seen as an irregular network of glistening linear yellow-white streaks known as laquer marks or cracks. Hemorrhages, probably originating from the choriocapillaris, can occur in such areas. These deep macular hemorrhages may leave a fibrotic scar or a pig-

Fig. 8 (Krill and Archer). Case 3. A 45-year-old man with normal vision and early angioid streaks. Note area of choriocapillaris atrophy around the disk with finger-like extensions in each quadrant.

mented fleck called a Fuchs spot.

Peripheral chorioretinal atrophic changes are a common counterpart to the posterior disease. Scattered, sharply delineated atrophic foci involving all choroidal vascular elements and a portion of the retina appear throughout the entire periphery. These are referred to as pavingstone or cobblestone degeneration.[26] Numerous small cystoid spaces often develop between the equator and ora serrata.

Vision is significantly impaired in malignant myopia, and large central scotomas are noted on visual fields. Peripheral visual fields are usually normal, because peripheral changes are usually beyond the visual field limits. Both the ERG and EOG are usually subnormal. Dark adaptation beyond the macular area is normal or slightly elevated.

Familial cases have been reported with either autosomal dominant or recessive inheritance, although the latter is more common.[27]

### Case report

*Case* 6—This 45-year-old woman had 20/200 vision in both eyes and choroidal vascular atrophy throughout the posterior eyegrounds. Several large discrete areas of almost total choroidal vascular atrophy were present around and near the optic disk (Fig. 13). Superior to the optic disk, there was only a partial atrophy of the larger choroidal vessels. Pavingstone degeneration and pseudocysts were widespread in the peripheral eyegrounds. Central scotomas were noted on visual fields and a subnormal ERG was obtained.

### Diffuse choroidal atrophies

The diffuse choroidal atrophies closely mimic the regional choroidal atrophies in the type of changes occurring in the choroidal vasculature. However, the diffuse choroidal atrophies are distinguished by the widespread nature of the disease process and greater disturbance of peripheral retinal function. The macula may be spared or only mildly involved until the later stages of the disease.

### Diffuse choriocapillaris atrophy

This condition has been referred to as generalized choroidal angiosclerosis, diffuse choroidal sclerosis, or generalized choroidal sclerosis.[7,8,28]

*Clinical features*—Typically, the choriocapillaris atrophy extends out to the equatorial region or beyond. There may be variability among affected members of a family.[8] Some members may show choriocapillaris atrophy only in the posterior eyegrounds, even at an advanced age.

The hereditary transmission is usually autosomal dominant, although several cases have occurred sporadically, suggesting an autosomal recessive inheritance. Sex-linked forms will be discussed later in this paper.

Choriocapillaris atrophy usually becomes clinically apparent in the third or fourth decade of life, although it has been occasionally observed in the first or second decade. It usually progresses slowly as age advances.

In our experience, the disease usually begins with retinal pigment epithelial atrophy accompanied by pigment stippling and mottling. There is increased visibility of the larger choroidal vessels in these areas which hyperfluoresce on fluorescein angiography. Typically, the process originates in the macula or peripapillary areas and slowly spreads

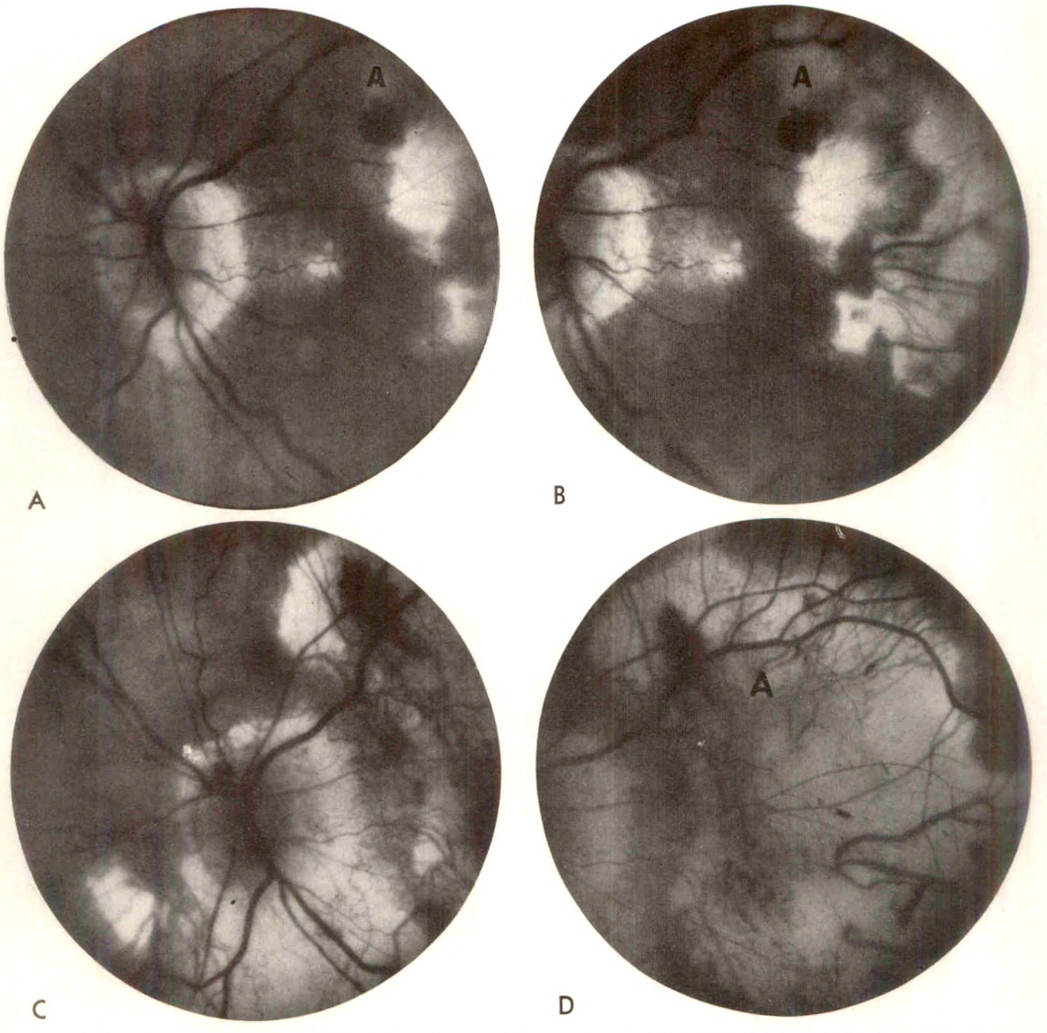

Fig. 9 (Krill and Archer). Case 4. Serpiginous-like areas of total choroidal vascular atrophy involving the left macula and peripapillary region. Figs. A and B were taken in 1963 and Figs. C and D in 1969. The geographic configuration is characteristic. Homogeneous gray areas were evident at the superior portions of the serpiginous lesion (letter A in Figs. A and B). This area is typical of the earliest change noted in this condition. There has been considerable extension of the atrophic process over the six-year period. Compare the site marked A in Fig. D, taken in 1969, with the same site in Figs. A and B, taken in 1963. In most areas there is a considerable absence of the larger choroidal vessels. The dark area seen in the superior portion of each photograph represents a pigment clump.

towards the periphery. In advanced disease, the retinal vessels become attenuated and the optic disk takes on a waxy appearance. Central visual loss may occur early in this condition, although the foveal area may be spared until relatively late in the disease. Night blindness is a characteristic early complaint.

*Retinal function*—Peripheral visual fields are abnormal. Dark adaptation studies and the EOG are markedly abnormal. The ERG is frequently abnormal and extinguished.

*Histology*—One eye, with what appears to be a diffuse choroidal atrophy, has been examined histologically.[29] There was an absence of much of the choriocapillaris, pigment epithelium, photoreceptors, and Bruch's mem-

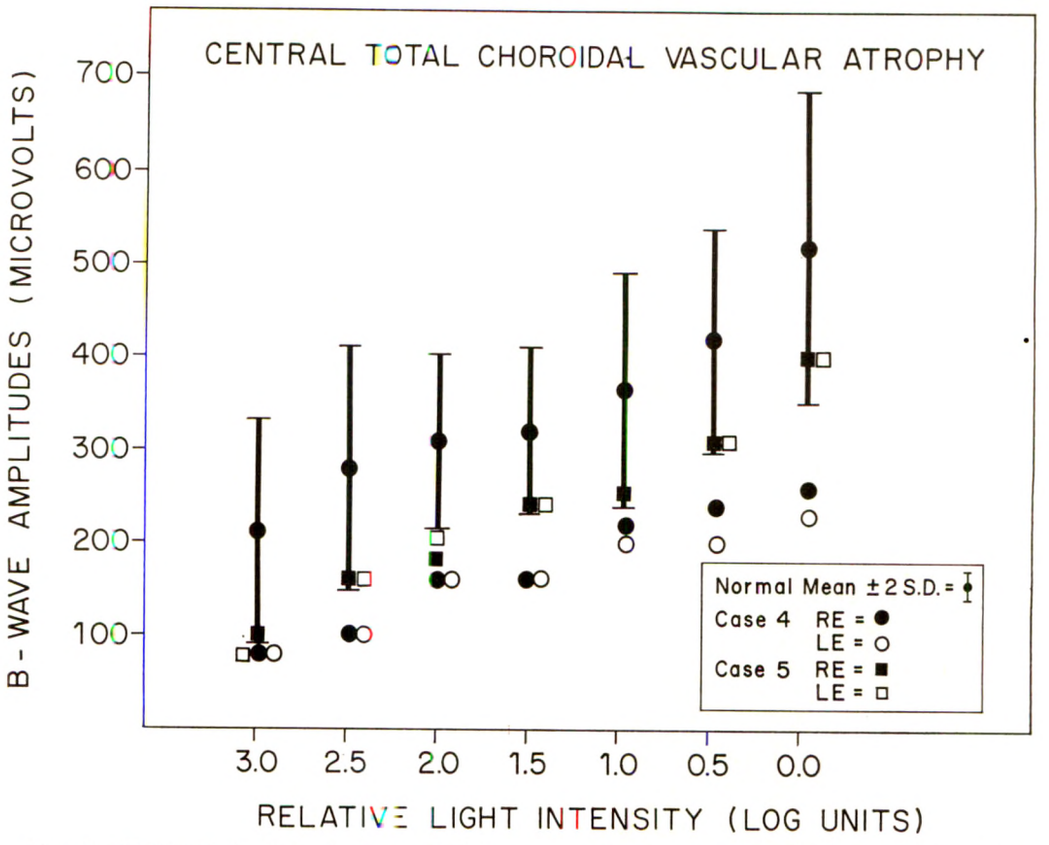

Fig. 10 (Krill and Archer). Cases 4 and 5. B-wave amplitudes at seven different intensities. These amplitudes are subnormal in Case 4 and at the lower limit of normal in Case 5, in spite of ophthalmoscopic changes only in the posterior eyegrounds.

brane extending out toward the equator. The most severe atrophy was noted in the posterior eyegrounds.

### Case reports

Case 7 illustrates the following points (1) early eyeground changes, (2) functional impairment and progression.

*Case 7*—This 36-year-old woman demonstrates an early form of the disease (Fig. 14). She noted central visual impairment at the age of 28 years. She had no other visual complaints. Other affected members of the family include a sister (Case 8), a 46-year-old brother with abnormal vision and severe night blindness, and two great aunts (maternal) with histories of blindness at middle age (Fig. 15). The inheritance is probably autosomal dominant with variable penetrance of the gene (accounting for the lack of disease in the mother).

*Early eyeground changes*—Fine and coarse pigment stippling, with increased visibility of the underlying choroidal pattern, is evident up to the equator. In the macula (Fig. 14-A) the disease was more advanced, and several sharply defined areas of choriocapillaris atrophy were noted. On fluorescein angiography, a diffuse hyperfluorescence reflected the widespread disturbance of pigment epithelium (Fig. 14-B). There was visibility of the underlying choroidal vessels in the macula throughout fluorescein angiography (arrow in Fig. 14-B).

*Functional impairment and progression*—Vision was 20/50 in the right and 20/40 in the left eye in 1957. In 1965, vision was 20/200 in both eyes. In 1969, peripheral visual fields, last studied in 1969, were normal except for large central scotomas. Dark adaptation studies, done in 1969, were slightly abnormal (one log unit above the normal mean plus two standard deviations). An ERG was normal in 1965, but was subnormal in 1969 (Fig. 16).

Case 8, the sister of the preceding patient (Case 7), illustrates the following points: (1) advanced eyeground changes, (2) pro-

gression of eyeground changes, and (3) progressive changes in visual function.

*Case* 8—This 56-year-old woman demonstrated an advanced form of the disease (Fig. 17). She had a 20-year history of poor visual acuity and night blindness.

*Advanced eyeground changes*—The larger choroidal vessels are visible throughout the fundus (Figs. 17-A and B). Most of these vessels appear narrowed, with white deposits along their walls. Some were evident as yellow-white cords. The larger choroidal vessels were visible throughout fluorescein angiography[12] (Fig. 17-C). (They normally are seen only during the early and mid-retinal venous phases.[1]) Many vessels which appeared to be "sclerosed" on ophthalmoscopic evaluation were patent to dye. There was a prolonged choroidal circulation time.

*Progression of eyeground changes*—Subtle changes occurred in areas of involvement. Some of the larger and intermediate-sized choroidal vessels became more sharply defined.

*Progressive changes in visual function*—Visual acuity was 20/200 in each eye in 1965 and 10/200 in 1969. Visual fields revealed bilateral ring and central scotomata in 1965. By 1969, peripheral fields had become constricted. Dark adaptation showed further deterioration (about 3.5 log units above the normal means plus 2 standard deviations in 1969 compared to about 2.5 log units above this value in 1965). In 1965, subnormal responses on the ERG were noted and in 1969, a practically extinguished record was obtained (Fig. 16).

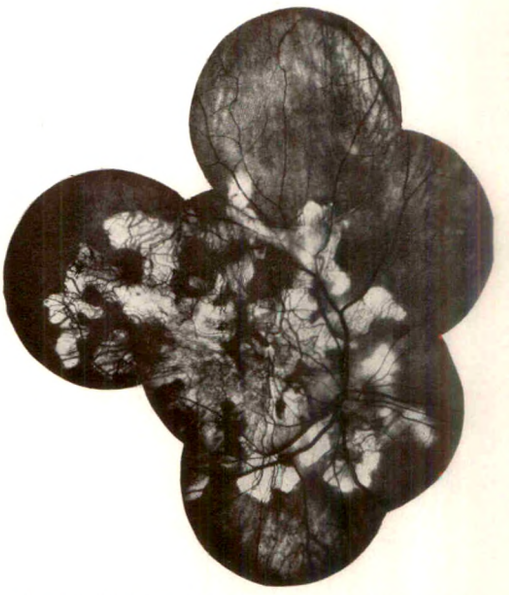

Fig. 11 (Krill and Archer). Case 5. Right fundus of a 50-year-old man with total choroidal vascular atrophy confined to the posterior eyegrounds. Note geographic configuration of the atrophic areas, with intervening normal retina and choroid. Pigment clumps are scattered at random in the involved areas.

### Diffuse total choroidal vascular atrophy

*Autosomal inheritance*—This condition has been called gyrate atrophy of the choroid and retina.[7,8,30] The inheritance is usually autosomal recessive and the disease typically starts in the mid-peripheral eyegrounds and extends centrally and peripherally. In the autosomal dominant form, there may be great variability in the degree of involvement.

*Clinical features*—The disease is usually first noted between the ages of 20 and 30 years. The youngest patient described was six years of age. The initial changes consist of sharply defined areas of choroidal atrophy in the equatorial fundus. Such areas have serrated or scalloped margins and appear in patches throughout the fundus. In time, the atrophic areas become confluent and expand centrally and peripherally. The fundus eventually assumes a yellow-white color (from the background sclera) with scattered pigment and choroidal vascular remnants. The macula generally remains intact until late in the disease. The retinal vessels may become attenuated, and in advanced cases optic atrophy may occur. Myopia and complicated cataracts frequently develop in association with the disease.

Night blindness is usually the earliest complaint. Visual field abnormalities correspond to ophthalmoscopic changes. A ring scotoma may be the initial visual field abnormality. Vision may be normal even in fairly advanced cases, since the macula is often spared until late in the disease. The ERG and EOG are usually abnormal, even in the early stages; in advanced disease, both tests are severely abnormal, indeed to the degree seen in retinitis pigmentosa.

### Case reports

The following three cases demonstrate these points: (1) typical eyeground changes,

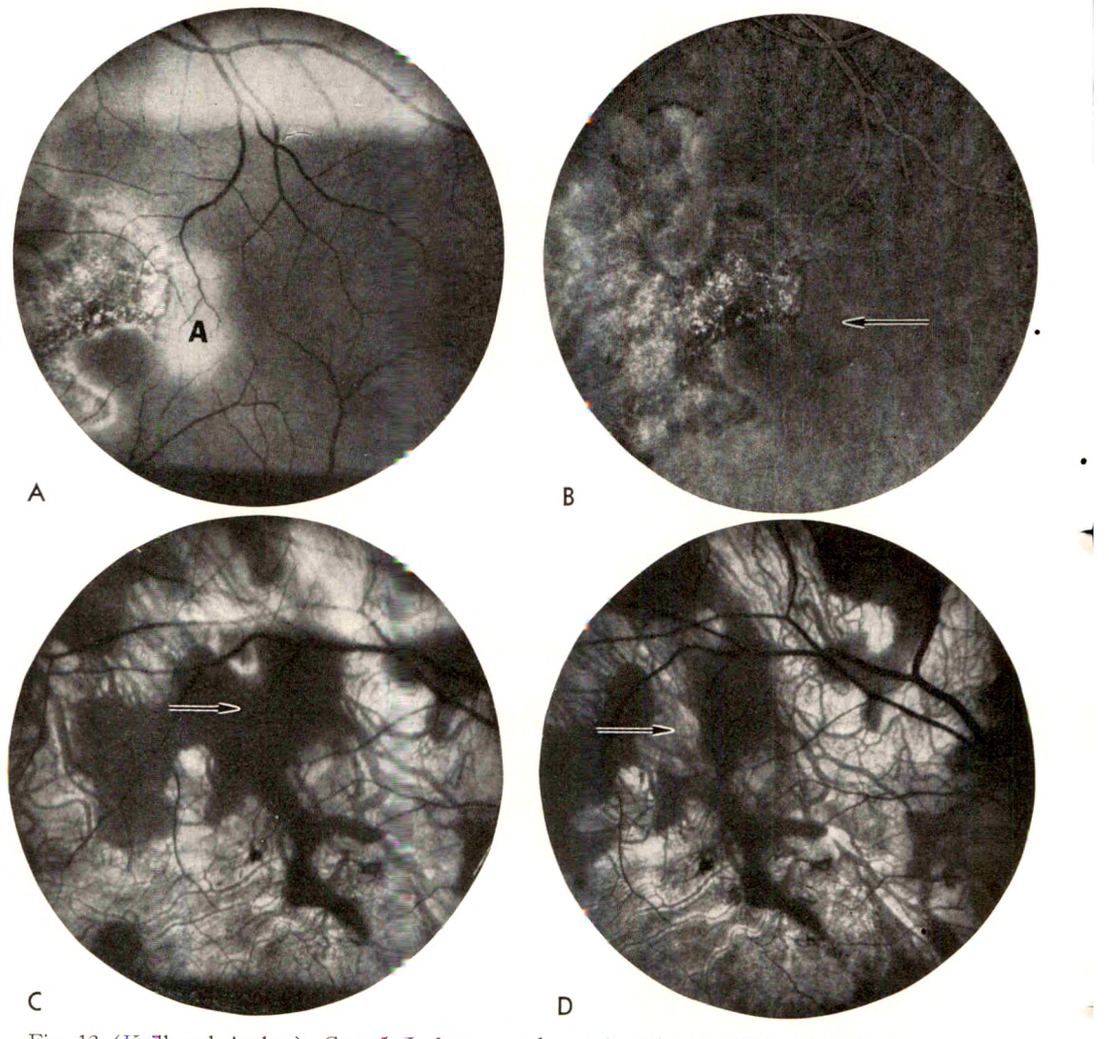

Fig. 12 (Krill and Archer). Case 5. Left temporal macula, taken in 1966. (A) Homogeneous gray opacification was seen at the advancing edge of a lesion (letter A is in the center of this area). At the nasal aspect of this area pigment epithelial atrophy and stippling are evident. The superior opacification is an artefact. (B) Fluorescein angiogram taken during the late retinal venous phase of the same area in Figure A. The site of gray opacification is hypofluorescent (see arrow). Fig. C (1968) and Fig. D (1969) demonstrate extension of areas of total choroidal vascular atrophy (compare arrows which point to the same site).

(2) late involvement of the fovea, and (3) severe impairment of peripheral retinal function.

*Cases* 9-11—These three siblings (Fig. 18) had various degrees of diffuse total choroidal vascular atrophy. The sister (Case 9) was 45 years of age and the two brothers were 46 (Case 10) and 50 (Case 11) years of age. All complained of night blindness for at least 20 to 25 years, and more recently, loss of peripheral vision. The sister had had abnormal central vision in both eyes for two years. The younger brother had had poor left central vision for four or five years. The mother had severe night blindness from an early age (Fig. 18). Therefore, it is likely that the inheritance of the choroidal atrophy in this family is autosomal dominant.

*Typical eyeground changes with variable involvement.*—All showed large areas of almost total chorcidal vascular atrophy throughout their posterior eyegrounds and to some extent in the periphery (Figs. 19 and 20). In Case 11, disease was confined mainly to the posterior eyeground area (Fig. 20-C).

Case 10 had changes almost up to the equatorial region (Figs. 20-A and B), and in Case 9 the disease extended beyond the equatorial region (Figs. 19-A and B). There were sharp zones of transition between normal and involved areas of the fundus. The border areas often had a scalloped appearance with evidence of abnormal pigment epithelium adjacent to the areas of choroidal atrophy. There were no such sharp transitional areas in the two patients with only choriocapillaris atrophy (Cases 7 and 8).

*Late involvement of the fovea.*—Despite a 20-year history of night blindness, Case 11 had vision of 20/20 in both eyes. Case 10 had 20/20 vision in the right eye and 20/80 in the left eye. Case 9, with the most extensive degree of involvement and most severe retinal function impairment, had 20/50 vision in both eyes. All three patients had myopic corrections of more than four diopters.

*Severe impairment of peripheral retinal function*—Cases 10 and 11 had large ring scotomas, with some peripheral constriction in Case 10. Only small islets of peripheral field remained in Case 9. Dark adaptation was markedly elevated in all three patients, but most severely in Case 9. The ERG was extinguished in Case 9, showed only minimal responses at the highest intensities in Case 10, and was subnormal in Case 11 (Fig. 21).

## X-LINKED INHERITANCE

This category includes a condition known as choroideremia, progressive tapetochoroidal dystrophy and progressive chorioretinal degeneration.[8,30,31] It is our belief that X-linked choroidal sclerosis is the same condition as choroideremia. We will discuss evidence for the identity of X-linked choroidal sclerosis and choroideremia in this section.

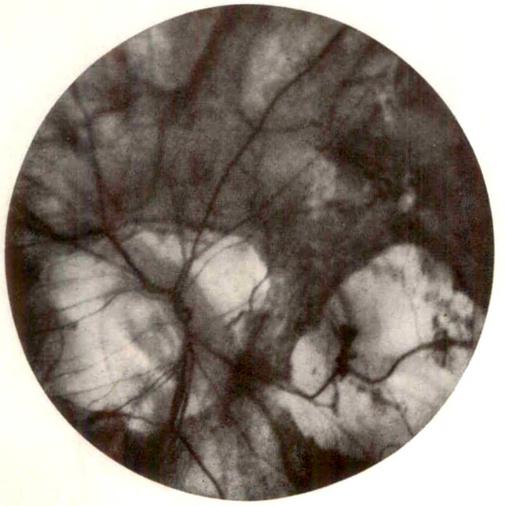

Fig. 13 (Krill and Archer). Case 6. Right posterior eyegrounds of a patient with malignant myopia. Discrete areas of total choroidal atrophy are evident around the optic disk and to its nasal side.

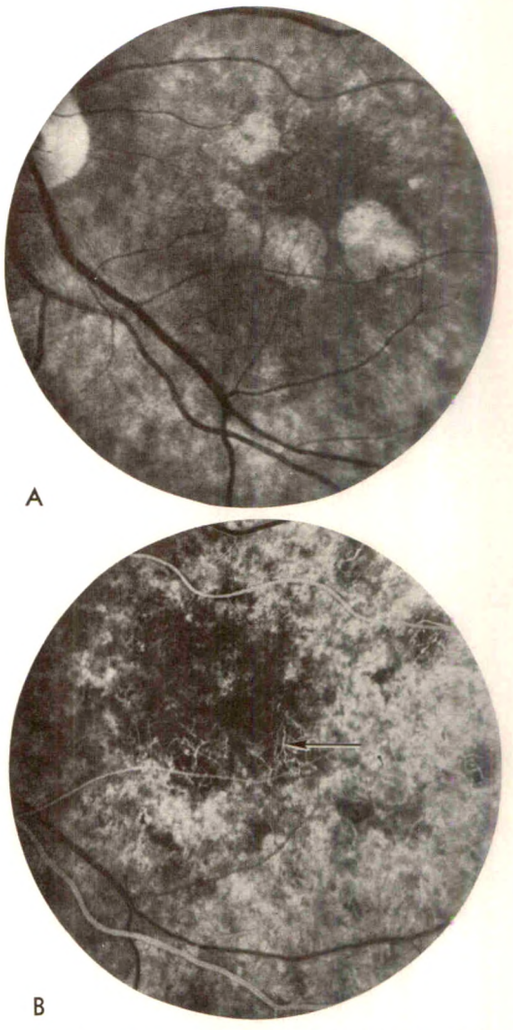

Fig. 14 (Krill and Archer). Case 7. Left macular area of a 36-year-old woman with an early form of diffuse choriocapillaris atrophy. (A) Several discrete areas of pigment epithelial and choriocapillaris atrophy are present at the macula. (B) Fluorescein angiography shows widespread hyperfluorescence typical of a pigment epithelial defect. At sites of choriocapillaris atrophy intermediate-sized choroidal vessels are visible (see arrow).

*Clinical features*—The onset of this condition is in the first decade, possibly in the first few years of life. Pigment epithelial stippling and atrophy in the equatorial and paramacular eyegrounds are seen initially. This

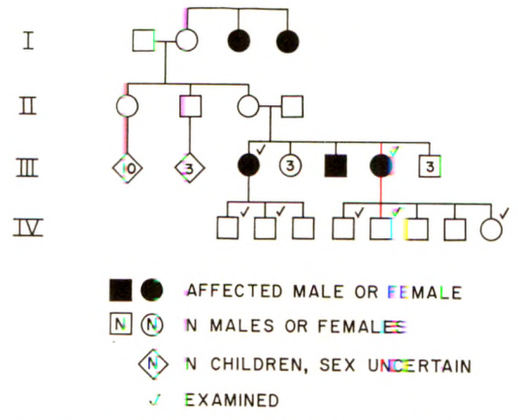

Fig. 15 (Krill and Archer). Pedigree of Cases 7 and 8 (diffuse choriocapillaris atrophy).

picture is similar to that noted in female carriers. Focal areas of choroidal atrophy with exposure of choroidal vessels represent the next stage of the disease. The areas of choroidal atrophy become larger and more numerous. Eventually most of the choroidal vessels disappear, leaving choroid only in the macula and scattered throughout the periphery. Clumps of retinal pigment are often seen in the equatorial retina. The retinal vessels may be attenuated in advanced cases.

Not all males will show the course described above. Frequently one or more males in a pedigree of known choroideremia will show eyegrounds with mainly choriocapil-

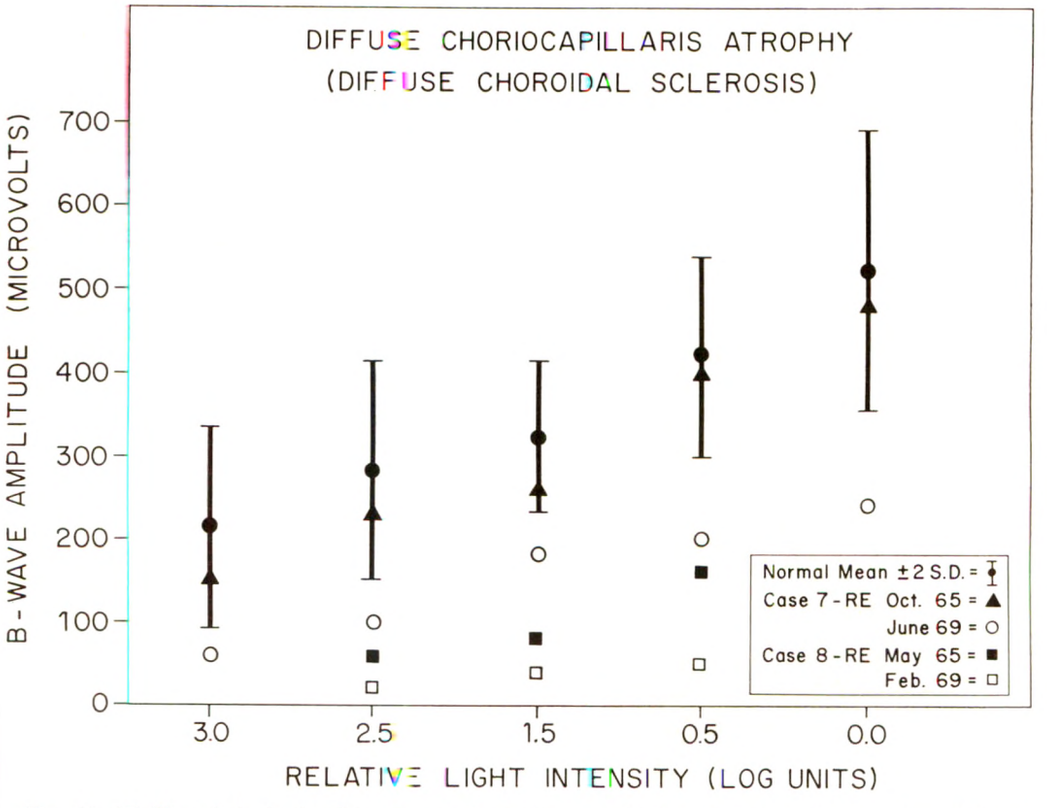

Fig. 16 (Krill and Archer). Cases 7 and 8. B-wave amplitudes plotted at three to five different intensities with normal control group. B-wave amplitudes are shown for the right eye in 1965 and 1969 from both patients. The ERG was initially normal in Case 7 (early disease), but by 1969 was definitely subnormal. In Case 8, with more severe involvement, the ERG was small in 1965 and almost extinguished in 1969.

laris atrophy,[30,31] and in such pedigrees, the disease is sometimes labeled X-linked choroidal sclerosis.[32] In fact, in some affected males some portions of the eyegrounds may show only choriocapillaris atrophy, and other portions total choroidal vascular atrophy.

*Retinal function*—Severe visual field constriction and night blindness are the first symptoms of the disease and occur at an early age. Visual acuity usually remains intact until at least the age of 30 years, but between the ages of 40 and 60, severe impairment of central acuity often occurs. Dark adaptation is markedly abnormal early in the disease, with relentless progression to severe night blindness. The ERG is subnormal in early cases and extinguished in advanced cases. The EOG is markedly abnormal in early as well as advanced cases.

*Histology*—Histologic studies have revealed extensive choroidal atrophy.[33] The only choroidal remnants were found at the macula and ora serrata. In these areas the walls of the choroidal vessels were thickened and lumina almost obliterated. In several areas Bruch's membrane had completely disappeared. The retinal vessels show atrophic changes as well.

Female carriers usually show eyeground changes.[34] These commonly consist of midperipheral pigmentation, localized deep in the retina, and spotty areas of pigment epithelial atrophy. The pigment may show clumping, particularly near the equator, and it is frequently distributed in a radiating pattern. Pigment in the macula may be fine and

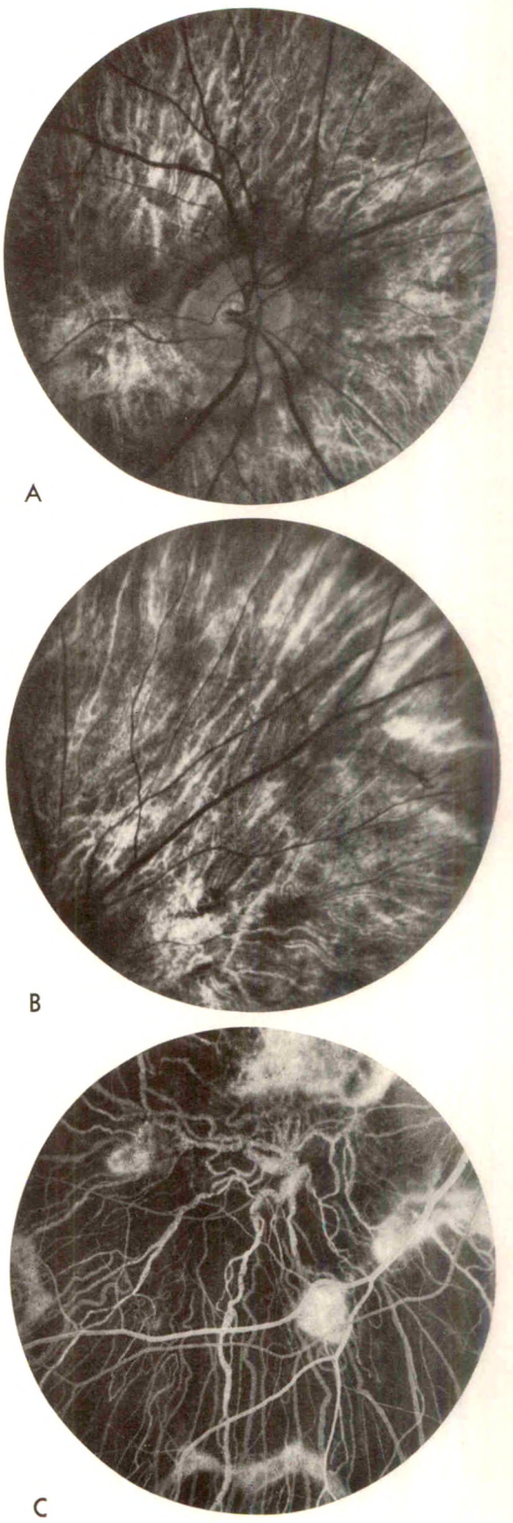

Fig. 17 (Krill and Archer). Case 8. (A) Posterior eyegrounds, and (B) periphery. There is pronounced visibility of the larger choroidal vessels in all areas. Many of the vessels are attenuated with whitish deposits along their course. Some even appear as thin white cords. (C) The larger choroidal vessels are visible throughout fluorescein angiography. Many of the choroidal vessels which appeared as white cords on ophthalmoscopic evaluation were patent to fluorescein.

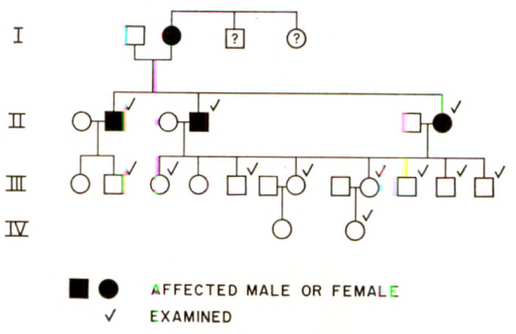

Fig. 18 (Krill and Archer). Pedigree of Cases 9, 10, and 11 (diffuse total choroidal vascular atrophy).

mottled. The optic disks and retinal vessels are usually normal. Occasionally, more extensive eyeground changes will be seen in the female intermediate between the typical carrier state and the fully affected male.[34] At least two females with a full form of the disease have been reported.[35,36] One carrier with typical eyeground changes was seen at the age of three and one-half years, but because the female does not show a progressive disease, it is possible that her changes were present at birth.

Occasionally, mild functional disturbances are noted, particularly dark adaptation. Abnormalities of the EOG and the ERG have been reported.[33]

Choroideremia has been described in great detail in a monograph on this subject.[30] The status of the female carrier has also been described in detail in another publication.[34] Only a few points will be made in this review, particularly in regard to eyeground changes.

## Case notes

Cases from pedigrees with known choroideremia described elsewhere[34] were chosen to illustrate the following points:

*Early disease in males*—A nine-year-old boy (Fig. 22) illustrates typical early eyeground changes. Note clumps of pigmentation and pigment epithelial atrophy in the midperipheral eyegrounds. The appearance is similar to that of female carriers (Fig. 23).

*Typical eyegrounds in carrier females*—The carrier usually shows pigment clumps in the equator and macula (Fig. 23-A) which tend to aggregate into larger clumps near the equator (Figs. 23-B and C). The pigment is often distributed in a striated or radiating pattern in the equatorial region (arrow in Fig. 23-B).

*Variation in degree of involvement in affected males*—This is well illustrated by a 20-year-old male who shows eyegrounds typical of choriocapillaris atrophy (Fig. 24-A). His 18-year-old brother shows changes typical of advanced choroideremia with total choroidal vascular atrophy (Fig. 24-B)

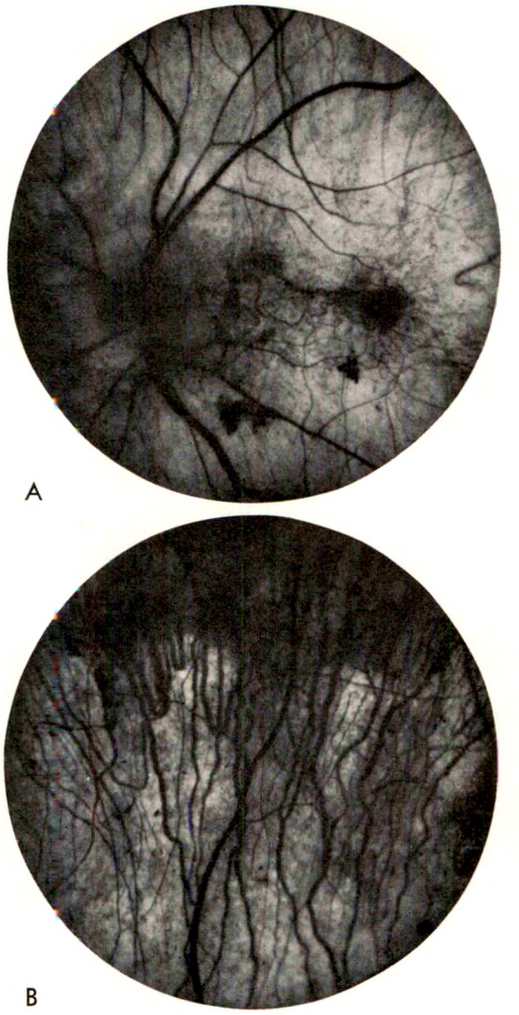

Fig. 19 (Krill and Archer). Case 9. (A) Posterior eyegrounds and (B) peripheral fundus, where there is a diffuse total choroidal vascular atrophy extending to the equator. A sharp transition zone with scalloped borders occurs at the junction of normal and involved areas.

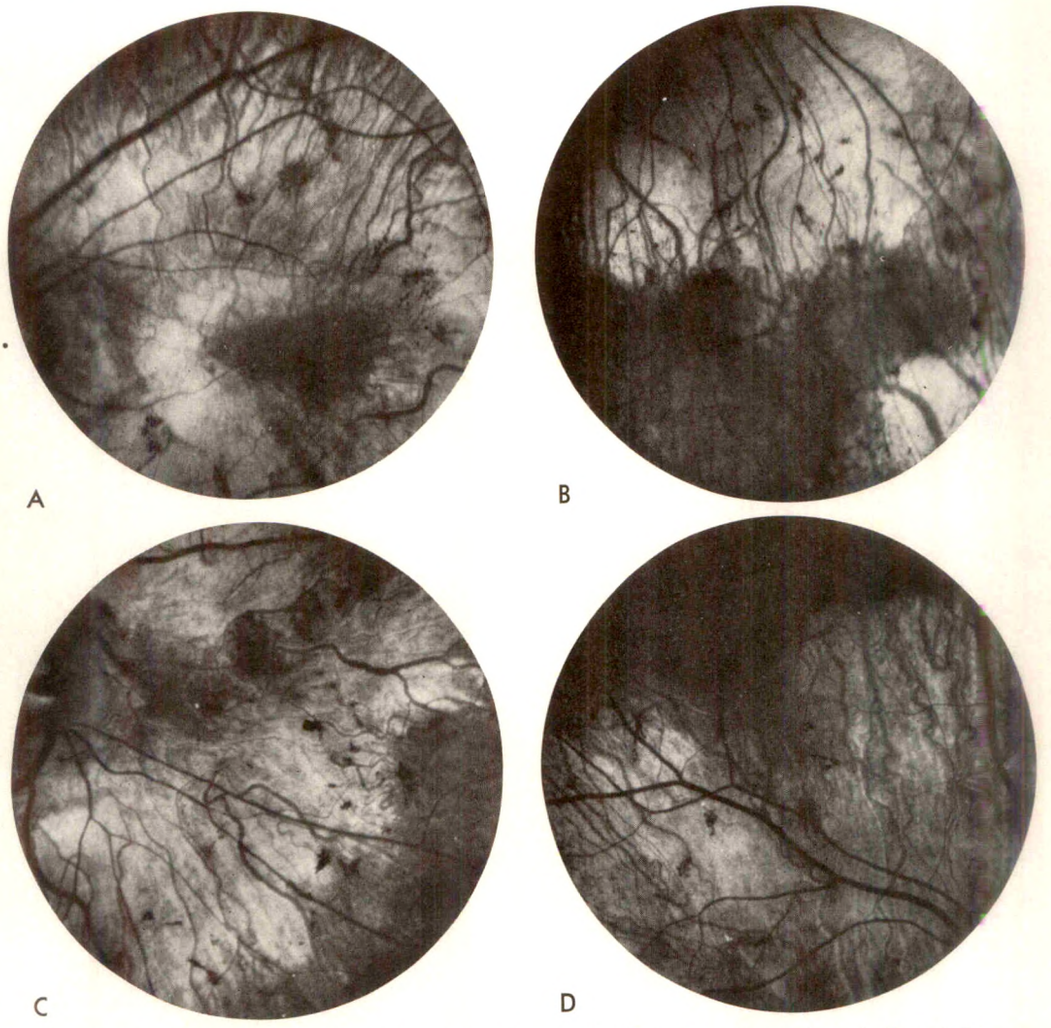

Fig. 20 (Krill and Archer). Cases 10 and 11. (A and C) Posterior eyegrounds and (B and D) preequatorial fundus. (B) Case 10 showed total choroidal vascular atrophy extending almost up to the equatorial area with sharp lines of demarcation. Notice the scalloped border. (C) Case 11 shows involvement confined mainly to the posterior eyegrounds. (D) Notice scalloped border of sharp demarcation line of a normal area and area of total choroidal vascular atrophy.

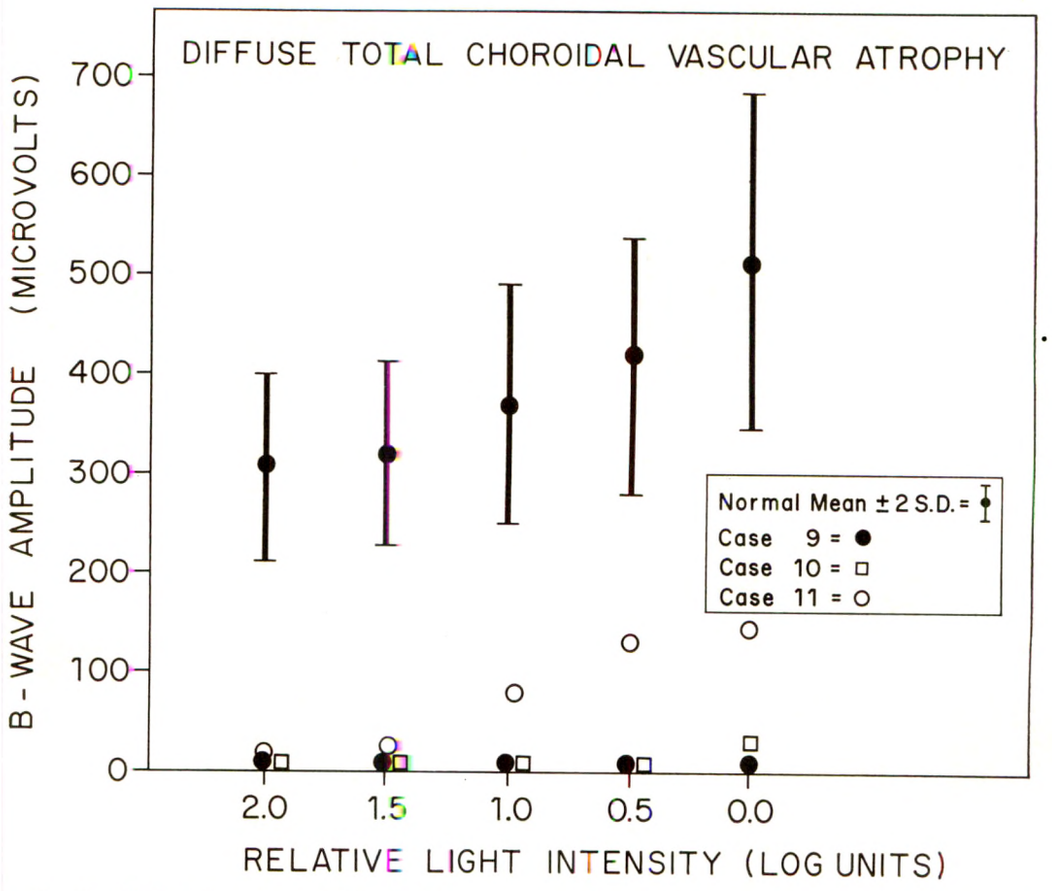
apart from the macula and far periphery. Obviously, the difference is not age-related.

This variability is also illustrated by three other affected male members from another family (Fig. 25). An 18-year-old male has the greatest degree of total choroidal vascular atrophy (Fig. 25-A). His 25-year-old uncle shows only choriocapillaris atrophy throughout most of his eyegrounds (Fig. 25-B). On the other hand, a 45-year-old uncle (brother of patient illustrated in Fig. 25-B) shows mainly choriocapillaris atrophy temporal to the disk (letter T in Fig. 25-C) and total choroidal vascular atrophy nasal to the disk (letter N in Fig. 25-C).

## Discussion

The choroidal vascular changes described in this paper are considered to be primary because of their progressive nature, the frequent evidence of a hereditary pattern, and the absence of toxic, traumatic, or inflammatory factors. The term "choroidal dystrophy" would apply to most of these conditions; however, as some of the cases lack evidence of a hereditary pattern, we



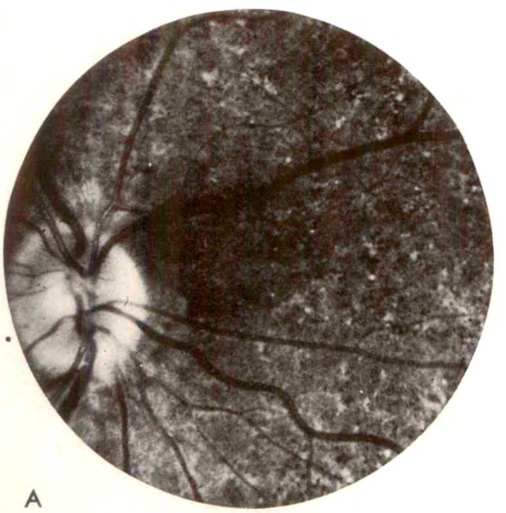


Fig. 21 (Krill and Archer). ERG of Cases 9, 10, and 11. Note extinguished records from Cases 9 and 10 and subnormal response from Case 11 with a lesser degree of involvement on ophthalmoscopic evaluation.

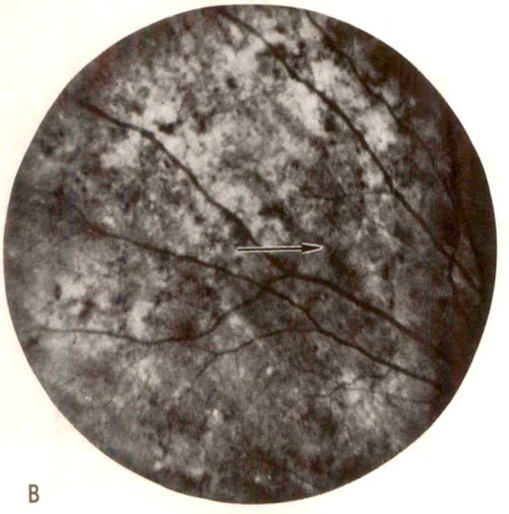
prefer to use the term "choroidal atrophies."



The cases described in this report have as their predominant feature atrophy of one or more layers of the choroidal vessels. In all instances, the vascular atrophy is associated with some measure of retinal pigment epithelial degeneration, in most cases corresponding precisely to the zone or focus of choroidal vascular change.

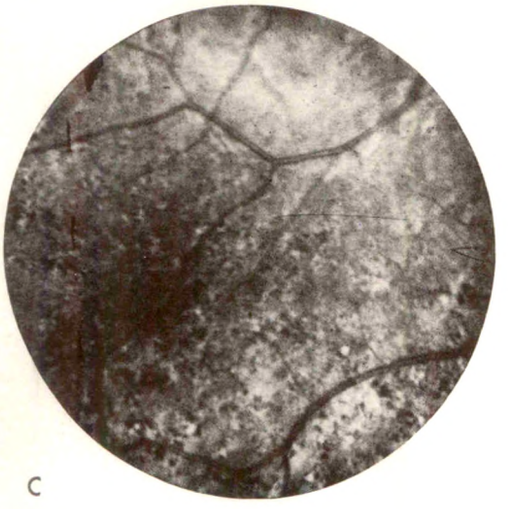


Fig. 22 (Krill and Archer). A nine-year-old with early choroideremia, illustrating the typical early eyeground changes seen in affected males. Pigment epithelial atrophy and clumping produce eyegrounds similar to those seen in the typical carrier female.

Fig. 24 (Krill and Archer). Two males from family with known choroideremia. (A) One, 20 years of age, shows choriocapillaris atrophy alone. Choriocapillaris atrophy is seen temporal to pronounced light reflex adjacent to disk. Note the white cord-like appearance of the larger choroidal vessels. (B) His 18-year-old brother has total choroidal vascular atrophy in all regions, apart from the macula and far periphery, typical of advanced choroideremia.

Fig. 23 (Krill and Archer). Three female carriers showing (A) typical changes at both equator and macula and (B) typical changes of pigment clumping at the equatorial fundus. (B and C). Large pigment clumps characteristically occur near the equatorial fundus. Striated or radiating patterns of pigment distribution may be noted at the equatorial region (arrow in Fig. B).

The choroidal atrophies, with certain exceptions, fall readily into two anatomic groups: those in which the atrophy is limited to the choriocapillaris, and those in which the larger choroidal vessels also disappear. The exception appears to be in choroideremia where both conditions may be seen in one eye, or where two members of an affected family show a different variety of the disease. However, in our experience, it seems that patients with choriocapillaris atrophy only rarely proceed to total choroidal atrophy, and patients with total choroidal atrophy continue to lose all vascular plexuses with progression of the disease.

Atrophy of the choriocapillaris and retinal pigment epithelium provides an unobstructed view of the large and intermediate-sized choroidal vessels. These vessels become surrounded by white deposits (probably by-products from the degenerating retinal pigment epithelium and choriocapillaris) which obscure the vessel lumen, and give the appearance of attenuated, cord-like or even totally obliterated vessels. The term "choroidal sclerosis" has been employed to describe these vessels. Fluorescein angiography has provided an accurate method of measuring luminal caliber, and most studies to date have indicated normal lumen size in the sclerotic vessels. Histologic studies also have shown no evidence of sclerosis. We thus recommend that the term "choroidal sclerosis" be abandoned.

The earliest changes leading to atrophy of the choriocapillaris appear to occur in the

Fig. 25 (Krill and Archer). Three male members of the same family showing variable degree of choroidal vascular atrophy. (A) An 18-year-old with a considerable degree of total choroidal vascular involvement. (B) A 25-year-old with only choriocapillaris atrophy throughout most of his eyegrounds. (C) A 45-year-old shows mainly choriocapillaris atrophy temporal to the disk (letter T) and large areas of total choroidal vascular atrophy nasal to the disk (letter N).

retinal pigment epithelium, as judged from early cases, extrapolization from changes occurring at the edge of an advancing lesion, and from relatives of patients affected with the overt disease. Pigment stippling and mottling are the characteristic ophthalmoscopic changes. Fluorescein angiography confirms the pigment epithelial defect and on occasion depicts small islets of choriocapillaris atrophy. We have not observed the retinal exudation and edema described by Sorsby and Crick[6] as the earliest changes in central areolar choroidal sclerosis, nor have we noted such changes at the border of an advancing lesion.

The difference between regional and diffuse choriocapillaris atrophy appears to be solely one of geographical extent. Both types of lesions have equivalent ophthalmoscopic and angiographic patterns, and appear to evolve in a similar fashion.

Visual field defects correspond to areas of obvious involvement on ophthalmoscopic evaluation. However, tests of diffuse retinal function, such as the ERG and EOG, show abnormalities that cannot be predicted from the extent of involvement noted in the eyegrounds. Optic atrophy and retinal vascular attenuation are usually indications of diffuse disease in those cases exhibiting a central lesion. In pedigrees with central choroidal atrophy, an occasional member may show much more widespread involvement, suggesting a further relationship between the regional and diffuse choriocapillaris atrophies.[8]

In the regional total choroidal atrophies the earliest changes are less well known. However, we have noted at the edge of expanding lesions a gray opacification located in the deeper retinal layers, obscuring all view of the underlying choroid. The retinal pigment epithelium eventually degenerates at this point, as evidenced by pigment clumping. In our series this finding is limited to the regional total choroidal atrophies, and has not been noted in the diffuse variety. Some workers feel that this disease represents an inflammatory process, and have designated the condition as geographic or serpiginous choroiditis.[16,37] We have not seen any evidence of inflammation in our patients. We feel that the slow, relentless progression is more typical of a degenerative process. In addition, retinal function evaluation frequently shows widespread impairment, despite the fact that most ophthalmoscopic changes are limited to the posterior eyegrounds. This finding also favors a degeneration rather than an inflammation. However, it is possible that such lesions may originate in either manner, and that we have not had the opportunity to see this type of patient. In the regional total choroidal vascular atrophies there appears to be a concomitant disappearance of small and large vessels; even the borders of advancing lesions reveal such changes. Fluorescein angiography shows that although vascular loss is extensive, it is rarely complete. Regional total choroidal vascular atrophies often have a distinct configuration. A serpiginous-like atrophy is seen at the macula, and the peripapillary atrophies typically show radial extensions emanating from the optic disk.

We feel that X-linked choroidal sclerosis is the same as choroideremia. In the original published pedigrees of X-linked choroidal sclerosis[32] there were males with typical eyegrounds of choroideremia and female carriers with eyegrounds identical to those described for choroideremia carriers. In our pedigrees with choroideremia, and those described by others,[30,38] there is great variability in the type of choroidal vascular atrophy which occurs. Atrophy of the choriocapillaris represents the earliest changes, but eventually atrophy of the larger vessels occurs. Both types of atrophy may at times be seen in the same eyegrounds of one individual with choroideremia, or different affected members of a family with this disease may show mainly one or the other type of choroidal vascular atrophy.

Variability in the total area of atrophy is fairly common in diffuse total choroidal vascular atrophy inherited in an autosomal dom-

inant manner, and, to a lesser degree, in choroideremia.

As stated previously, total choroidal vascular atrophies may result from primary diseases of the outer retina. Stargardt's macular degeneration, the cone degenerations, fundus flavimaculatus, and drusen may produce a choroidal, as well as retinal, atrophy in the macula in advanced stages. Degenerative, or arteriosclerotic disease of the larger choroidal vessels may precipitate choroidal hemorrhage and consequential choroidal atrophy. An inflammation can produce choroidal atrophy.

Small regional areas of choroida atrophy outside the macula, particularly of the choriocapillaris, may be seen with retinitis pigmentosa.[39] The choroideremia carrier may show total choroidal vascular atrophy around the optic disk. A toxin, such as thioridazine, may produce a diffuse choriocapillaris atrophy.[24]

Enhanced visibility of the choroidal vasculature may result from pigment migration and loss in otherwise normal retinal pigment epithelial cells. This is a not uncommon finding in myopic persons and aged individuals, and has been labeled depigmentation in situ by Klien.[40] These fundi may be differentiated from those with choriocapillaris atrophy by normal vision, retinal function studies, and fluorescein angiography.[12]

## Summary

At attempt is made to classify the primary choroidal vasculature atrophies. The patients can be divided into those with mainly choriocapillaris atrophy and those with atrophy of the large choroidal vessels as well. The atrophies can also be divided according to extent of involvement into regional and diffuse choroidal vascular atrophies.

All diseases, except choroideremia, have either atrophy of only the choriocapillaris or atrophy of all sized choroidal vessels in early as well as advanced stages. Only one disease, choroideremia, shows both types of atrophy.

Unique configurations are seen in the regional total choroidal vascular atrophies and in the autosomal forms of diffuse total choroidal vascular atrophy, known as gyrate atrophy of the choroid and retina.

Many of the regional choroidal vascular atrophies showed evidence of more widespread impairment on functional evaluation.

It is likely that most, if not all, of the conditions discussed could be considered genetic in origin and therefore labeled as dystrophies. We speculate that the primary abnormality in all of the choroidal atrophies of genetic origin is probably in the pigment epithelium.

# BILATERAL INFLAMMATORY PSEUDOTUMORS OF THE CILIARY BODY

STEPHEN J. RYAN, JR., M.D., ROBERT N. FRANK, M.D., AND WILLIAM R. GREEN, M.D.
*Baltimore, Maryland*

Non-neoplastic inflammatory pseudotumors have been reported to arise at extraocular sites within the orbit[1-3] as well as in the posterior uveal tract.[4-7]* Since their clinical appearance was indistinguishable from that of a malignant melanoma of the choroid, psuedotumors presenting as intraocular masses have been treated by enucleation and their true nature was not apparent until histologic examination of the eye had been performed.

The case that is presented here is the first to our knowledge in which intraocular inflammatory pseudotumors presented initially as bilateral masses of the anterior uvea. This report illustrates that a nonspecific inflammatory process, reactive lymphoid hyperplasia, may reach large proportions suggesting the diagnosis of tumor. Thus, such a pseudotumor should be considered in the differential diagnosis of mass lesions of the anterior uveal tract. This case is of additional interest because of the patient's striking response to corticosteroids administered systemically as compared to the topical or subconjunctival route.

## CASE REPORT

A 51-year-old white man was referred to the Wilmer Institute for evaluation of a ciliary body mass in the right eye. He had enjoyed excellent health except for mild, bilateral neural hearing loss of long duration and unknown etiology. His ocular history was unremarkable save for a number of corneal foreign bodies which were removed without incident followed by uneventful recovery. He had worked in the coal mines of West Virginia and, more recently, he was employed as foreman of a machine shop.

Two months prior to admission, he consulted his ophthalmologist in West Virginia because of the onset of pain and redness in the right eye. His vision was noted to be RE:20/40, and LE:20/20. The right eye showed injection of the bulbar conjunctiva, 1+ ray and cells, and granular keratic precipitates. The patient was given neomycin/polymyxin B, plus 0.1% dexamethasone eye drops every two hours, homatropine drops twice daily, and oral prednisolone, initially 20 mg per day, tapered over a four-day period and then discontinued. Although the topical corticosteroids were continued, no improvement occurred over the next six weeks, and once again a course of systemic prednisolone, 5 mg/daily, was given for one week. At this time increased vascularity of the iris was noted, and a mass which extended circumferentially around the peripheral iris and ciliary body from six to 12 o'clock was seen for the first time. Because of the possibility that this lesion might represent a melanoma of the iris and ciliary body, he was referred to Wilmer.

On initial examination at Wilmer, best corrected vision in the right eye was 20/60 and in the left eye 20/40. The bulbar conjunctivae of both eyes were moderately injected. The pupil of the right eye was irregular and poorly reactive due to numerous posterior synechiae. Granular keratic precipitates and 2+ ray and cells were present bilaterally with 1+ cells in the vitreous. Early nuclear and moderately advanced posterior subcapsular lens opacities were present in the right eye. An unusual circumferentially oriented, nonpigmented mass was seen to elevate the peripheral iris from six to 12 o'clock in the right eye. Where the iris stroma was thinned peripherally, the mass had a pinkish coloration and seemed to have a gelatinous consistency. Dilated blood vessels traversed the mass in a radial direction. Slit lamp examination of the iris of the left eye revealed no abnormalities. Gonioscopic examination of the right eye demonstrated the iris root to be pushed well away from the trabecular meshwork as though by a posterior mass extending from six to 12 o'clock. The ciliary cleft was very deep and broad, giving almost the appearance of angle recession. Markedly dilated circumferential and radial vessels traversed this cleft. The remaining half of the angle, from 12 to six o'clock, appeared normal with a Grade III approach (Fig. 1). Gonioscopic examination of the left eye demonstrated a similar appearance of the angle from the 12 to the three o'clock position, but there was no evidence of a

* Beasley[4] initially considered his case to be a solitary choroidal lymphosarcoma. Zimmerman,[6] however, later reviewed the sections and concluded that the lesion was inflammatory and not malignant in nature.

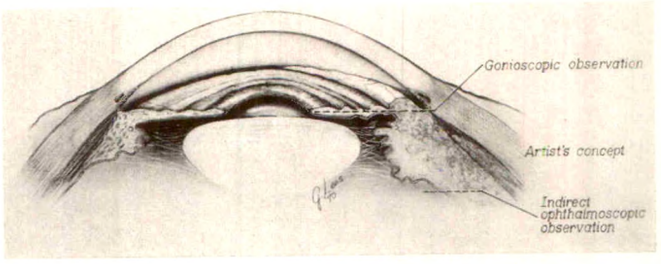

Fig. 1 (Ryan, Frank, and Green). Artist's conception of the appearance of the chamber angle of the right eye at the time the patient was initially presented to Wilmer. A large, ring-shaped mass elevates the peripheral iris in the temporal half of the eye. The greater arterial circle of the iris is dilated, and dilated vessels, arising from the greater circle, traverse the mass and run over the iris in a radial direction toward the pupil. The nasal half of the iris and angle appear relatively normal.

mass and no abnormal vessels were observed. Over the remaining 270 degrees in the left eye, the chamber angle was normal. Intraocular pressures were 14 mm Hg bilaterally, and examination of the fundi with the indirect ophthalmoscope and scleral depression revealed no abnormalities. However, examination with the slit lamp and the Goldmann three-mirror prism contact lens demonstrated posterior and inward displacement of the ciliary processes and pars plana by the mass from six to 11 o'clock in the right eye. Transillumination demonstrated a normal transscleral pattern with no defect posterior to the ora serrata.

An exhaustive systemic evaluation performed in conjunction with our medical consultant, Dr. Leigh Thompson, was normal except for the physical signs of emphysema. While exhibiting equivocal changes, quantitative assay of immunoglobulins revealed no significant elevation or depression. Multiple cytologic examinations of sputum were negative for tumor cells.

Cytologic examination of aqueous obtained by paracentesis of the right eye demonstrated only mononuclear inflammatory cells, mostly lymphocytes, and a few histiocytes. No neoplastic cells were evident. A biopsy of the conjunctiva from the fornix of the right eye revealed normal tissue. Biopsy of a scalene lymph node showed mild reactive hyperplasia, and percutaneous liver biopsy revealed scattered foci of mononuclear inflammatory cells but no indication of tuberculosis, fungal disease or sarcoidosis. "Bone-free" radiographic studies[8] of the anterior segment of both eyes showed no evidence of radiopaque foreign bodies.

Since this extensive evaluation gave no clue as to the nature of the ocular lesion, and in particular because it failed to differentiate between an inflammatory process and primary or metastatic intraocular malignancy, direct biopsy of the ciliary body was undertaken. A modified Stallard-type incision[9–11] was made over the ciliary body, with the circumferential cut extending from eight to 11 o'clock and the radial incision at right angles to this in the nine o'clock meridian. Upon retracting the scleral flaps, a gelatinous mass involving the ciliary body was encountered (Fig. 2). A wedge of tissue was removed for histologic examination.

Hematoxylin-eosin stains of the tissue demonstrated a diffuse, moderately cellular chronic inflammatory infiltrate, consisting of plasma cells, lymphocytes, and a few histiocytes (Fig. 3). No multinucleated giant cells were present, and there were no plasma-cytoid cells or Russell bodies. Several dilated blood vessels and ciliary muscle fibers were seen, and no necrosis was evident. Special stains for bacteria, fungi, and acid-fast organisms were negative, as were stains for iron. Periodic acid-Schiff (PAS) stained sections demonstrated no intranuclear, PAS-positive inclusions.[12]

It was concluded that the patient had an inflammatory pseudotumor of the ciliary body of the right eye, and probably a similar lesion at an earlier stage of development in the left eye. The pathogenesis of these lesions remained undetermined. Because of the inflammatory nature of the ocular disease, it was elected to treat the patient with 60 mg of oral prednisone daily, covered with 300 mg of isoniazid (INH) and antacids. Topical 1.0% prednisolone

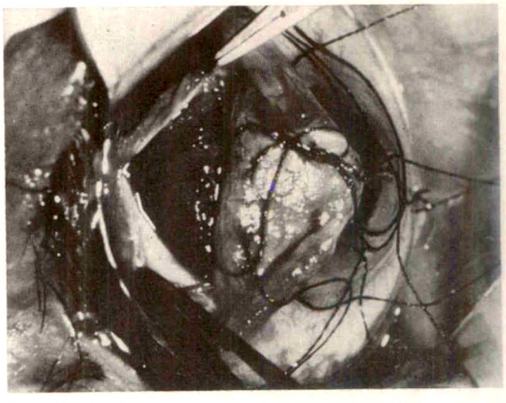

Fig. 2 (Ryan, Frank, and Green). Appearance of the mass in the ciliary body of the right eye at the time of surgery. Forceps retract the edges of the radial arm of the T-shaped cyclectomy incision. The mass, which had a pinkish coloration, appears dark in this photograph and lies between the retracted flaps.

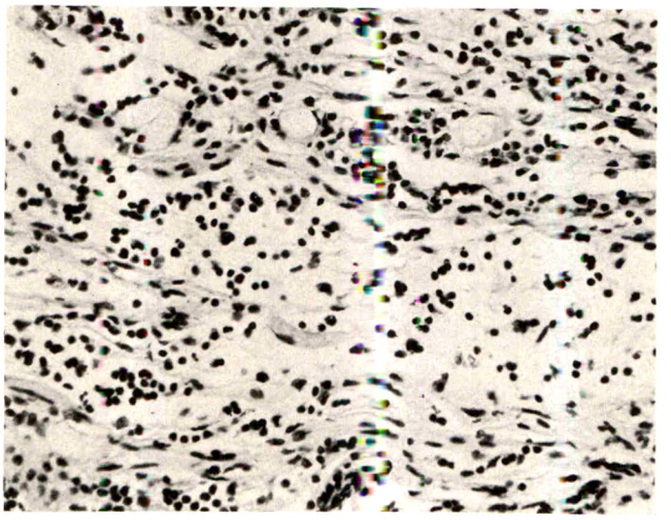

Fig. 3 (Ryan, Frank, and Green). Representative field from a section of the ciliary body biopsy from the right eye. Mononuclear inflammatory cells including lymphocytes and rare plasma cells are present. No giant cells are found, and there is no necrosis. Note blood vessels and ciliary muscle fibers. The lesion is much less cellular than pseudotumors of the posterior uvea which have been reported previously[4-7] (hematoxylin-eosin, ×370).

acetate to both eyes every three hours and 3% atropine twice daily were continued.

The response of the ocular lesions to this therapy was prompt. The cellular reaction in the vitreous the ray and cells in the anterior chamber, and the keratic precipitates disappeared, initially in the less severely affected left eye and eventually in the right eye. One month following the patient's discharge from the hospital, the gonioscopic appearance of the chamber angle in the left eye was normal, and during the second month after discharge the prominent vessels disappeared from the iris and angle of the right eye. The ciliary body mass was much less in evidence, and the region of the angle from six to 12 o'clock demonstrated changes suggestive to atrophy of the ciliary body and an appearance similar to that of angle recession. Visual acuity at this time was RE:20/60, and LE:20/20-3, and tensions were 8 and 17 mm Hg, respectively. Because of marked weight gain and a Cushingoid habitus, the systemic corticosteroids, which had been maintained at 60 mg/day for two months, were tapered over a two-month period and then discontinued. One month later the topical corticosteroids to the left eye were stopped. The patient returned the following month, however, with a one-week history of redness and decreased visual acuity in the left eye. Vision was RE:20/200, and LE:20/60 intraocular pressures were 3 and 9 mm Hg, respectively, with granular keratic precipitates and marked ray and cells in the anterior chamber of the left eye. Only minimal inflammatory signs without keratic precipitates were present in the right eye. Gonioscopically the angle of the right eye was unchanged, while in the left eye there were now many widely dilated radial and circumferential vessels in the temporal and most prominently in the inferior quadrants of the angle (Fig. 4). There was a moderate outpouring of cells in the anterior vitreous of both eyes, but again no abnormalities were noted on detailed fundus examination.

The frequency of topical corticosteroid administration was increased and, in order to provide a higher local corticosteroid concentration, as well as to minimize the possibility of systemic side effects, dexamethasone was injected subconjunctivally in 4 mg doses. One week later the dilated vessels had virtually disappeared from the angle in the left eye, leaving an atrophic appearance, but there was an

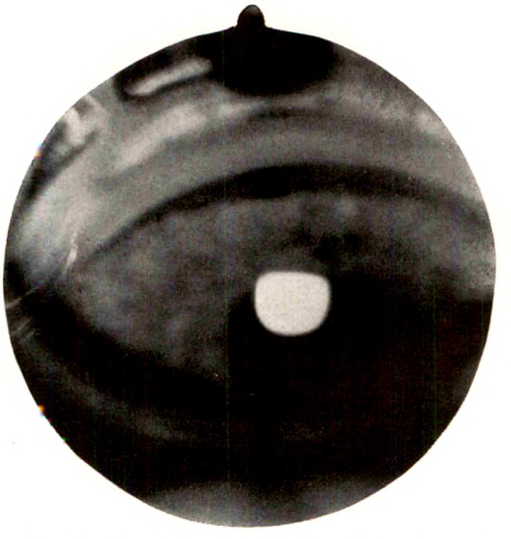

Fig. 4 (Ryan, Frank, and Green). Goniophotograph of the inferior quadrant of the chamber angle of the left eye during a relapse. Dilated blood vessels arising from the greater circle of the iris are seen in the angle. These occurred during relapse and resolved on oral prednisone therapy. The blurred appearance of the photograph is due to the intense anterior chamber reaction.

increased cellular reaction in the right eye and new vessels in the inferior quadrant of the angle. Hourly topical corticosteroids were continued and over the next two weeks the patient received five doses of subconjunctival dexamethasone to each eye. Visual acuity did not improve and the signs of inflammation persisted on this form of therapy, however, and oral prednisone, 60 mg/daily, was begun. Once more there was a prompt response. One week after starting the oral corticosteroids vision was RE:20/200, and LE:20/30. The cellular reaction in the anterior chamber had diminished, although many vitreous cells remained in both eyes, tensions were RE:6 mm Hg, and LE:14 mm Hg, and the chamber angle of both eyes now displayed a recessed appearance with the iris root drawn centrally and a deepened ciliary cleft (Fig. 5). No vessels were evident. The patient was maintained on oral prednisone, 60 mg every other day, along with topical prednisolone and atropine, and oral INH and antacids, until the inflammation once again became quiescent.

In order to prevent a rebound, systemic corticosteroids were tapered by very small increments. There was slow progression of the bilateral cataracts. Potentially contributing factors for both lenses were the anterior segment inflammation and systemic corticosteroid therapy. The right eye, in addition to the possible direct effects of cyclectomy, had presistent hypotony postoperatively; when vision in this eye had been reduced to hand motions, and to 20/80-1 in the left, cataract extraction was advised. While receiving 40 mg prednisone per day, the lens was removed uneventfully.

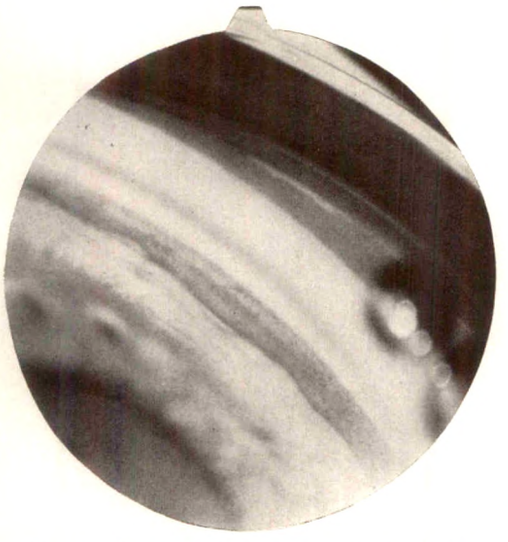

Fig. 5 (Ryan, Frank, and Green). Goniophotograph of the temporal quadrant of the chamber angle of the left eye 15 months after initial presentation and following remission of the inflammatory process on cortirosteroid therapy. All angle structures are easily seen, and the ciliary cleft appears markedly deepened, as in traumatic recession of the angle. No mass is evident, and there are no abnormal blood vessels.

Two weeks postoperatively visual acuity was 20/200 in the right eye with a +10.00 and pin hole. Intraocular pressure was 6 mm Hg with a 1-2+ ray and cells and anterior vitreous debris. Systemic corticosteroids are now being slowly tapered. The left eye exhibits posterior subcapsular cataract and moderate iris atrophy.

Continued medical evaluation has demonstrated no evidence of systemic disease. Serum protein electrophoresis, done while systemic corticosteroids were being tapered, disclosed mild hypogammaglobulinemia. Three immunoglobulin assays, done one month apart while corticosteroids were being tapered and two months after they were discontinued, showed moderate decrease of IgG, in the range 570-660 mg% (normal, 900-1500 mg%) with normal IgA and IgM. A Kveim test, performed during a period when the patient was off systemic corticosteroids, was negative. Despite the negative results of his repeated thorough physical and laboratory evaluation, he is presently followed with the awareness that some associated systemic disease may be diagnosed in subsequent years.

## Discussion

When dealing with a patient who presents with a mass in the anterior segment, the clinician must consider a variety of possibilities.[7,13,14] These include several types of neoplasms, both primary and metastatic, infectious granulomata (e.g., tuberculosis or syphilis), those of presumably noninfectious origin (e.g., sarcoidosis), and a reaction around an encysted and previously unsuspected intraocular foreign body. Finally, one must consider various disorders of the serum proteins such as Waldenstrom's macroglobulinemia.

In the present case, the bilaterality of the disease process (although a mass was initially prominent only in the right eye) made certain of these diagnostic possibilities less likely. For example, our patient's occupational history and his history of multiple corneal foreign bodies suggested to us that an intraocular foreign body might be the source of his difficulties, but it would be most remarkable for foreign bodies to be present in bilaterally symmetrical locations, or for a single one to cause bilateral anterior inflammation. Similarly, primary ocular tumors

(except retinoblastoma) are almost invariably unilateral.

On the other hand, involvement is bilateral in 20-25% of metastatic ocular tumors, according to several series cited by Reese.[13] Occult carcinomas of the lung may present with anterior ocular lesions before the primary site has been discovered.[15-17] For this reason, and because our patient had some clinical evidence of pulmonary disease, we were particularly anxious to exclude this possibility. Tumors primary in other organs may also metastasize to the eye,[15-17] and this consideration was important in our evaluation. Lymphomas may involve orbital and ocular tissues, including the anterior segment,[13] although according to Zimmerman,[6] "Most of the obviously malignant lymphomas of the orbit occur in patients who already have an established diagnosis or who present other evidence of systemic involvement."

Infectious and other systemic inflammatory disorders are, of course, relatively frequent causes of bilateral ocular lesions. An infectious basis is not likely in view of the exhaustive systemic evaluation and histologic appearance of the ciliary body and other biopsy specimens. Similarly, evidence for sarcoidosis was lacking in all biopsy material as well as in chest x-ray films, and a Kveim test was negative. Relatively mild and inconstant abnormalities of serum immunoglobulins have been demonstrated, but in over 18 months of follow-up there has been no evidence of systemic disease. The possibility remains, of course, that such a disorder might become apparent at a later date.

Blodi and Gass,[5] in their discussion of inflammatory pseudotumors of the orbit, note that bilateral involvement is unusual, but when it occurs, a relatively high percentage of these patients later show manifestations of systemic disease, most notably Wegener's granulomatosis, lymphomas, or leukemias. Little[18] has recently described a patient with Waldenstrom's macroglobulinemia who developed bilateral masses in his lacrimal glands. Biopsy of one of these lesions revealed a histologic picture similar to that in the present case, except that Little was able to demonstrate numerous PAS-positive intranuclear inclusions in the lymphocytes and plasma cells. Moreover, there had been a long history of prior disease, with tissue considered to be lymphomatous in the wall of the patient's stomach and in a mass behind the urinary bladder. There was also significant elevation of serum gamma globulins and of the IgM peak on immunoelectrophoresis. Such cases emphasize the need for close medical follow-up of patients with inflammatory pseudotumors.

This report documents the value of cyclectomy as a biopsy procedure. While certainly not a procedure to be taken lightly, iridocyclectomy has been used increasingly in recent years to excise malignant[9,10] and (where the preoperative diagnosis was uncertain) benign[11] tumors of the iris and ciliary body without necessitating loss of an eye. Its efficacy and safety seem to be moderately well established. When used for diagnostic purposes only, it need hardly be emphasized that cyclectomy should not be done unless appropriate attempts have been made preoperatively to establish a diagnosis by other means.

Finally, it is worth commenting on the rapid response of this inflammation to corticosteroid therapy. Intraocular pseudotumors which have been reported previously[4-7] have presented as lesions of the posterior uveal tract, and have eventually been treated by enucleation because they were suspected to be malignant melanomas of the choroid. If the inflammatory mass lesions in the present case bear any similarity to those discussed in the past, then their response to corticosteroids lends weight to the suggestion of Gass[5] that suspicious lesions of the posterior uvea might merit a diagnostic trial of corticosteroid therapy before enucleation. Since such lesions, whose neoplastic nature is clinically uncertain, are usually "treated" by an initial period of watchful waiting, the addition of

high-dose corticosteroids during this interval may be beneficial. If such a diagnostic/therapeutic approach is taken, the clinician must remain fully cognizant that some neoplasms (e.g., the lymphomas and the inflammatory components of others) can show a dramatic response to systemic corticosteroids.

## Summary

A 51-year-old man presented with bilateral ciliary body masses associated with signs of iridocyclitis. The differential diagnosis included malignant melanoma, lymphoma, metastatic tumor, and granulomatous inflammation of the ciliary body. After an exhaustive systemic evaluation to rule out extraocular disease, diagnosis was made by biopsy of the ciliary body. The lesion proved to be a nonspecific inflammatory process, consisting of numerous lymphocytes, plasma cells, and histiocytes. There was a good response to systemic corticosteroid therapy.

# UNUSUAL COURSE OF A CILIARY BODY MELANOMA

BRIAN R. MATAS, M.D.
*San Francisco, California*

Extrabulbar extension of uveal melanomas is usually associated with a grave prognosis.[1] However, this communication presents a follow-up report of an unusual case, originally reported by Hogan,[2] of ciliary body melanoma which presented as an epibulbar pigmented nodule and pursued a remarkably benign course for 19 years.

## CASE REPORT

A 37-year-old white woman was first examined by an ophthalmologist in December, 1960, for a pigmented lesion of the sclera (Fig. 1) which had remained unchanged for the preceding 10 years. The scleral lesion was grey, 4 mm in diameter, and located 5 mm posterior to the superior limbus in the vertical meridian. The lesion was neither elevated nor vascularized. On gonioscopic examination, a tumor mass was detected in the angle in a position corresponding to the location of the scleral lesion (Fig. 2). The ciliary body was unremarkable, and the visual acuity and intraocular pressure were normal. The pupil was of normal size and shape and dilated normally. Examination in 1961 demonstrated no change in the findings. In 1962, the scleral lesion was slightly elevated and had increased to a diameter of 10 mm. At this time, a smooth, slightly elevated ciliary body tumor was noted which corresponded to the site of the scleral lesion. There was no further change until 1969, when progressive growth of the ciliary body and angle tumor became obvious (Figs. 3 and 4). The extrascleral extension at this time measured 5 mm in diameter. The apparent decrease in size since 1962 was attributed to loss of pigment. The patient was referred to the University of California, San Francisco, for consultation and the eye was enucleated on October 23, 1969.

*Pathology*—Gross examination revealed a pigmented ciliary body tumor superiorly which was contiguous with a nonpigmented peripheral iris angle tumor. A black pigmented epibulbar tumor measuring 5 mm in diameter was present near the limbus overlying the intraocular tumor.

On microscopic examination, a tumor was seen arising from the ciliary body superiorly and extending into the chamber angle (obliterating the angle) and iris root (Fig. 5). The tumor extended via

scleral channels to give rise to an episcleral mass near the limbus (Fig. 6). The episcleral tumor had a fibrous capsule.

The tumor was lightly pigmented and consisted largely of cohesive, spindle-shaped cells with hyperchromatic nuclei and prominent nucleoli. The cellular cytoplasm was relatively scanty.

The diagnosis was melanoma of the ciliary body and angle, spindle cell B type,[3] with epibulbar extension.

## Comment

This case is of interest because of its unusual course in which the ciliary body melanoma was present as an extrascleral extension for 19 years before the tumor could be clinically detected within the ciliary body. At the time of enucleation the patient was asymptomatic and without the usual clinical features[4,5] associated with ciliary body melanomas. It is unusual for a pigmented epibulbar mass to be the initial finding of a ciliary body or choroidal melanoma, but occasionally such cases are reported.[6] The prognosis is generally considered to be compromised by extrascleral extension. In the series reported by Starr and Zimmerman,[7] the five-year mortality rate in cases with extrascleral extension was 66% compared to 33% in cases without extension. This difference in mortality may be partially explained by the apparent tendency of the more malignant cell types (epithelioid, necrotic, mixed) to extend more frequently than do spindle cell tumors. The cell type of the ciliary body tumor reported here was spindle B, a finding that is perhaps related to the unusually slow progression of this lesion over a period of so many years.

## Summary

In a case of ciliary body melanoma with extrabulbar extension, both the presentation and subsequent course were unusual. The tumor cell type was spindle B, considered to be less malignant than the mixed or epithelioid cell types that are more frequently associated with extrabulbar extension. There was a 19-year interval in this case between the appearance of the scleral pigmented lesion and the subsequent enlargement of the ciliary body tumor. The slow growth of this ciliary body tumor may be related to the tumor cell type.

# CONJUNCTIVAL MALIGNANT MELANOMA ORIGINATING IN ACQUIRED MELANOSIS SINE PIGMENTO

WILLIAM R. GRIFFITH, M.D., W. RICHARD GREEN, M.D., AND GEORGE W. WEINSTEIN, M.D.

*Baltimore, Maryland*

Malignant melanomas of the conjunctiva are encountered infequently.[1] Clinical significance is based upon the high mortality rate (about 40%) and the usual necessity of exenterating the orbit.[2] The pathogenesis of conjunctival malignant melanoma is attributed to two antecedent melanotic lesions: conjunctival nevi and acquired conjunctival melanosis. Some melanomas arise de novo without such antecedent lesions.[3] The case reported here is attributed to an unusual and apparently previously unreported form of acquired melanosis.

## CASE REPORT

The patient, a 54-year-old white man, was first admitted to the Wilmer Institute of the Johns Hopkins Hospital on January 14, 1970, for treatment of multiple pigmented nodules within the medial portion of the right upper eyelid (Fig. 1). The nodules had been noted three weeks prior to admission. Eight months previously, a malignant melanoma had been excised from the medial bulbar conjunctiva and caruncle of the right eye.

Ocular examination revealed a visual acuity of 20/15 in each eye. There was a well-healed, slightly hypertrophic scar of the medial bulbar conjunctiva of the right eye. Two small, lightly pigmented nodules were palpable within the deep tissues of the upper eyelid of this eye medially. These nodules could be seen through the skin and conjunctiva, neither of which was ulcerated. The rest of the conjunctiva appeared unremarkable. The remainder of the ocular examination—including ocular motility, slit-lamp examination and ophthalmoscopy—disclosed no abnormalities. No palpable lymph nodes could be found. A careful general examination, including roentgenologic and extensive liver function studies, revealed no evidence of distant metastatic disease.

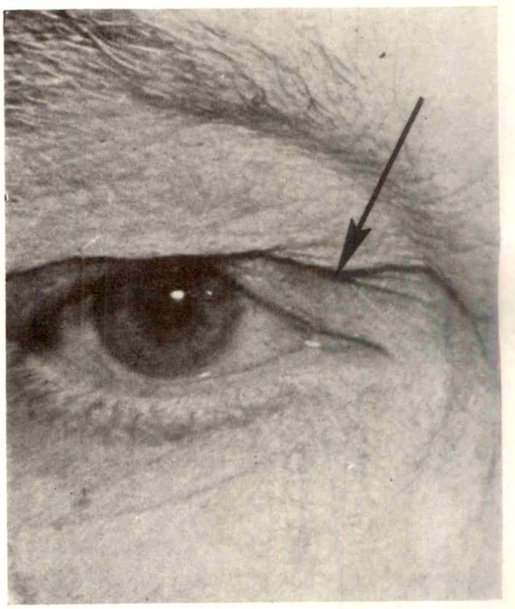

Fig. 1 (Griffith, Green, and Weinstein). Preoperative appearance, showing pigmented nodules (arrow) which are partly obscured by redundant upper eyelid. No conjunctival pimentation is visible.

The clinical impression was locally recurrent malignant melanoma of the conjunctiva. Several attending ophthalmologists at the Wilmer Institute, and two visiting physicians who are distinguished in the field of ocular oncology (Zimmerman and Blodi) concurred with this diagnosis. In the absence of any discernible conjunctival pigmentation, a diagnosis of antecedent acquired melanosis was not entertained.

Examination of sections from the original resection, obtained from the patient's local hospital, confirmed the diagnosis of malignant melanoma of the conjunctiva and also disclosed features of acquired melanosis both of which were similar to the more recent material.

On January 23, 1970, under general anesthesia, a biopsy of the lesions, using immediate frozen sections, revealed malignant melanoma (Fig. 2), and a complete exenteration of the right orbit was then performed. The bony socket was lined with split-thickness skin graft from the thigh. The postoperative course was uneventful. Eleven months later, however, an enlarged lymph node developed in the

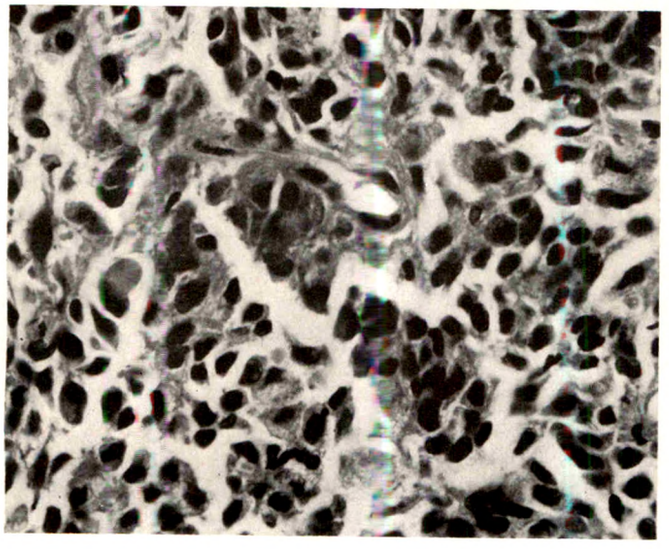

Fig. 2 (Griffith, Green, and Weinstein). Surgical biopsy specimen from right upper eyelid. Highly anaplastic tumor cells with cytoplasmic melanin granules are seen (hematoxylin and eosin, ×700).

right cervical area. This node was excised and disclosed metastatic melanoma.

*Pathology*—Gross examination of the exenterated tissue revealed a specimen measuring 55 × 45 × 48 mm, consisting of the right eyelids and orbital contents. An 8 mm horizontal biopsy incision was present in the upper eyelid nasally. Periosteum was generally intact. Within the upper eyelid and inferior to the biopsy incision several lightly pigmented nodules were found, the largest of which measured 5 mm in diameter. No further neoplasm was seen. The conjunctiva was free of pigmentation. Vertical sections were taken.

On microscopic examination, the neoplasm was seen to occupy almost the complete thickness of the medial upper eyelid, involving the upper tarsal border, levator aponeurosis, substantia propria of the upper forniceal conjunctiva, and the external aspect of Tenon's capsule (Fig. 3). Sheets and clumps of spindle and epithelioid cells formed the neoplasm. The epithelioid cells in particular were quite anaplastic, with three or four mitotic figures per high-power field. Moderate amounts of intracellular melanin granules were seen in the central areas of the tumor. Along some margins, a lymphocytic infiltrate was seen.

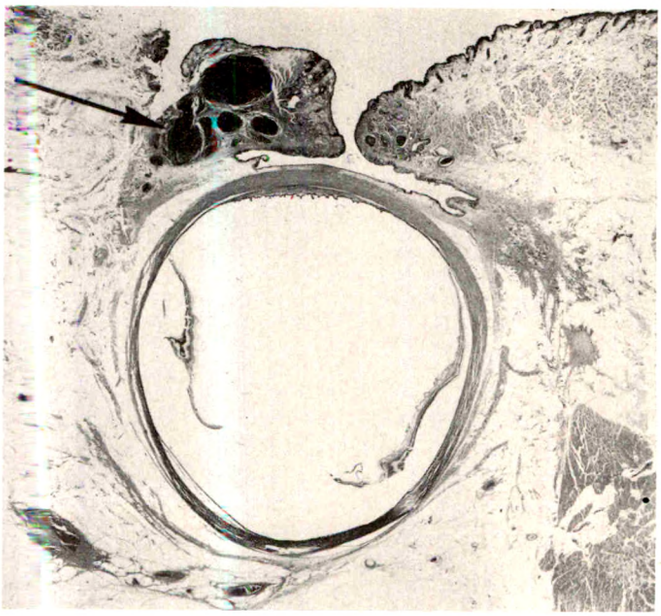

Fig. 3 (Griffith, Green, and Weinstein). Vertical sections of medial portion of exenteration specimen, showing the biopsy incision and tumor nodules (arrow) in the upper eyelid (hematoxylin and eosin, ×2.5).

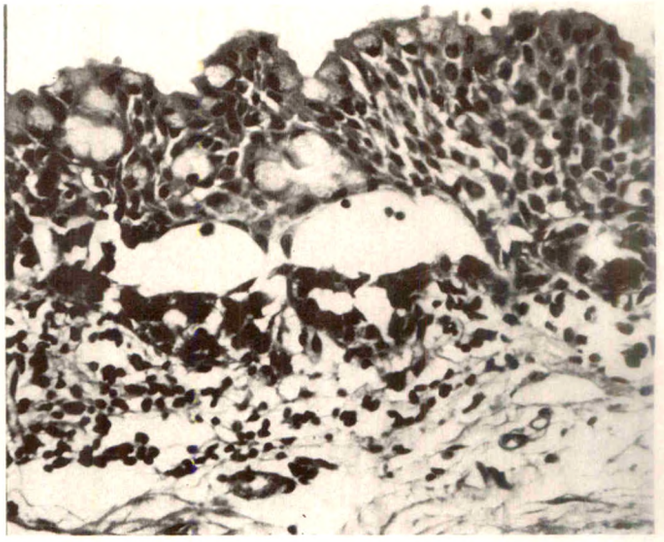

Fig. 4 (Griffith, Green, and Weinstein). Inferior bulbar conjunctiva. Nests of hyperchromatic, melanin-free cells are seen at the epithelial junction, with subjacent inflammatory infiltrate (hematoxylin and eosin, ×290).

Widespread areas of intense junctional activity were present and involved the bulbar, upper and lower foniceal and upper and lower tarsal conjunctiva. These areas consisted of nests of mildly pleomorphic cells with hyperchromatic nuclei (Fig. 4). Nests of similar cells containing more abundant, vacuolated cytoplasm and eccentric and hyperchromatic nuclei were also seen. An intense mononuclear inflammatory response was present in the substantia propria adjacent to some of these areas (Fig. 5). No pigment granules were seen in these areas of junctional activity, either in the hematoxylin-and-eosin-stained sections or in those stained by the Fontana silver impregnation technique.

The globe was unremarkable. The margins of the total specimen were well clear of the neoplasm, and no further neoplastic deposits were seen deeper in the specimen. A careful search showed no evidence of lymphatic invasion.

The diagnosis was: locally recurrent malignant melanoma of the conjunctiva originating in amelanotic acquired melanosis of the conjunctiva.

## Comment

It has been known since the turn of the century[4,5] that acquired melanosis of the skin can lead to malignant melanoma. Appreciation by ophthalmologists that a similar

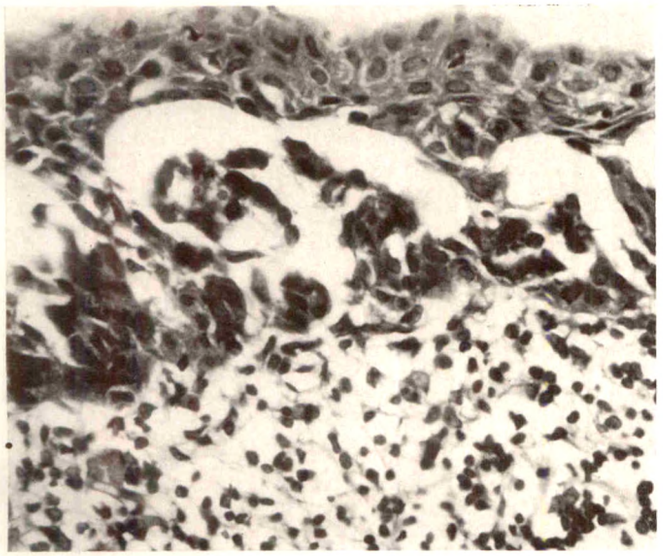

Fig. 5 (Griffith, Green, and Weinstein). Inferior forniceal conjunctiva. Nests of melanin-free, pleomorphic, hyperchromatic cells occupy the junctional zone. An intense inflammatory response is present in substantia propria (hematoxylin and eosin, ×390).

process can occur in the conjunctiva is due mainly to the writings of Dr. Algernon Reese. His early papers, based in part on cases from the literature, suggested that malignant transformation was a constant feature of acquired melanosis of the conjunctiva. The resulting malignant melanomas seemed, also, to have a uniformly bad prognosis; therefore, aggressive therapy during the precancerous stage seemed indicated.[6,7] Subsequently, his continuing interest in this condition and meticulous long-term observation enable Dr. Reese to assemble a large personal series of cases of malignant melanoma of the conjunctiva. His 1966 paper,[2] in which he described 83 cases of precancerous melanosis (42 with follow-up exceeding five years) and 62 cases of cancerous melanosis (36 of which were followed five years or longer), remains the definitive clinical study. Dr. Reese reported that precancerous melanosis progressed to cancerous melanosis in 17% of cases. The 36 cases of cancerous melanosis had a mortality rate of 40%.

There was a striking variability, however, in the clinical courses of both lesions. To quote Dr. Reese[2]: "The erratic course of precancerous and cancerous melanosis in contrast to the constant and predictable course of uveal melanomas makes the selection of treatment most difficult. . . . In general, an exenteration is indicated when it can be established that the tumor has advanced to the cancerous stage."

Other reports, although based on smaller series and often with less follow-up, seem to be in general agreement with Reese.[3-10]

Lederman[11] reported good results using primary radiation therapy for selected conjunctival malignant melanomas. However, he did not advocate radiation therapy during the precancerous stage. A recently reported study[12] from the Memorial Hospital, New York, reviewed 1483 cases of cutaneous malignant melanomas in an attempt to assess the value of lymph node dissections performed routinely. However, neither conjunctival melanomas nor head and neck melanomas were analyzed separately.[12]

There is some controversy as to the relative importance of the two types of antecedent lesions. Reese[13] has attributed two-thirds of conjunctival malignant melanomas to precancerous or acquired melanosis, and he attributed the remaining third to conjunctival nevi. Zimmerman,[3] citing his own experience at the Armed Forces Institute of Pathology, found that the antecedent lesion could not be determined in one-half of the cases. Of the remainder, two-thirds were attributable to nevi and one-third to acquired melanosis.

Of what significance is the present case? Dr. Reese's original paper, as well as the other reports cited, stress that acquired melanosis of the conjunctiva is a diffuse, nonelevated, pigmented lesion, with the melanin pigment often having a somewhat granular distribution. The diffuse nature of the condition was emphasized, suggesting that junctional activity may extend beyond the obvious areas of pigmentation. Nonetheless, increased pigmentation was the crucial diagnostic feature.

Our case suggests that, in the complete absence of such pigmentation, a clinical diagnosis may be all but impossible, with the junctional activity being appreciated only upon biopsy and histologic examination. This may be termed "acquired melanosis sine pigmento," analagous to retinitis pigmentosa sine pigmento. Certainly, whenever a melanotic lesion is excised, the margins of the specimen should be carefully examined for evidence of acquired melanosis. Where such examination is inconclusive, further conjunctival biopsies, even of nonpigmented areas, would be valuable.

Final understanding of this puzzling condition will require both accurate initial histologic diagnosis and long-term follow-up.

## Summary

A case of malignant melanoma of the conjunctiva arising from clinically unrecognized acquired melanosis is described. Clinically,

no conjunctival pigmentation was observed. Histopathologic examination of the exenteration specimen disclosed widespread junctional melanocytic activity characteristic of acquired melanosis. No melanin was observed in the areas with routine and special staining techniques.

# REPORT OF A CASE OF SPHENOID FISSURE SYNDROME STUDIED BY ORBITAL VENOGRAPHY

BERNARD A. MILSTEIN, M.D., AND LUIS B. MORRETIN, M.D.
*Galveston, Texas*

The sphenoid fissure syndrome arising from inflammation surrounding the cavernous sinus or the superior orbital fissure is a condition with many synonyms: painful ophthalmoplegia,[1,2] orbital apex syndrome,[3] superior orbital fissure syndrome,[4] Tolosa-Hunt syndrome,[2] or superior orbital fissuritis.[5] The etiology of the inflammatory process has not been determined. The purpose of this paper is to describe a case of sphenoid fissure syndrome in which occlusion of the superior ophthalmic vein was demonstrated by orbital venography.

## CASE REPORT

A 15-year-old black girl, a high school student, presented on August 22, 1969, at the University of Texas Medical Branch Hospitals complaining of pain in her left eye and was admitted for further evaluation. Four weeks earlier, the patient noted a left-sided headache and this was followed two weeks later by progressive diplopia. There was no history of trauma, recent upper respiratory infection, previous headaches or earaches, or any syncopal episodes or seizures. She had a gonococcal genitourinary infection six months prior to the onset of her symptoms.

The visual acuity was 20/20 in the right eye and 20/30-1 in the left. Intraocular pressure by applanation tonometry was 10 mm Hg on the right and 16 mm Hg on the left. Hertel exophthalmometer readings with a base of 105 mm were 16 mm on the right and 19 mm on the left. Blepharoptosis was present on the left. There was paralysis of the fourth and sixth nerves, and partially of the third (Fig. 1). The right eye was normal. The pupil was 3 mm in diameter in both eyes and they reacted to light and accommodation equally. The conjunctiva, cornea, anterior chamber, and lens were normal in both eyes. No evidence of venous stasis was observed. The fundi were normal. Peripheral visual fields by Goldmann perimetry were normal. The remainder of the physical examination, including neurologic evaluation, was within normal limits.

Chest, skull, and sinus radiograms were normal. A thorough laboratory study, including $^{3}$Tm resin uptake and fluroescein treponema antibody test, was normal. A spinal tap revealed no cells; glucose, 59 mg%; protein; 25 mg%, and chloride, 124.5 mEq. A carotid arteriogram revealed no lesions.

Orbital venography (Fig. 2) performed via the frontal vein demonstrated occlusion of the left su-

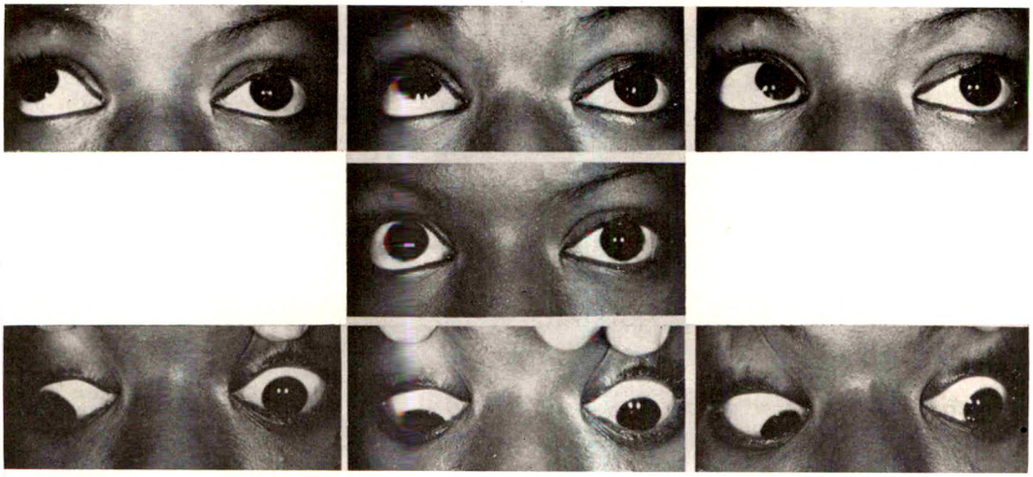

Fig. 1 (Milstein and Morretin). Pretreatment demonstration of blepharoptosis, and partial third, fourth, and sixth nerve paralysis.

perior ophthalmic vein in the superior orbital fissure with no displacement of the vessel suggestive of obstruction by a mass. No filling of the left cavernous sinus was noted. On September 3, the patient was started on prednisone, 60 mg daily. By September 5, the patient's headaches ceased, and a day later, improvement of lateral rectus function was noted. Over a two-week period, the patient gradually regained full extraocular muscle function and was discharged on September 23 with no residual ophthalmoplegia and with a final visual acuity of 20/20. Repeat orbital venography at the completion of treatment demonstrated a patent superior ophthalmic vein with filling of the cavernous sinus (Fig. 3).

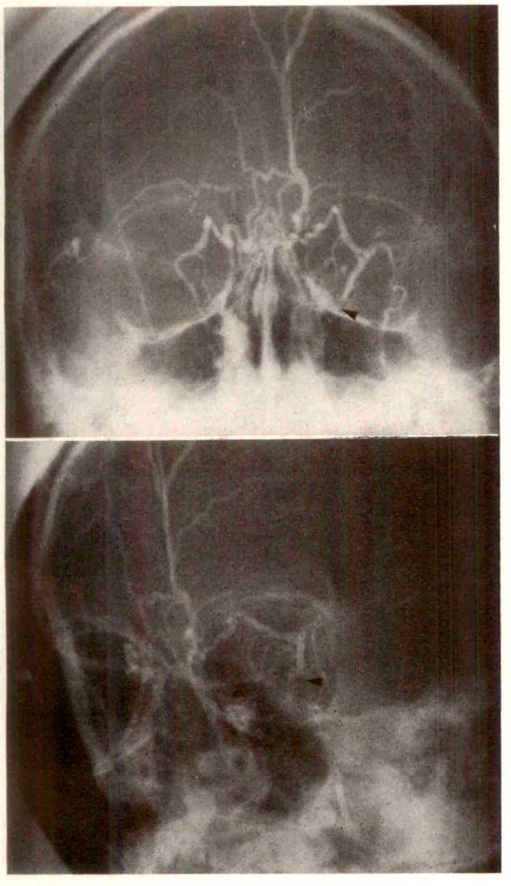

Fig. 2 (Milstein and Morretin). Orbital venogram. Top: Frontal view. The left ophthalmic vein is slightly dilated and tapers progressively to the point of obstruction (arrows) at the superior orbital fissure. The cavernous sinus is opacified on the right side (normal) and not on the left side. Bottom: Oblique view. The lumen of the obstructed superior orbital vein is irregular. Note the small collateral venules adjacent to the obstruction.

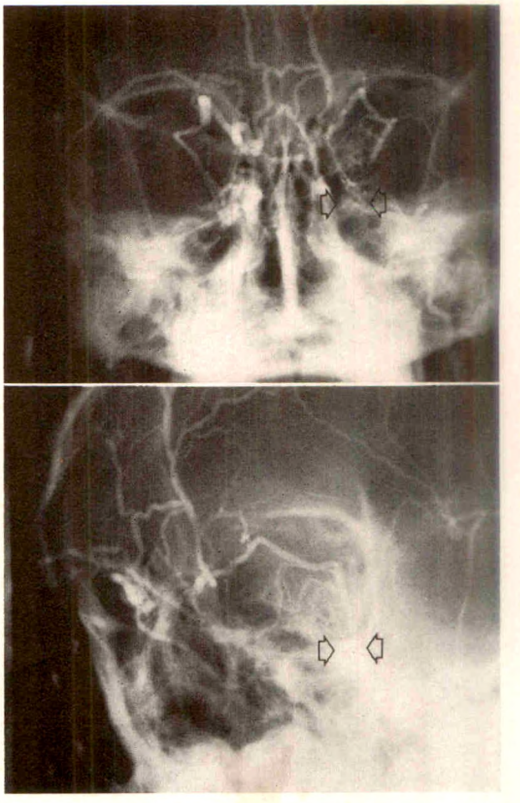

Fig. 3 (Milstein and Morretin). Repeat orbital venogram after treatment. Top: Frontal view. Bottom: Oblique view. The left superior ophthalmic vein, although still narrowed, is patent. The left cavernous sinus is now opacified (arrows).

## Discussion

The etiology of superior orbital fissure syndrome has been attributed to: (1) aneurysm of the internal carotid artery at the posterior communicating junction, (2) neoplasm, (3) carotid cavernous fistula, (4) gummatous periostitis about the orbital fissure, (5) meningovascular syphilis with oculomotor palsy, and (6) trauma.[5] Other causes of superior orbital fissure syndrome include ophthalmic migraine and diabetes mellitus. Diabetic third nerve palsy typically does not include pain as a significant symptom. The patient presented in this study demonstrates an additional etiology recognized by previous authors—inflammation of the sphenoid fissure or the cavernous sinus.[2-6]

Painful ophthalmoplegia was originally described in the French literature in 1865.[7,8] In 1896, Rochon-Duvigneaud named this constellation of symptoms and signs "le syndrome de la fente sphenoidale," or the sphenoid fissure syndrome.[7] More recently, in 1954 Tolosa[9] described a man with superior orbital fissure syndrome in whom a pathologic study of the cavernous sinus revealed granulomatous tissue which surrounded, but did not completely obstruct, the lumen of the cavernous sinus.

Seven years later, Hunt and associates[6] reported six cases of retro-orbital pain and involvement of the structures lying within the cavernous sinus and its walls. Lakke[4] reported a similar case in which he included a rather extensive review of the literature on the superior orbital fissure syndrome. He found local pachymeningitis in the area of the cavernous sinus.

In 1966, Smith and Taxdale[2] described five cases of painful ophthalmoplegia and its excellent response to systemic corticosteroids, an observation also made by Hunt and associates,[6] indicating that indolent inflammation of the cavernous sinus or the sphenoid fissure was the etiology.

Retro-orbital pain is one of the earliest and most constant symptoms of the sphenoid fissure syndrome, as seen in the present case. Limitation of ocular movements usually follows. The superior rectus muscle is generally the first to lose its function.[4]

The present case is similar to the one reported by DeJean,[3] Holt,[3] Tolosa,[9] Hunt,[6] and Smith[2] in that: (1) pain preceded the ophthalmoplegia, (2) neurologic involvement included the third, fourth, fifth, and sixth cranial nerves, (3) the symptoms lasted for weeks, and (4) extensive studies, including angiography, demonstrated no lesions outside the cavernous sinus. Hunt[6] and Smith[2] both felt that spontaneous remissions occur, some with residual deficits, and that attacks may recur.

The present case is unique in that this syndrome has rarely been recorded in a patient so young. It is also the only case to document, by orbital venography, occlusion of the superior orbital vein and then its patency after treatment. Venography established a tentative diagnosis of a localized inflammatory process because of the tapering characteristics of the obstruction of the superior ophthalmic vein and the irregular lumen of this vessel. It was felt that orbital venography supported the impression that this was not neoplastic since the vein showed no displacement (Fig. 2). As previous investigators have found, the etiology of the inflammation remained obscure.

Occlusion of the superior ophthalmic vein does not help to establish the etiology of this rather bizarre inflammatory disease of the sphenoid fissure and cavernous sinus, but it is a useful diagnostic technique. Every effort should be made in cases of painful ophthalmoplegia to discover an etiology and to rule out malignancy. When this has been done, the suggestion by Hunt[6] and Smith[2] that these patients be treated with systemic corticosteroids seems most prudent and effective.

## Summary

A 15-year-old black girl was seen with painful ophthalmoplegia of four weeks' duration. Two weeks earlier, blepharoptosis had occurred which was followed by progressive paralysis of the third, fourth, and sixth nerves with pupillary sparing. Orbital venography via the frontal vein established occlusion of the superior ophthalmic vein as a concomitant finding. Treatment with prednisone was followed by complete regression of signs and symptoms within two weeks.

OPHTHALMIC MINIATURE

The colour metamorphosis of the sea was studied by the Undersea Research Group. We took down colour charts with squares of pure red, blue, yellow, green, purple, orange, together with a range of greys from white to black, and photographed the chart at various levels down to the twilight zone. At 15 feet red turned pink, and at 40 feet, became virtually black. There, also, orange disappeared. At 120 feet yellow began to turn green, and everything was expressed in almost monochromatic colours. Ultraviolet penetrated quite deeply, while infrared rays were totally absorbed in inches of water.

# SCANNING ELECTRON MICROSCOPY OF THE LENS AND ZONULAR FIBERS

ARTHUR E. OBERMAN, M.D.
*Los Angeles, California*

Application of scanning electron microscope techniques offers startling photographs of surface features of biological materials. Due to the great depth of field, several hundred times greater than by transmission electron microscopy and optical microscopy, a three-dimension-like picture is obtained. Resolution of surface features is limited only by fixation techniques of the specimen and electron beam damage to the surface at higher magnifications. Structures, which previously could be surmised by serial section transmission microscopy, can now be viewed directly. This technique was recently applied in the examination of the trabecular meshwork by Spencer[1] and Anderson.[2]

Classically,[3] the lens capsule is described as a clear membrane surrounding the lens, composed of a capsule proper or cuticular layer, and the zonular lamella, or superficial layer. The zonular fibers insert into the zonular lamella of the lens, each point of attachment producing a tent-like elevation of the lamella. No direct connections between zonular fibers and the cuticular layer is noted.

## MATERIALS AND METHODS

A total of four lenses were examined in this study, two samples being surgical specimens of cataract, and the other two, removed from bank globes, considered to be normal.

All material was fixed in 10% formalin for several days, then dehydrated in 70% alcohol for 24 hours and absolute alcohol for 30 minutes. The dissected specimen was attached to fragments of standard glass slides by vinyl adhesive and air-dried for six to 12 hours. Dehydration was completed by a vacuum evaporator, after which the specimens were coated with a thin layer (20 nm) of gold deposited at multiple angles. Appropriate grounding was accomplished by use of silver cement between the specimen and the microscope stage. Viewing was performed with a model JSN-2 scanning electron microscope (Japan Electron-Optics Laboratory).

## RESULTS

The anterior face of the lens consists of a moderately smooth surface marked by gentle undulations and a regular cobblestone-like mound pattern. These mounds are presumed to be the cells of the subcapsular epithelium. The mounds measure approximately 10μ in diameter. Spacing between the cobblestone mounds is small, generally no more than a micron or two. Prominence of the anterior epithelial cells in bold relief can be attributed to the dehydration process in preparation of the specimen. Areas of the posterior lens surface show a pitted surface structure. The crevices, measuring 0.5 to 1.5μ in size, are scattered in an irregular pattern, and may represent a type of capsular pore structure. Such openings were not noted on scanning the anterior lens surface.

Study of the equatorial region of the lens shows the zonular fibers attaching to the lens capsule. Larger fibers measuring 10μ or more subdivide into numerous smaller zonular fibers as the point of insertion is approached. The smallest fibers measure between 1 to 3μ and run a tangential course of nearly 0.5 mm semi-fused to the zonular lamella before the two structures blend imperceptibly together. Nearing the point of insertion, the fiber is adherant to the capsule by a mucoid-like substance which fills the gutter

between that fiber and the surface of the capsule. At the actual point of attachment of the fiber to the zonular lamella, the two appear to be interfused, both structures showing a common homogenous surface pattern.

## Comments

The microscopic anatomy of the lens surface and zonular attachments has been extensively described by techniques of conventional microscopy, phase-contrast microscopy,[4] and by transmission electron microscopy. The scanning electron microscope provides yet another means of examining the eye and its many surface features. Pictures obtained parallel the ophthalmologist's direct view of ocular structure by his standard office instruments.

Insertion of the zonular fibers into the zonular portion of the lens capsule is demonstrated with added realism by scanning electron microscopy. Division of the larger fibers into multiple smaller fibrils is well visualized, as is the long contiguous course of the fibril with the lens capsule prior to insertion. Visible morphology does not appear to differ from description of the insertions noted by other microscopic techniques.

Of particular interest was the demonstration of surface crevices. Capsular pores, as noted by Monahan,[5] have been postulated to serve as channels of diffusion into the lens substance. These channels, of 0.2 to 0.5μ size, were found to be less numerous with age and with degree of cataract. In contrast to this study, the channels were noted only on the anterior surface of the lens and were smaller in size.

Since it is known that the lens is metabolically active, consideration should be given to such crevices as being a route of entrance and exit of molecules through the capsule. Alteration of the pore structure may bear some relationship to the formation of posterior subcapsular cataract and the disturbed lens metabolism which is presumed to be present. These considerations deserve further study. Other investigators[6] feel the pores are artifacts in the fragile lens capsule, developing during removal and sectioning

and not observed with transmission electron microscopy. This possibility of artifact must always be considered in any process requiring severe dehydration of fragile tissues.

## Summary

The scanning electron microscope provides a study of the surface features of the lens and the zonular insertions. Because of the three-dimensional effect of this technique, views of zonular fiber insertion into the lens capsule are seen with improved realism. In addition, crevices representing a pore structure of the capsule are noted in several specimens. These openings may be related to the metabolic activity of the lens.

# LOCALIZATION OF TRITIATED DIGOXIN IN THE RAT EYE

WILLIAM LISSNER, M.D., JAMES E. GREENLEE, M.D., J. DOUGLAS CAMERON, M.D., AND SEYMOUR B. GOREN, M.D.

*Chicago, Illinois*

The ocular symptoms of digitalis toxicity may include visual hallucinations, chromatopsia, blurred vision, pupillary changes, and decreased visual acuity. However, the mechanisms involved in the production of these ocular manifestations are not completely understood. Additionally, the biochemical interactions between the cardiac glycosides and the formation of aqueous humor are of interest. Sodium-potassium-ATPase, an enzyme active in transport systems, may be inhibited by the cardiac glycosides. Therefore, digitalis may be useful in the study of aqueous humor dynamics.

By means of tritium-labeled digoxin and autoradiographic and scintillographic techniques, the localization of digoxin in the rat eye was investigated.

## METHOD

Sprague-Dawley rats, each weighing approximately 350 mg, received a single intraperitoneal dose of 0.048 to 0.250 mg/kg of tritiated digoxin having a specific activity of 9 curies per millimole. At times varying from 15 to 180 minutes after injection, the animals were anesthetized with ether, the eyes and brain removed, and the tissues studied as described below.

*Autoradiographic studies*—After the eyes were enucleated and portions of brain excised, a freeze-dry technique was employed to eliminate leeching. The tissues were frozen immediately and stored in liquid nitrogen until sectioned. Sections 4 to 6 μ thick were cut with a cryostat under vacuum. The tissues were mounted on glass slides and covered with Kodak NTB-3 liquid emulsion, using the dipping technique. Following the exposure of the emulsion to the radioactivity, the emulsion was developed and the underlying tissue stained with hemotoxylin and eosin. Ten eyes were examined in this manner.

*Scintillographic studies*—Both eyes were enucleated and the cornea, iris, lens, retina, and sclera separated by microdissection. Multiple samples of proximal and distal optic nerve, occipital lobe, and cardiac blood were obtained. In some experiments, samples of aqueous and vitreous humor were removed prior to enucleation. Each tissue sample was placed in a Packard low-potassium glass counting vial and weighed.

The tissues were solubilized with 1.5 ml Soluene (Packard) and incubated for 20 hours at 40°C and 30% hydrogen peroxide was added to bleach the solution and to reduce color quenching. Glacial acetic acid was then added to acidify the solution and to minimize chemical luminescence. Scintillation solution (5 g PPO and 300 mg POPOP per liter of toluene) was added to each vial.

The samples were counted in a Packard Tri-Carb liquid scintillation counter. Quenching was compensated for by using internal standard techniques. The data was statistically analyzed using the Signed-Ranks test. Grouped data were used to compare the retina to other ocular tissues, to optic nerve, to brain, and to blood to determine if the differences in radioactivity were statistically significant.

## RESULTS

*Autoradiography*—Autoradiograms revealed extremely high concentrations of ra-

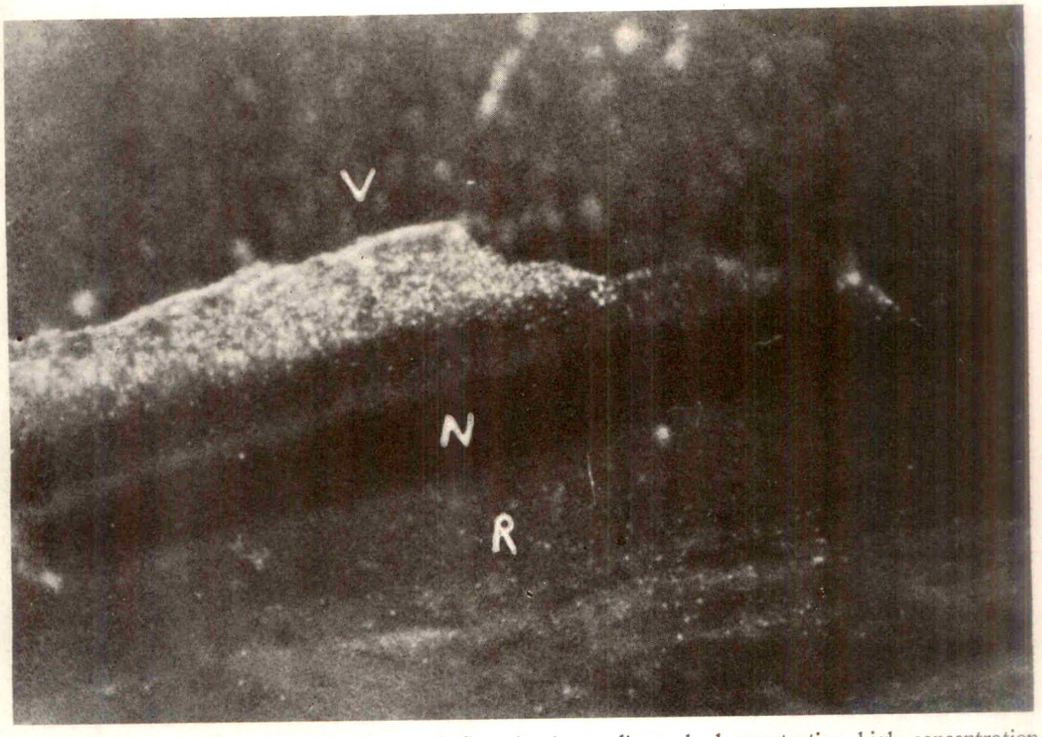

Fig. 1 (Lissner, Greenlee, Cameron, and Goren). Autoradiograph demonstrating high concentration of digitalis in the inner retinal layers and ganglion cells. The receptor cells (R), nuclear layer (N) and vitreous (V) contain minimal amounts of radioactivity.

dioactivity in the inner retinal layers, especially the ganglion cells (Fig. 1). Negligible amounts of digitalis were found in the outer retinal layers and receptor cells. Large amounts of radioactivity were spread diffusely throughout the iris (Fig. 2). Radioactivity was seen between the extraocular muscle bundles but not within the muscle fibers (Fig. 3). The conjunctiva contained moderate amounts of radioactivity (Fig. 4). The blurred quality of the photographs is due to the fact that the radioactive emulsion is being focused upon and not the underlying tissue. The cornea, lens, anterior and posterior chambers, vitreous, and sclera contained no radioactivity on the autoradiograms. Multiple sections of proximal and distal optic nerve and brain also revealed no radioactivity by autoradiographic techniques.

*Scintillography*—Using the scintillation counter, we found the retina and iris to have the highest concentration of digoxin. The sclera, cornea, lens, aqueous, and vitreous had progressively less. Most importantly, digoxin localized in the retina in concentrations 50 times that of the brain and 20 times that of the optic nerve (Table 1).

The Signed-Ranks test was used for statistical analysis of the data. Absorption of digitalis after intraperitoneal injection is variable and therefore it is not significant to compare absolute values in one animal with those of another. Additionally, different doses were administered in various experiments. However, the relative values between various tissues remained constant regardless of the time interval between injection and sacrifice or of the dosage given. Unfortunately, attempts at intravenous administration caused death in most animals. The Signed-Ranks test confirmed that the retinal concentration was significantly higher than brain, blood, and all other ocular tissues except the iris when P is 0.01 (Table 2).

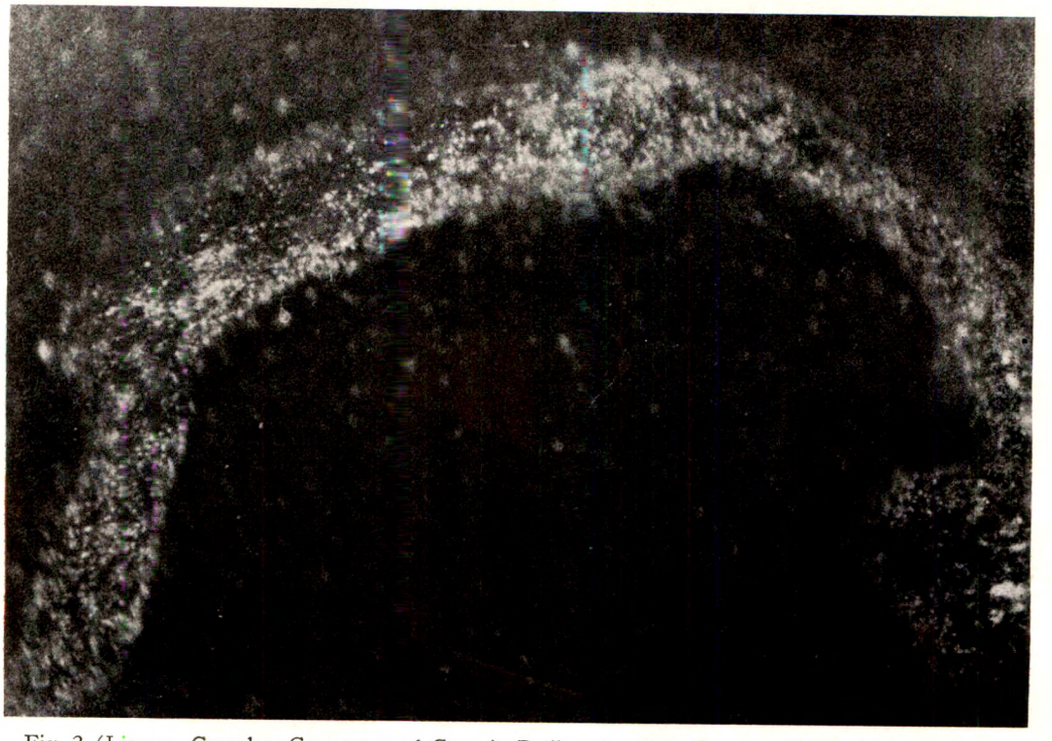

Fig. 2 (Lissner, Greenlee, Cameron, and Goren). Radioactive digitalis spread diffusely throughout the iris.

## Discussion

In his classic study of the medical uses of digitalis, Withering[1] stated that "foxglove, when given in very large and quickly repeated doses, occasions sickness, vomiting, purging, giddiness, confused vision with objects appearing green or yellow." The most common ocular symptoms of blurred vision and chromatopsia occur in 11[2] to 25%[3] of patients who develop digitalis toxicity. Less frequently, photophobia, scotomata, amblyopia, and even blindness may occur.[4]

The mechanisms by which these visual disturbances are produced are not clear. Wagener and his co-workers[5] felt that the cardiac glycosides caused a toxic effect directly upon the optic nerve. Sprague and associates[6] and Turtz[7] believed that the visual symptoms resulted from a toxic amblyopia.

Langdon and Mulberger[8] concluded that the visual disturbances arose from the cerebral cortex rather than from the optic nerve or retina. Changes in the cerebral cortex and spinal cord have been produced in cats with toxic doses of digitalis.[9]

Other investigators feel that the site of visual disturbances is the retina. Denden[10] found electroretinographic changes in a patient with visual symptoms secondary to digitalis toxicity. Gibson, Smith, and Alpern,[11] using electroretinograms, foveal photopic spectral sensitivity, and dark adaptation, concluded that digitalis acts directly upon the retina. These authors demonstrated a selective disturbance in the red-cone color system. Lufkin and his co-workers,[12] using tritiated digoxin, showed that the cat retina has a marked affinity for the drug.

Robertson, Hollenhorst, and Callahan[4] found abnormal receptor function in patients with digitalis toxicity. These same authors later found an elevation of dark adaptation in subjects maintained on non-toxic doses of long-term digitalis.[13] These elevated

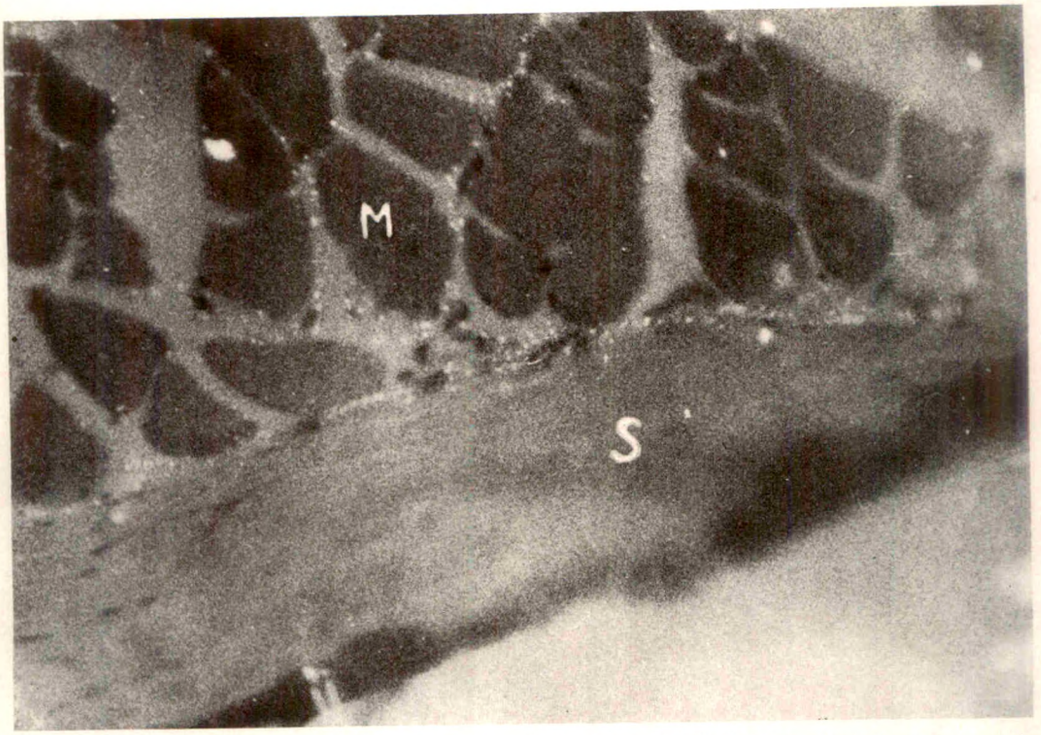

Fig. 3 (Lissner, Greenlee, Cameron, and Goren). Radioactive digitalis between the extraocular muscle bundles but not within the muscle fibers (M). The sclera (S) is free of radioactivity.

thresholds returned to normal after digitalis was discontinued. They felt that digitalis can disturb the receptor cell and interfere with the function of the visual cortex, ciliary body, and cornea.

In addition to the well-known clinical symptoms of digitalis toxicity, interest in the cardiac glycosides received great impetus when it was found that digoxin reduces aqueous humor inflow and intraocular pressure in man.[14] It was believed that digoxin exerts its effect by inhibiting the enzyme Na-K-ATPase in the ciliary body. Studies by Bonting, Simon, and Hawkins[15] revealed high concentration of Na-K-ATPase in the ciliary body in both cat and man. It was felt that Na-K-ATPase was a significant factor in aqueous humor production.[16] This enzyme is involved in active transport mechanisms. After a cell has been depolarized, Na-K-ATPase facilitates the pumping out of excess sodium ions from the cell and potassium ions back into the cell, thereby preparing the cell for further excitation.

Smith and Mickatavage[17] found that the topical application of various cardiac glycosides caused a slight decrease in intraocular pressure, but that these drugs caused a toxic keratopathy. Peczon[18] showed that systemically administered digitalis had only a small questionable effect on intraocular pressure in man. Although the cardiac glycosides have been found to be of little clinical value in the treatment of glaucoma, the research implications of these drugs in the study of aqueous humor dynamics are significant.[19]

By using both autoradiographic and scintillographic techniques in the present investigation, we are able to support the theory that digitalis causes its toxic effects by direct action upon the retina. However, unlike previous studies in which the receptor cell was considered to be the site of action, this work points to the inner layers of the retina, espe-

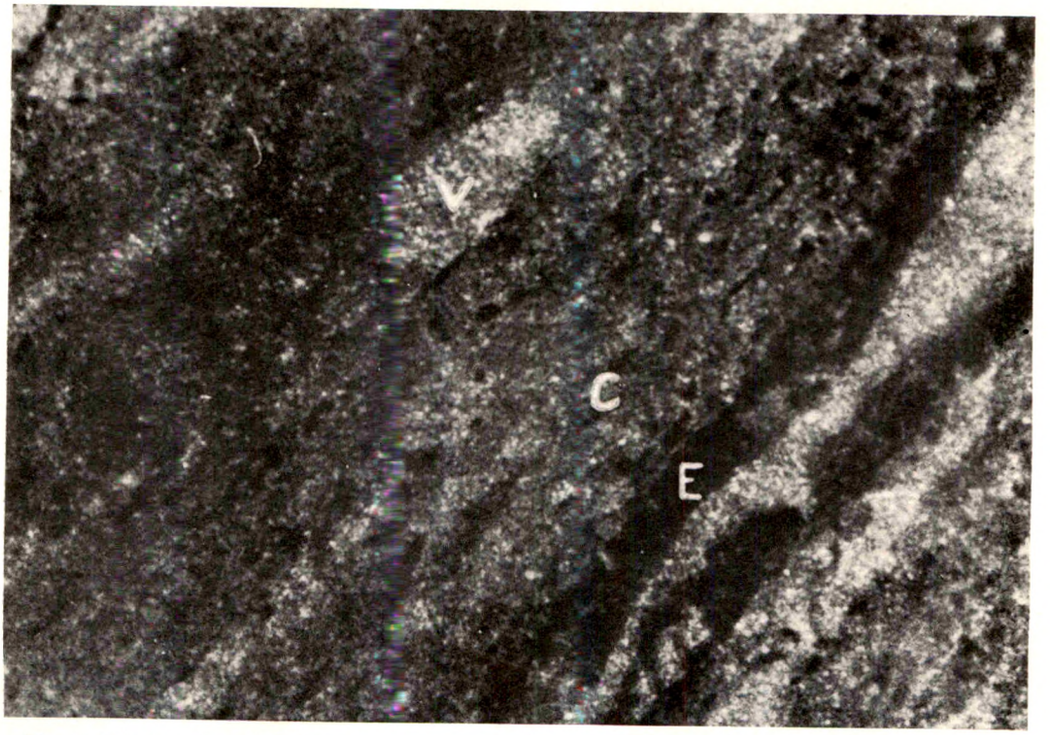

Fig. 4 (Lissner, Greenlee, Cameron, and Goren). Radioactivity throughout the conjunctiva. The epithelium (E), connective tissue (C) and vein (V) contain radioactive digitalis.

cially the ganglion cells, as the binding site of digitalis. It is true, however, that the localization of a drug in a cell does not necessarily imply that the drug acts on that specific cell. The concentration of a drug in a particular tissue is not necessarily related to its pharmacologic activity. Minimal amounts of digitalis were seen in the outer retinal layers and receptor cells. Autoradiographic studies done at varying time intervals after digitalis administration failed to demonstrate significant amounts of radioactivity in any area of the retina except the inner layers, especially the ganglion cells. While digitalis may diffuse throughout the retina, this study shows that the drug is rapidly bound to the ganglion cell. High concentrations of Na-K-ATPase have been found in the retina, especially in the rod fraction.[20] Possibly, digitalis acts by inhibiting the action of Na-K-ATPase in restoring the ionic gradients in the ganglion cell. However, an attempt to find Na-K-ATPase in the ganglion cell has not yet been successful. Further investigation is being conducted in this area.

Significant amounts of digoxin were also found in the iris. A definitive ciliary body was not found in the rat eye but iris processes were abundant. Radioactivity was found evenly dispersed throughout the iris processes and a specific cellular binding site could not be visualized autoradiographically. Lufkin and his associates[12] also found relatively high concentrations of tritiated digoxin in the ciliary body and iris of cats. These findings support the thesis that digoxin acts upon the secretory mechanisms by inhibiting Na-K-ATPase and thereby decreases aqueous inflow.

Using autoradiographic techniques, no digitalis was found in various sections of optic nerve, brain, sclera, lens, cornea, or ocular fluids. Although small quantities of digitalis were found in these tissues with scintillo-

graphic techniques, this was probably due to contamination during the microdissection.

## SUMMARY

Localization of tritium-labeled digoxin in the eye of the rat was investigated, using autoradiographic and scintillographic techniques. The iris and inner retinal layers were found to be the primary binding sites of digitalis. Negligible amounts of radioactivity were found in the outer retinal layers, brain, and optic nerve.

## ACKNOWLEDGMENT

We thank Mrs. Cleoma Smith for her technical assistance.

# METHOD OF CORRECTION OF TARSAL ECTROPION

J. H. WHITE, M.D.
*Newark, New Jersey*

The term tarsal ectropion is used by Fox[1] to describe lower eyelid eversion that is limited to the tarsal-containing portion only. It has sometimes been described as spastic ectropion, a term which, according to Duke-Elder,[2] erroneously relates its development to spasm of the marginal fibers of the orbicularis muscle and which should be reserved for those cases of ectropion occurring in young people and characterized by a facile reduction. Tarsal ectropion (Fig. 1) cannot be reinverted by manual reduction.

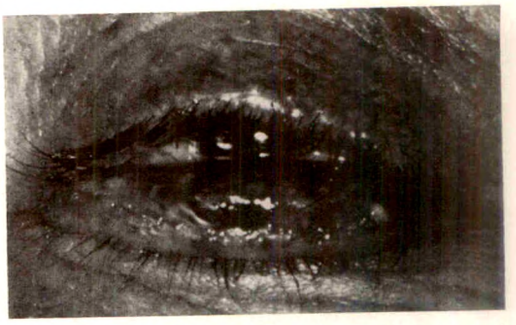

Fig. 1 (White). Preoperative appearance of tarsal ectropion.

In tarsal ectropion, Fox further observes that there is no relaxation of the tissues of the eyelid below the tarsus as in senile ectropion. Further, an actual shortage of skin appears to develop (Fig. 2). The following technique uses the skin to reinvert the tarsus.

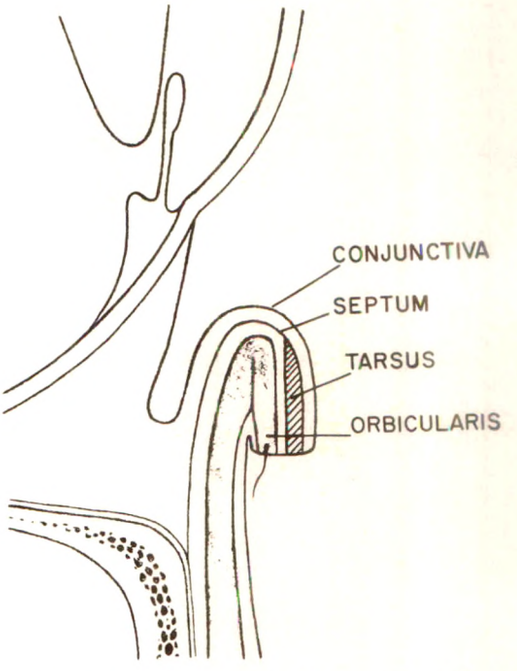

Fig. 2 (White). Diagramatic cross-section of tarsal ectropion.

## TECHNIQUE

Two traction sutures are first placed through the margin of the lower eyelid and traction is exerted in an upward direction. A horizontal incision is then made through the skin about 4 mm below and parallel to the margin of the lower eyelid, preferably in the line of a skin fold. The incision should extend over the middle two-fourths of the eyelid. The skin above and below the incision is carefully freed from the underlying orbicularis muscle (Fig. 3). It is important that adequate mobilization of the skin below the incision be obtained. Dissection is then carried upward between the folded layers of the orbicularis until the inferior border of the tarsus is reached (Fig. 4). The orbicularis is incised at this point and the inferior border of the tarsus is exposed for its entire length (Fig. 5). Three double-armed sutures of 5-0 silk are inserted horizontally in the inferior border of the tarsus, one in the midline and one to each side. The sutures are then brought out through the skin below the incision line. The distance

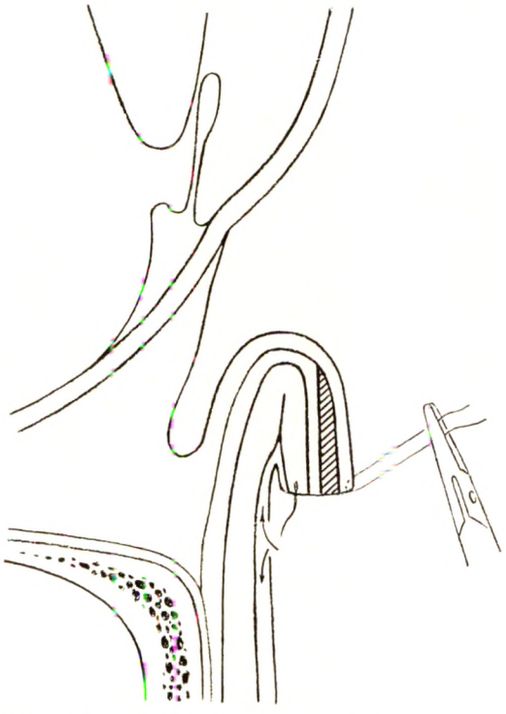

Fig. 3 (White). Skin freed from orbicularis muscle.

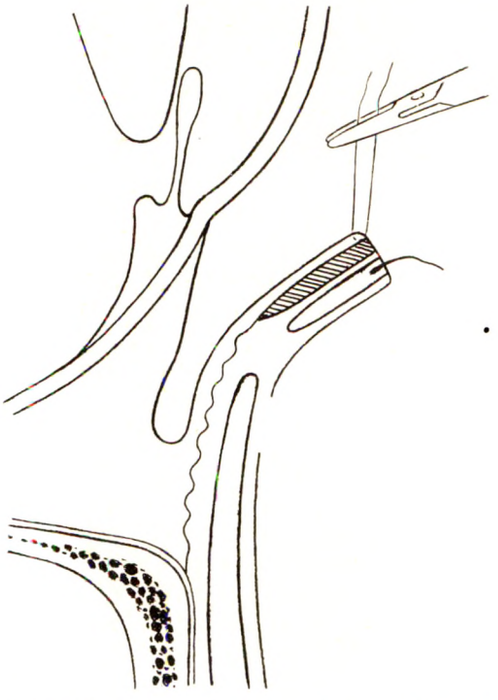

Fig. 5 (White). Lower border of tarsus dissected free.

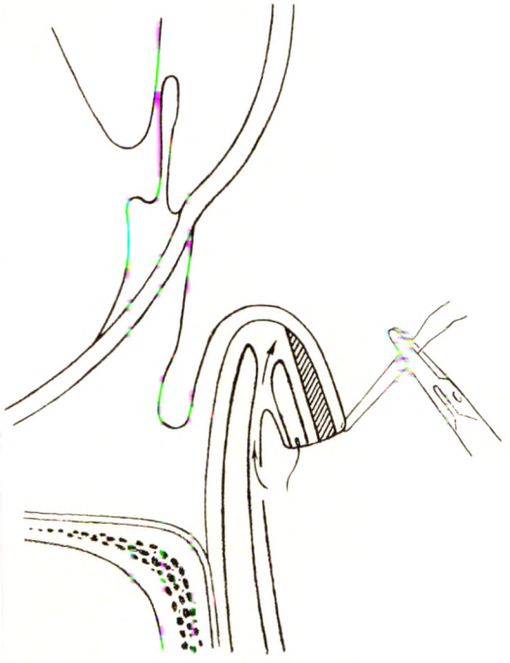

Fig. 4 (White). Incision of orbicularis to reach lower border of tarsus.

of the suture from the incision is usually about 2 mm, but this distance may be varied according to the need for inversion. Overcorrection, with consequent dragging down of the lower eyelid margin, should be avoided. Each suture is passed through a peg of rubber tubing and pulled tight (Fig. 6). Overcorrection and undercorrection can be adjusted, if necessary, by replacement of the sutures. Finally, the sutures are tied over the rubber pegs. They should be left in place for approximately 10 days. The skin incision is closed with interrupted silk sutures which may be removed after five days. The postoperative appearance after removal of all sutures is shown in Figure 7.

The result of this procedure is that the lower border of the tarsus becomes firmly attached through the opening in the orbicularis to the skin beneath the incision, thus correcting the ectropion.

Eight such procedures have now been performed, with satisfactory reinversion of the

tarsus in all. In one case residual horizontal eyelid laxity required bilateral correction by the Kuhnt-Szymanowski procedure. In another case residual eyelid laxity was corrected at the time of the original surgery by a modified Szymanowski procedure. This was achieved by extending the horizontal skin incision 2 cm in an upward and lateral direction and then making a downward vertical incision in the usual manner.

## Discussion

Procedures such as the Kuhnt-Szymanowski operation which exert their effect by horizontal shortening of the eyelid do not correct advanced cases of tarsal ectropion where the defect is in a vertical direction. They may even make the ectropion worse by fixing the tarsus more tightly in its everted position.

Shortening of the orbital septum would appear to be one logical approach to the problem. Jones and associates[3] describe a method of tucking the orbital septum for the correction of senile entropion. In one case of tarsal ectropion, satisfactory inversion was obtained by this method, but the lower eyelid was drawn down well below the normal position. This result appears to be the result of failure to resolve the problem of lack of skin in the lower eyelid.

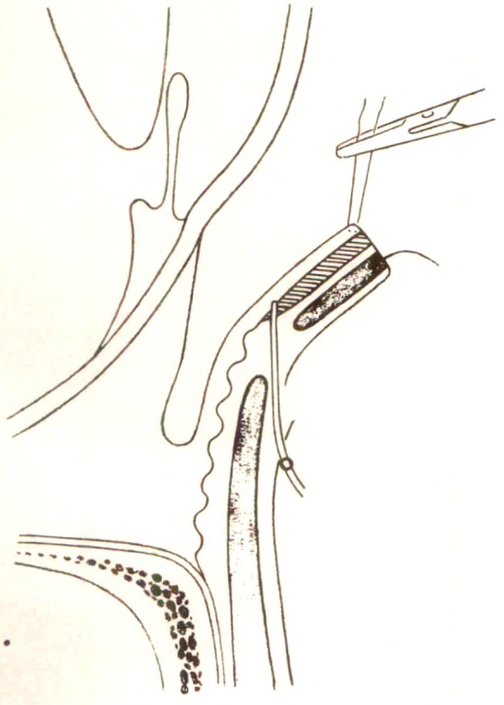

Fig. 6 (White). Insertion of sutures through tarsus and skin.

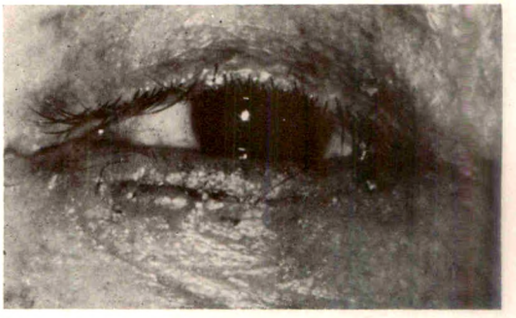

Fig. 7 (White). Postoperative appearance 10 days after surgery.

The technique described earlier is an extension of the Snellen suture technique.[4] It transfers the pull of the skin from the upper margin of the tarsus to the anterior lower border. This reinverts the tarsus around its horizontal axis through the medial and lateral palpebral tendons. Any further downward pull of the skin holds the tarsus in its vertical position.

## Summary

To correct tarsal ectropion, the lower edge of the tarsus is exposed through a horizontal skin incision. This edge is sutured to the skin below the incision. Subsequent downward pull of the skin reinverts the tarsus.

# GOLDENHAR'S SYNDROME AND PHOCOMELIA

## Case Report and Etiologic Considerations

M. S. Mandelcorn, M.D., S. Merin, M.D., and J. Cardarelli, M.D.

*Toronto, Canada*

Goldenhar's syndrome,[1] in which epibulbar dermoids are associated with ear abnormalities, is one of four syndromes in which congenital malformations that involve the eye result from an abnormal development of the first, or first and second, branchial arches.[2] The others are Franceschetti-Klein (Treacher Collins), and the Pierre Robin, and Hallerman-Streiff syndromes. Although sometimes showing a few manifestations seen in Franceschetti-Klein's syndrome, which is a dominantly inherited condition, Goldenhar's syndrome is an entirely distinct clinical entity.[3-9] In all cases Goldenhar's syndrome is sporadic and nonfamilial; its etiology is unknown.

This paper describes the occurrence of phocomelia in a patient with Goldenhar's syndrome, an association not previously reported. The features of this case are presented in detail in an attempt to throw some light on the etiology of the syndrome.

### Case report

The patient, a boy, was first admitted to the Hospital for Sick Children, Toronto, at the age of two and one-half years for investigation of skeletal malformations and recurrent vomiting. His mother, was 21 years old at the time of his birth. In the seventh week of gestation, unaware that she was pregnant, the mother had developed abdominal pains, nausea, and vomiting for which she had taken three pills thought to be Midol (acetyl salicylic acid, phenacetin, caffeine, and cinnamylephedrine). A few days later she was treated for a threatened abortion, but the pregnancy continued. In the 10th week she had an appendectomy. The operation was without complication, and the rest of the pregnancy was uneventful; the patient was born at term and delivery was normal.

On admission the child was alert and intelligent, of average height and weight for his age. His right arm consisted of a hypoplastic humerus, short ulna, three metacarpals, and two fingers. His left arm consisted of a normal humerus, short ulna, four metacarpals, and four fingers (Fig. 1). On the right side of the face he had a preauricular skin tag, atretic external ear canal, and poorly formed pinna (Fig. 2). He had a grade I presystolic murmur at the left sternal border.

Eye examination revealed a fleshy, yellowish tumor of the bulbar conjunctiva of the right eye and a coloboma of the right upper eyelid.

The chromosome pattern was normal male (46XY) and routine laboratory tests on blood and urine gave normal results. Spinal roentgenograms showed a spina bifida; an intravenous pyelogram demonstrated hypoplasia of the left kidney and a normal right kidney; and an upper gastrointestinal series revealed partial obstruction of the third stage of the duodenum. Exploratory laparotomy showed a partially annular pancreas, incomplete rotation of the cecum, and a partial duodenal stenosis. In order to relieve the partial obstruction of the small bowel, a duodeno-duodenostomy was performed.

Surgical treatment of the eye lesions was postponed because of the surgery on the small bowel.

At the age of five years the boy was readmitted for treatment of his eye problems. His general clinical condition was unchanged. His visual acuity was 20/30 in the right eye (refractive error +1.50 sph. ⊃ +3.50 cyl. ax. 110) and 20/20 in the left (refractive error +1.00). The corneal diameters were 10.0 mm in the right eye and 10.5 mm in the left. A fleshy, yellowish, noncystic mass involved the lower half of the temporal bulbar conjunctiva of the right eye and barely encroached on the limbus (Fig. 3). The coloboma of the right upper eyelid was unchanged (Fig. 4), and further examination revealed no other ocular abnormality. At operation the conjunctival tumor was totally excised.

### Discussion

The patient described in the original article by Goldenhar[1] had epibulbar dermoids, accessory auricular appendages, and a congenital auricular fistula, anomalies resulting from faulty development of the first and second branchial arches and the first branchial cleft. Other manifestations of the syndrome include coloboma of the upper eyelid, anti-

mongoloid slant of the palpebral fissures, microphthalmos, microcornea, coloboma of the uvea, hypoplastic upper and lower jaw, microtia, and macrostomia.[10] In the 50 or so reported cases of Goldenhar's syndrome, however, several malformations are also described that involve structures other than those derived from the branchial arches. Anomalies of the cervical vertebrae, for example, are so common that Goldenhar's syndrome is often called the oculo-auriculo-vertebral dysplasia.[3,11] Other systemic, skeletal, neurologic and cardiovascular anomalies occur, including Duane's syndrome,[12] heart disease,[11,13] cleft palate,[11] mental retardation,[11,14] hydrocephalus, meningoencephalocele,[15] and B-group chromosomal disorder.[14]

The broad nature of the syndrome is espe-

cially well illustrated in the present case, where the patient not only had the typical eye and ear anomalies leading to the diagnosis of Goldenhar's syndrome, but also had phocomelia, renal hypoplasia, a partially annular pancreas, incomplete rotation of the cecum, and duodenal stenosis. These findings emphasize that in the management of every case of Goldenhar's syndrome one must suspect and search for the presence of other systemic malformations.

Broadening the view of Goldenhar's syndrome to admit the generalized malformations is important with regard to the etiology. To date, those authors who consider Goldenhar's syndrome solely as a branchial arch malformation have come to no definite conclusions about etiology. Only three authors have suggested possible causes, despite the many cases reported. Smithells[13] reported a case of Goldenhar's syndrome in which the patient's mother had developed influenza in the sixth week of gestation. Ladekarl[14] reported on the occurrence of Goldenhar's syndrome in a patient whose mother had had a cholecystogram in the fourth week of gestation. In the case reported by Zweymüller and Stur,[16] the patient's mother had had rubella in the eighth week of pregnancy. Our case leads to the hypothesis that the etiologic agent was active during the seventh week of gestation—that is, when the patient's mother suffered from the abdominal pains and the threatened abortion and also ingested the three pills. This hypothesis of an external agent acting on the embryo during the seventh week of gestation can easily account for all the malformations seen in our patient—the ocular and external ear defects, the phocomelia, the renal atrophy, and the duodenal stenosis—because the development of all the affected structures normally occurs in the embryo at the same time, the seventh week. The branchial arches involved in Goldenhar's syndrome appear in the sixth week of gestation, but disappear by the eighth week when their derivatives, such as the ear, face, and eyelids, have differentiated. Similarly, in the sixth week, when the intestinal loop enters into the umbilical cord, the duodenal epithelium proliferates to occlude the lumen until the eighth week, when vacuolation restores a continuous lumen. By the seventh week, also, the metanephros has formed and the upper arm, forearm, and hand have separated from the trunk.[17] Clearly, one agent acting during the seventh week could easily have caused all the malformations seen in the present case.

Fig. 4 (Mandelcorn, Merin, and Cardarelli). The right eye of the patient at five years of age, showing a notching of the right upper eyelid.

The main skeletal abnormality in our patient was phocomelia, a malformation typically seen in "thalidomide babies." Even though those cases of phocomelia described before the thalidomide period were never associated with ocular abnormalities,[18] we cannot neglect the possibility that in the present case thalidomide was the cause of the phocomelia and the Goldenhar's syndrome. The case history, however, did not record any ingestion of thalidomide; and, although thalidomide does produce ocular abnormalities, Goldenhar's syndrome has never been described in thalidomide-damaged children.

We believe that in this case Goldenhar's syndrome was caused by a noxious agent active during the seventh week of gestation. What this teratogenic factor was, we cannot be sure. It might have been the same agent that caused the threatened abortion. It might have been the drug which the mother ingested, whether this was a mixture of acetyl salicylic acid, phenacetin, caffeine, and cinnamylephedrine as claimed, or thalidomide, as might be suspected from the phocomelia. It might have been a virus as suspected in Smithells'[13] and Zweymüller and Stur's[16] cases. Whatever the agent might have been, our findings imply that it acted on the embryo during the seventh week of development.

## Summary

Goldenhar's syndrome, associated with phocomelia and intestinal and renal malformations, was seen in a two and one half year old boy. In the seventh week of gestation the mother had ingested an analgesic drug for abdominal pains, and this was followed by a threatened abortion. The concept is advanced that Goldenhar's syndrome consists of a group of generalized rather than localized malformations, and it is suggested that Goldenhar's syndrome is caused by an external teratogenic agent acting in the seventh week of embryogenesis.

# A TECHNIQUE FOR VISUAL APPRAISAL OF MENTALLY RETARDED CHILDREN

LAWRENCE J. LAWSON, JR., M.D., AND GREG SCHOOFS, M.D.
*Evanston, Illinois*

Because of their intellectual handicap, it is of utmost importance that visual deficiencies of retarded children be recognized and corrected to provide maximum potential for learning. Unfortunately, many of these children have never had a visual examination; further, if one is performed, reliable data may be difficult to obtain. The child may be difficult to deal with, and frequently the ophthalmologist does not have a satisfactory method of examination in this situation. In working with a group of children with mental handicaps, we developed a practical system for their visual evaluation which we have described in this paper.

## METHODS

A group of 103 day students was examined from the Orchard School for mentally handicapped children in Skokie, Illinois. These students, whose mental retardation resulted from various causes (Table 1), ranged in age from three to 22 years; each child's intelligence quotient was 60 or less. The school nurse devised a routine for familiarizing the students with the general procedure to be used in the examination. This resulted in a definite reduction of apprehension and permitted the children to be more cooperative, thus allowing a more thorough and accurate appraisal. The tests were performed in the Eye Clinic of Evanston Hospital at a time when other activities were not scheduled in order to provide a quieter and less disturbing environment. Each child was examined alone, with the nurse from the school in attendance for identification and reassurance. Because these children generally have a short attention span and are easily distracted, the test procedures were performed rapidly. When a test proved beyond the comprehension of a child, it was eliminated and the next procedure presented.

The initial approach was a general appraisal of the eyes and adnexa. Visual acuity was then recorded. Lippmann[1] has stated that young children do not have the concept of direction and therefore the illiterate "E" is usually unreliable. He also reported that these children require identification of one symbol at a time. These statements were confirmed in our study. "Pictographs" utilizing symbols familiar to children, as devised by Allen,[2] were attempted, but these children were unable to recognize these symbols and so another method was developed. We attempted the use of the Stycar test,[3,4] which employs cut-out symbols placed on a table to be matched with similar objects at a distance. This system did not prove successful because children with mental retardation frequently do not comprehend the concept of "likeness" or similarity.

Since most of the children could recognize food items (and often no others), selected items from the Peabody series[5] were photo-

From the Departments of Ophthalmology of Evanston Hospital and of Northwestern University Medical School. This work was supported by a grant from the Ben Levin Memorial for Retarded Children.

graphed in color to provide a series of 2×2 slides to be used with a projector. Because of the resolution of the projected picture, smaller symbols could not be satisfactorily reproduced. We therefore designed a wall chart printed in color using the food items, (apple, banana, "hot dog," and ice cream cone) calibrated for the standard 20-foot distance.* Each symbol can be framed by an adjustable framer to stimulate attention. This method proved successful in a high percentage of cases. (Fig. 1)

* The chart used in this study may be ordered as "Apple Chart" from Medical Contact Lens Service, 1225 Circle Tower, Indianapolis, Indiana 46204.

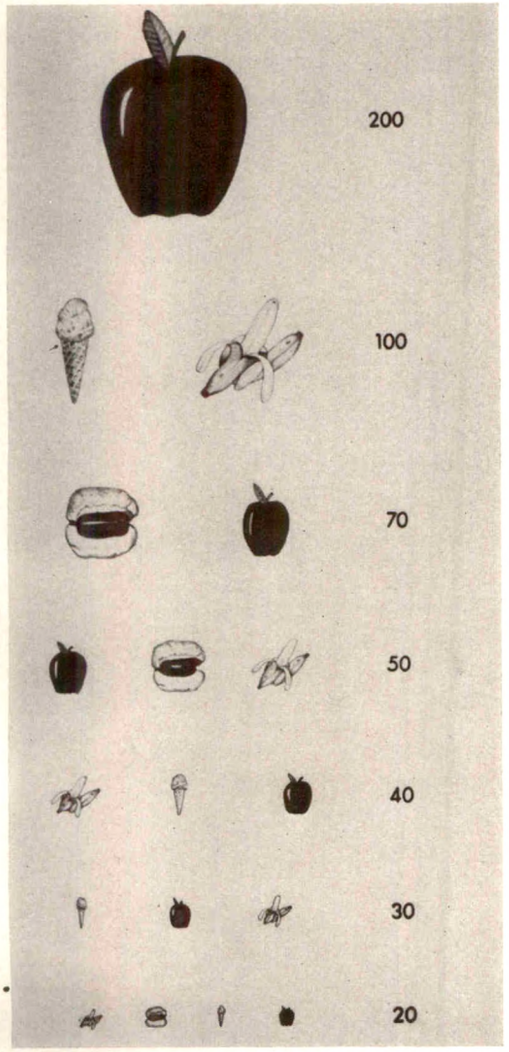

Fig. 1 (Lawson and Schoofs). Wall chart, printed in color and calibrated for the standard 20-foot distance, devised to test mentally retarded children.

Ocular muscle coordination and the fusion status were then ascertained when possible, utilizing the Worth 4-dot, the Maddox rod and the Wirt Stereotest. Prism cover tests were also used. All of the children had retinoscopy performed under cyclopegia. The use of the refractor or trial frame was generally too frightening to the child. Therefore, either the loose lenses or the Foster retinoscopy rack was used; these methods were preferred because of their rapidity, and a fairly accurate measurement was possible in the majority of cases. The ocular fundi were examined for defects by indirect ophthalmoscopy, which proved to be vastly superior to the direct method because it enabled us to perform the examination without touching the child.

## RESULTS

With the system described above, we were able to determine the visual acuity of a significant number of this group of mentally retarded children. (Table 2) Unfortunately, there remain some children for whom no system yet devised is satisfactory. In our series there were 18 children who initially had less than 20/70 uncorrected vision in their better eye (sight-saving cut-off level), 15 of whom could be corrected to better acuity. These children had not previously been identified as having visual problems. Only 28% of our children were considered to be ophthalmologically normal, whereas in a general school population approximately 75% are usually found to be without visual motor or sensory difficulties.

A total of 44 children had significant re-

fractive errors (Table 3). In 25 of these the visual defects were unknown to the school or to the parents, and required corrective lenses. There were 19 children who were already wearing glasses, nine of whom needed significant changes in the power of their spectacles.

There were 33 of the 103 children who had some degree of ocular muscle imbalance (Table 4). This incidence is almost 10 times that of a normal population of this age group. There were nine students with an amblyopic eye who had never received treatment, and the majority of the parents had no previous knowledge of the condition. There were 18 with definite esotropia and four with significant esophoria. Six children had a constant exotropia, and four had an intermittent exotropia. Two children had had previous eye surgery.

## CONCLUSIONS

The results of our study demonstrate the need for an ophthalmic appraisal of the mentally retarded child. These children have a high incidence of visual defects which may influence their level of functioning, especially in a learning situation. The need for treatment of a visual defect must be individually determined and the school alerted to the special problems and visual needs of the child.

## SUMMARY

A group of 103 mentally retarded children varying in age from three to 22 years were examined for visual difficulties. Because of the inability to determine the visual acuity in many of these children by any available technique, a chart was designed utilizing food items printed in color and calibrated for the standard 20-foot distance. By this method, a substantial number of children can be added to those in whom the visual acuity can be determined. Only 28% of our children were considered ophthalmologically normal as contrasted to the approximately 75% in a normal school population. Among other ocular findings, 44 had significant refractive errors, 33 children were found to have ocular muscle imbalance, and there were nine students with an amblyopic eye.

# BLEPHAROPTOSIS, BLEPHAROPHIMOSIS, EPICANTHUS INVERSUS, AND TELECANTHUS—A SYNDROME WITH NO NAME

ROGER KOHN, B.A., AND PAUL E. ROMANO, M.D.
*Chicago, Illinois*

Over the past 50 years, there have been numerous reports[1-32] of the triad of blepharoptosis, blepharophimosis, and epicanthus inversus. The consistency of the triad and its hereditary background make it a true clinical syndrome, and yet it has escaped both collation and appellation over the years.

This paper presents a collection and comparison of all cases previously reported. We think these illustrate that a fourth finding, telecanthus, is so consistent that it should be added to the triad. A family with this syndrome and several associated features not previously described is also reported.

In 1921, Komoto[4] described the first case with the triad, a patient who had, in addition, wide set eyes, ectropion, excessive brow hair, and hypoplasia of the caruncle and plica semilunaris. Three unspecified relatives of this patient were reported to have the same disorder.

Later that same year, Dimitry[6] reported a family with "blepharophimosis." He did not specify other findings, but from the photographs accompanying his report, it appears that this family had the complete triad. Dimitry did, however, trace the pedigree of the "blepharophimosis," which is the first and longest (after revision by Owens in 1960) pedigree of this syndrome (Fig. 1). In this pedigree, the syndrome appears in both sexes and is transmitted as a Mendelian dominant characteristic. This mode of inheritance is now well documented.

Since these early descriptions, 125 additional cases were reported. Of these, 12 were male, six were female, and in 107, sex was unspecified. A familial association appeared in 37, while two were definitely nonfamilial; in the remaining 86 cases, the possibility of familial association was not specified.

The three primary features of this syndrome are reported or evident in all cases. These findings tend to accentuate one another—their total effect is to constrict the palpebral fissure by reducing it in both height and width.

Numerous other findings are reported which are either compensatory responses or coexistent deformities. The levator palpebrae superioris is markedly hypoactive and fibrotic.[8,9] There is also a hypoplasia of the tarsal plates of the upper eyelids.[8,10,12] To compensate for the blepharoptosis, these patients assume a characteristic posture with the head tilted backward and the chin arched upward. The eyelids are covered by remarkably smooth skin without eyelid folds.[13,21] Several authors found deficient amounts of skin in both eyelids at surgery.[14,15] Vertically increased eyebrow width has been observed [12,14,15] and is attributed to a stretching of hair-bearing skin with constant contraction of the frontalis muscle. There are two changes associated with the epicanthus inversus—an increased length of the medial canthal ligament[10,16,17,30] and a lack of the normal depression seen at the internal canthus.[12,18] The caruncle and plica semilunaris are secluded to varying degrees beneath the epicanthal fold and usually have a hypoplastic appearance.

Abnormalities of the eyelid margin are frequently seen. The upper margin is characteristically S-shaped,[12,16,30] while the lower margin has a concavity downward, particularly in the lateral aspect, with or without slight ectropion.[4,12,16,17,30] Two authors found an inequality in the lengths of the upper and lower eyelids when measured at

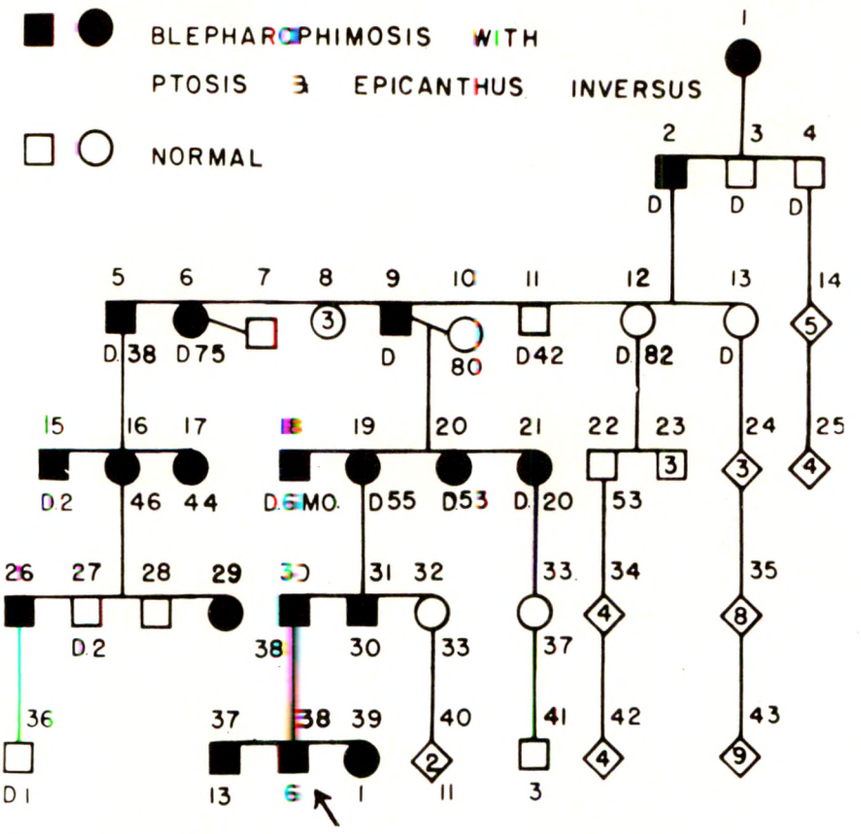

Fig. 1 (Kohn and Romano). Dimitry's original pedigree after revision by Owens.[12]

their margins.[7,10] Trichiasis was present on several occasions.[9,11]

The lacrimal system is often affected. Numerous reports describe a lateral displacement of the lower punctum, and two authors also describe a medial displacement of the upper punctum.[13,17] Other variations such as stenosis of all canaliculi,[17] elongation of the horizontal canaliculi,[7,10] and punctal reduplication[7,17] are noted.

Microphthalmos is described by one author,[19] and there are two reports of divergent strabismus and nystagmus.[26,31] As in simple blepharoptosis, underaction of the superior rectus and limitation of upward gaze are often found in this syndrome. No other muscle deficits are reported, with the exception of the inferior rectus—represented by limitation of downgaze.[20] Visual disturbances and amblyopia are considered uncommon.[10,30]

Several deformities of the facial bones are often seen in association with this syndrome. Many authors describe the root of the nose as being flat and broad, while one author also note a boney deficiency in the supraorbital rim and brow.[14] There are two isolated reports of a high arched palate.[11,12] Additionally, one study recorded 10 cases with "lop ears" (i.e., ears with an overhanging helix).

In contrast to their somewhat obtunded appearance, the mental status of individuals with this syndrome is usually normal, but some develop secondary psychological problems as a result of their cosmetic handicap.[18,15]

The hereditary pattern of this entity is well documented.[4-6,8,10-13,21,26,31] It is nor-

mally transmitted as an autosomal dominant with essentially 100% penetrance. Although seen in both sexes, it occurs more commonly in the male and is expressed more commonly through the male. Pedigrees have been recorded in eight families. All chromosome studies have been negative and a metabolic anomaly has not been discovered.

The surgical management of this condition is well covered in the current literature, and is beyond the scope of this paper.[7,9,10,16,18,22,25,35] Surgery should be undertaken early enough to prevent deprivation amblyopia, a possible sequela of severe blepharoptosis.

Throughout the literature the syndrome is constantly described as a triad consisting of blepharoptosis, blepharophimosis, and epicanthus inversus. We feel it should be considered a tetrad since telecanthus is also invariably present.

The term, telecanthus, was originated and defined by Mustardé[7,25] as an increased distance between the internal canthi. In primary telecanthus, this increase is clinically apparent, but there is no true hypertelorism (i.e., no radiologic evidence of increased distance between the orbits). Secondary telecanthus is an increased distance in the presence of true hypertelorism.

In virtually every case report reviewed, the triad was reported in association with either "increased intercanthal distance," "hypertelorism," "pseudohypertelorism," "increased distance between the eyes," or else such an increase in distance between the eyes was apparent from photographs. Since telecanthus is always present in hypertelorism (according to Mustardé[7]) and is synonymous with increased intercanthal distance, telecanthus may be said to have been present in all cases and the syndrome should be defined as a tetrad including it.

## Case reports

A family demonstrating this syndrome was recently seen at Children's Memorial Hospital Eye Clinic of Northwestern University. We examined three of these children, brothers, and obtained the pedigree from their unaffected mother. Our pedigree (Fig. 2), comprising four generations, consists of 30 individuals (19 males and 11 females). Sixteen of the 30 are affected (12 males and 4 females), closely approaching the classical 50% ratio of an autosomal dominant characteristic.

*Case* 1—This eight-year-old white boy (Figs. 3-5) was noted to have "small eyes" at birth. His condition is unchanged, but the family has consis-

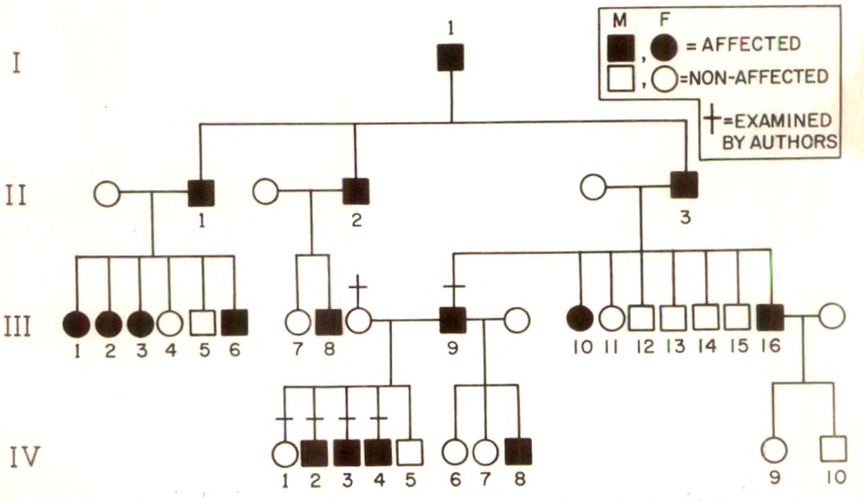

Fig. 2 (Kohn and Romano). Pedigree of the propositi through four generations.

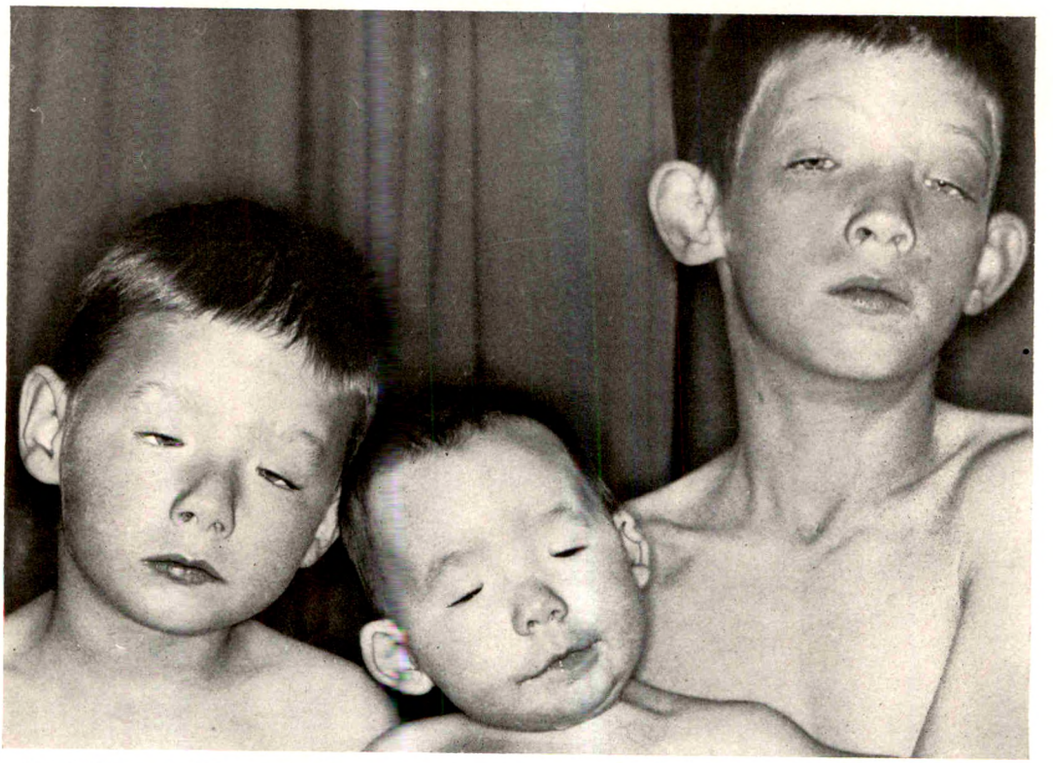

Fig. 3 (Kohn and Romano). Photographs of the three propositi in 1963 (left to right: Case 2, Case 1, and Case 3) at the ages of five, one, and 11 years, respectively.

Fig. 4 (Kohn and Romano). Photographs of the three propositi in 1970 (left to right: Case 2, Case 1, and Case 3) at the ages of 12, eight, and 17 years, respectively.

tently refused surgery. Best corrected visual acuity is RE: 20/200, LE: 20/50 (RE: +2.00 sph.⊃+2.00 cyl. ax. 95° and LE: +2.50 sph.⊃+1.75 cyl. ax. 90°). Blepharoptosis, blepharophimosis, epicanthus inversus, and telecanthus are present bilaterally and symmetrically. The blepharoptosis is severe, as the upper eyelid crosses the cornea at the lower third of the pupil (in primary position) and levator action is essentially absent (with frontalis immobilized). No eyelid folds are apparent, the tarsal plates feel moderately hypoplastic, and the skin overlying the upper eyelids is smooth and somewhat atrophic. Both eyebrows show increased vertical width. Blepharophimosis is evidenced by a narrowing of the palpebral fissure, both horizontally and vertically (even when frontalis action is maximal). Both caruncle and plica semilunaris are hypoplastic and secluded beneath the epicanthus inversus fold. Telecanthus is clinically present, although the interpupillary distance is unremarkable at 49 mm. The upper eyelid margins assume an S-shape, but the lower eyelid margins are essentially normal. The puncta are normal in appearance and abnormal in location—the lower displaced laterally with respect to the upper which appears displaced medially. The nasal bridge is flat, but bone structure is normal at the supraorbital rims and brows. Both corneal diameters are 10 mm without other evidence of microphthalmos. An esotropia of 20 diopters for near and distance is noted by the Hirshberg and Krimsky tests, along with horizontal endpoint nystagmus. A limitation of duction is present in the field of action of both superior recti, while there is overaction of both inferior obliques. Fundi are entirely normal. There are two additional striking characteristics—a high arched palate and low set ears with deformed pinnas (cupped ears). The child's mentality and school performance are appropriate for his age.

Fig. 5 (Kohn and Romano). Case 1.

Fig. 6 (Kohn and Romano). Case 2.

*Case* 2—This 12-year-old white boy (Figs 3, 4, and 6) was also noted to have "small eyes" since birth. Surgery is consistently refused by the family. Best corrected visual acuity is RE: 8/200, LE: 20/70 (RE: −7.00 sph⊃+1.50 cyl. ax. 180° and LE: −5.50 sph.⊃+2.00 cyl. ax. 180°). Blepharoptosis, blepharophimosis, epicanthus inversus, and telecanthus are again bilateral and symmetrical. The blepharoptosis is less severe than in Case 1, as the upper eyelid crosses the cornea at midpupil, but levator action is essentially absent. No eyelid folds are apparent, the tarsal plates feel moderately hypoplastic, and the skin overlying the upper eyelids is smooth and somewhat atrophic. Both eyebrows show increased vertical width. Blepharophimosis is evidenced by a narrowing of the palpebral fissure, both horizontally and vertically (even when frontalis action is maximal). The epicanthus inversus is less prominent than in Case 1 with a hypoplastic caruncle and normal plica secluded below. Telecanthus is present, but the interpupillary distance is again unremarkable (54 mm). The eyelid margins are of normal contour, in contrast to Case 1. The puncta appear normal, but the lower is displaced laterally with respect to the upper, which is in relatively normal position. The nasal bridge is flat, but bone structure is normal at the supraorbital rims and brows. Both corneal diameters are 11 mm. An esotropia of 20 diopters is again noted by the Hirshberg and Krimsky tests along with horizontal end-point nystagmus. Both superior recti demonstrate limitation of duction, while both inferior obliques are overactive. This patient demonstrates colobomas of both optic disks. As in the previous case, the palate is high arched, but no ear deformities are present. Mentality and educational performance are normal.

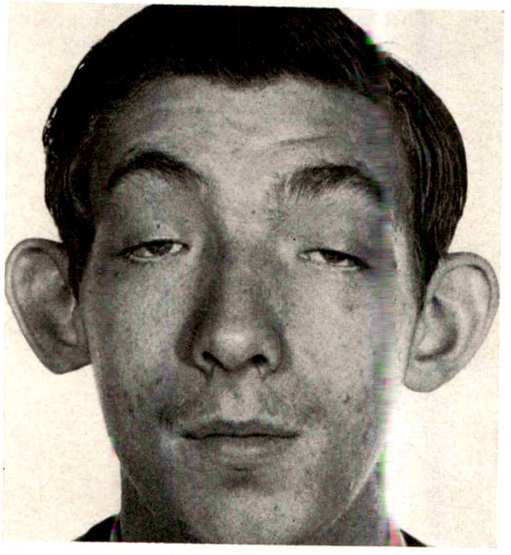

Fig. 7 (Kohn and Romano). Case 3, utilizing the frontalis to raise eyelids.

*Case* 3—This 17-year-old white boy (Figs. 3, 4, 7, and 8), the eldest of these three brothers, was also known to have "small eyes" since birth, and surgery has been refused. Visual acuity is RE: 20/20, LE:20/40, unimproved by refraction or pinhole. Blepharoptosis, blepharophimosis, epicanthus inversus, and telecanthus are bilateral and symmetrical, but the epicanthus is minimally prominent and its inverse character is recognizable only on close inspection. The blepharoptosis is less severe than in Case 1, as the upper eyelid crosses the cornea at midpupil, but levator action is essentially absent. No eyelid folds are present, the tarsal plates are only slightly hypoplastic, and the skin overlying the upper eyelids is smooth and atrophic. Both eyebrows show increased vertical width. Blepharophimosis is evidenced by a narrowing of the palpebral fissure, both horizontally and vertically (even with maximal frontalis action). Both caruncle and plica are moderately hypoplastic and secluded beneath the epicanthus inversus fold. Telecanthus is present along with an interpupillary distance of 67 mm. The upper eyelid margins are S-shaped, but the lower eyelid margins are unremarkable. The puncta appear normal with the lower displaced laterally and the upper displaced medially. The nasal bridge is flat, but bone structure is normal at the supraorbital rims and brows. Both corneal diameters are 11 mm. The patient is orthophoric, but does demonstrate some limitation of duction of both superior recti. No end-point nystagmus is evident. On ductions, the blepharoptosis of each eye is moderately accentuated as that eye is adducted. The fundi of both eyes are normal with the exception of a localized area of pallor inferiorly on the right optic disk. This may represent another coloboma, but it is not as classic as those seen in Case 2. The palate is high arched and the ears are low set with deformed pinnas (cupped ears). Mentality and educational performance are normal.

## Discussion

All three cases demonstrate blepharoptosis, blepharophimosis, epicanthus inversus, telecanthus, and many of the previously reported features associated with the syndrome. In addition, they present several findings not previously reported. These include esotropia with overaction of the inferior obliques, colobomas of the optic disk, and low set, "cupped" ears.

Because of the prominent epicanthus inversus, this syndrome manifests an apparent esotropia. Actually, in Cases 1 and 2, true esotropia does exist along with overacting inferior obliques.

Colobomas of the optic nerve heads are present in Case 2. They are estimated to be 1 mm in diameter (two-thirds of a disk diameter) and appear bilaterally and symmetrically. This may be a factor in this patient's markedly depressed vision in both eyes.

The low set, "cupped" ears are unique features in Cases 1 and 3. In both these pa-

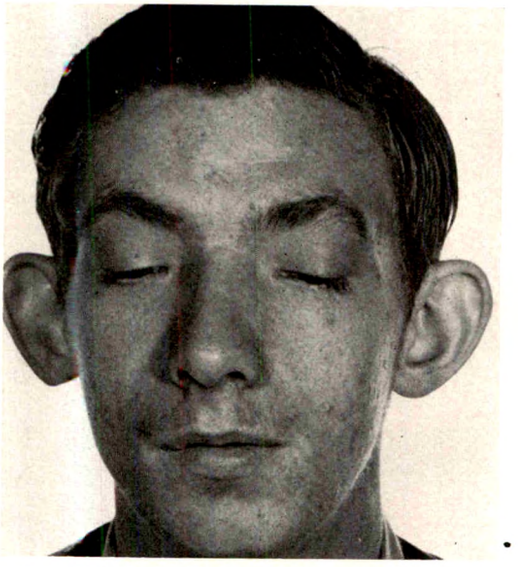

Fig. 8 (Kohn and Romano). Case 3. Note severity of blepharoptosis when patient voluntarily relaxes frontalis.

tients, the ears protrude at right angles from the side of the face, and should be distinguished from "lop ears" which are essentially normal in form, but with the helix folded back upon itself.

Visual deficits, although previously reported, are uncommon and rarely marked. Yet, all three of these cases show some visual loss.

It is not possible to pinpoint a precise cause for the visual loss in each eye because a variety of abnormalities are present which may explain it. In Case 2, for example, the depressed acuity in the right eye is probably due to strabismic amblyopia. But this visual loss may also be due to deprivation amblyopia from blepharoptosis, refractive amblyopia (glasses have not been worn regularly), or anisometropic amblyopia (spherical equivalent difference of 1.75 D.). The boy also has colobomas of the disks of both eyes and small corneal diameters which may contribute to the visual deficiency. Similar factors are present in the other cases as well. Further diagnostic studies are planned to elucidate the causes of these visual deficiencies.

## Summary

The syndrome of blepharoptosis, blepharophimosis, and epicanthus inversus includes many associated anomalies. Chief among these is telecanthus, which is so consistent an association that the disorder should be considered a tetrad including it. The syndrome is inherited as an autosomal dominant with essentially 100% penetrance. To the 125 previously reported cases three more are added, each with unique features—esotropia with overaction of the inferior obliques, colobomas of the optic disk, and low set "cupped" ears.

### Acknowledgment

We thank Dr. David E. Shoch for his comments and advice and Drs. Joseph Alfano, Mary Kaper and Robert Wertz for bringing this family to our attention.

## Ophthalmic miniature

State Attorney General Louis J. Lefkowitz charged yesterday that an oral test of reasoning "used to select steamfitting apprentices was discriminatory . . ." and that the test had no relation to the skills required in the trade. The Attorney General cited the following illustrations of questions that were put to candidates: (1) What is the relationship of Shakespeare to Othello? (2) What is Brahms to music and Whitman to poetry? (3) How can the relationship of a stag to a doe be compared with that of a ram to an ewe? (4) What is the relationship of Dante to the Inferno?

# IRIS HEMANGIOMA AND ABNORMAL RETINAL VASCULATURE IN A CASE OF DIFFUSE CONGENITAL HEMANGIOMATOSIS

MICHAEL A. NAIDOFF, M.D., KENNETH R. KENYON, M.D., AND W. RICHARD GREEN, M.D.

*Baltimore, Maryland*

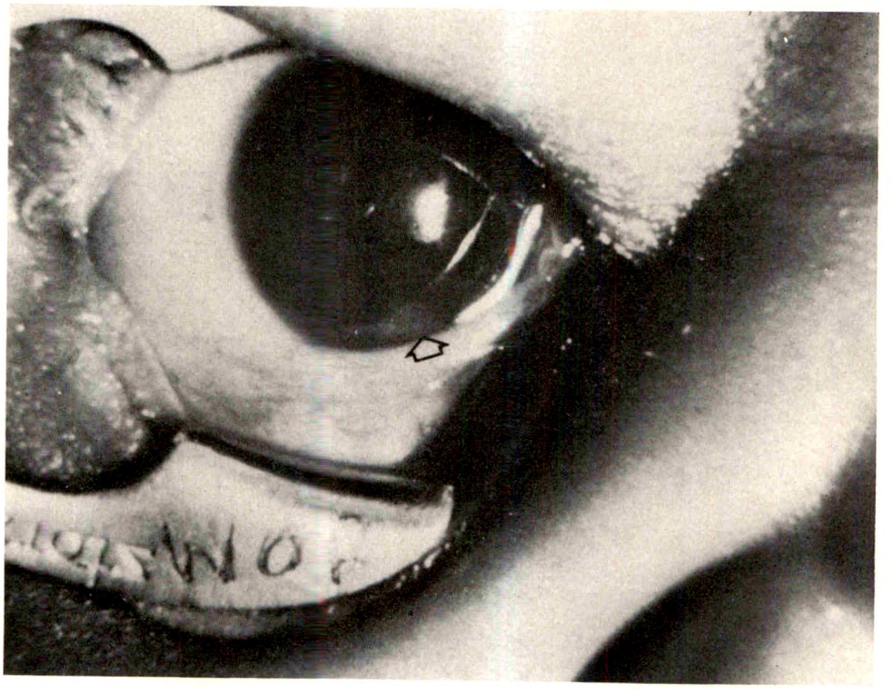
Generalized cutaneous and visceral hemangiomas in the neonate are a rare and serious phenomenon; there are only eight reported cases.[1,2] This is a report of an infant with diffuse congenital hemangiomatosis; in addition to a unilateral cavernous hemangioma of the iris, retinal vasculature was found to be abnormal bilaterally. In the other affected tissues, the lesions consisted of vascular hamartomas in which abnormally dilated capillaries were sometimes associated with a reduced number of the vessel-wall pericytes.

## CASE REPORT

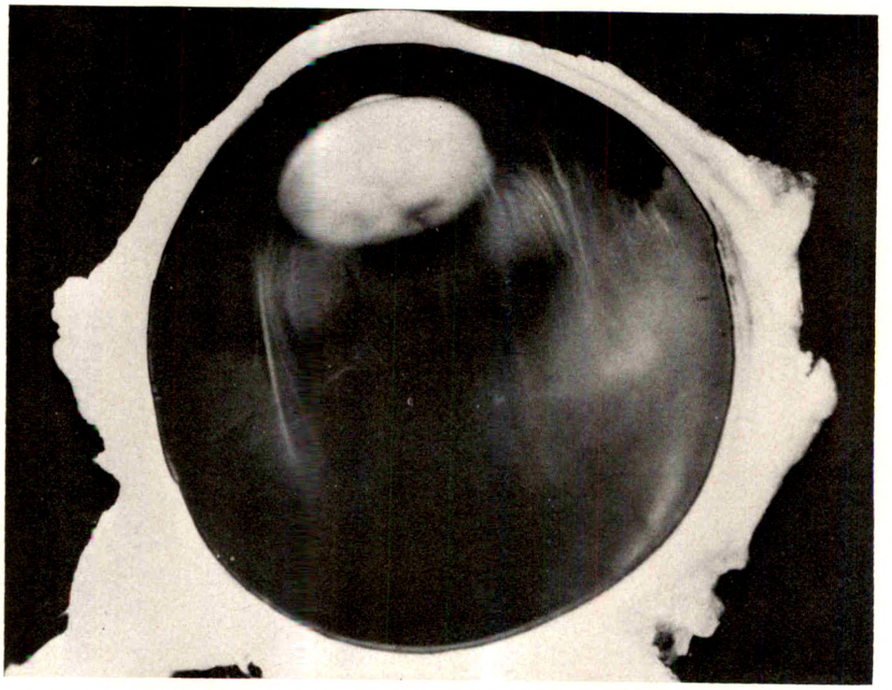
This black infant girl weighed 3.08 kg at birth on January 5, 1969. The medical history of her 25-year-old mother included asthma, glucose-6-phosphate dehydrogenase deficiency, three normal pregnancies and one unexplained stillbirth. There was no family history of hemangiomas. Pregnancy, induced labor, and delivery were all normal, and no hemangiomas were observed in the placenta.

At birth, however, multiple blue to purple subcutaneous nodules ranging from 1 to 20 mm in diameter were apparent over the infant's scalp, neck, trunk, and extremities. Red sessile hemangiomatous-appearing lesions were seen on the cheek, tongue, leg, and right iris. The discrete iris lesion measured 2-3 mm, had a bright red, irregular surface, and was situated at the iris base at five o'clock (Fig. 1). Chest x-ray films revealed multiple lung nodules. A biopsy of a leg-skin nodule showed a capillary hemangioma. At the time of the skin biopsy, dilated fundus and intraocular pressure examinations of both eyes were normal.

The infant did well for two weeks, but then developed a paralysis of the left arm, a right lateral rectus palsy, blepharoptosis of the left eyelid, and a visibly abnormal enlargement of the head circumference. Repeat chest x-rays revealed enlargement of the previously noted lung nodules. Treatment with oral prednisone at 3 mg/kg/day was begun and continued for three weeks. The electroencephalogram was normal, but a brain scan showed bilateral superficial areas of uptake, being more prominent on the right side than the left. A cerebral arteriogram revealed only moderate hydrocephalus. The skull continued to enlarge, and separation of the cranial sutures was seen on x-ray. A bulging anterior fontanelle, vomiting, and lethargy developed. A right ventricular tap showed increased pressure and xanthochromic fluid. A pneumoencephalogram revealed two-pedunculated lesions in the lateral ventricles, and posterior and lateral displacement of the aqueduct, suggesting a midbrain mass. The four-week-old infant rapidly declined, presenting bilateral lateral rectus palsies, bilateral wrist drops, and a right foot drop. A ventriculoperiotoneal shunt was attempted, but failed. The infant developed meningitis, subsequently experienced periods of intermittent apnea and tachycardia, and died at the age of 35 days.



## PATHOLOGY



Postmortem examination disclosed hemangiomas in the skin, subcutaneous tissue, esophagus, stomach, intestine, mesentery, mesocolon, lungs, diaphragm, bladder, lymph nodes, cervix, muscle, heart, thymus, larynx, tongue, kidney, spinal cord, meninges, brain and iris. Hemangiomas at the roots of C-7, C-8, T-1 and the lumbosacral regions of the spinal cord correlated well clinicopathologically with the brachial palsies and the foot drop, as did the marked hemangiomas of the midbrain and pons with the third and sixth nerve palsies, and the aqueduct compression by midbrain hemangiomas with the dilated third and lateral ventricles.

*Ocular tissues*—On gross examination, the right eye measured 18 × 19 × 19 mm, with 12.5 mm of optic nerve attached. The cornea measured 10.5 × 10 mm. The pupil was round and central and measured 3.5 mm in diameter. There was a ring of limbal pig-

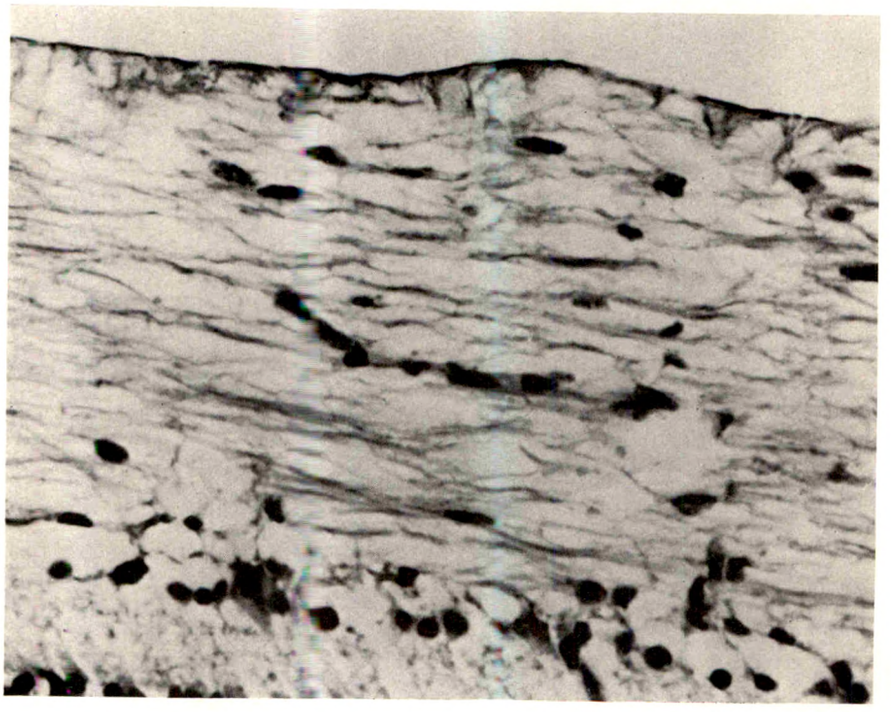
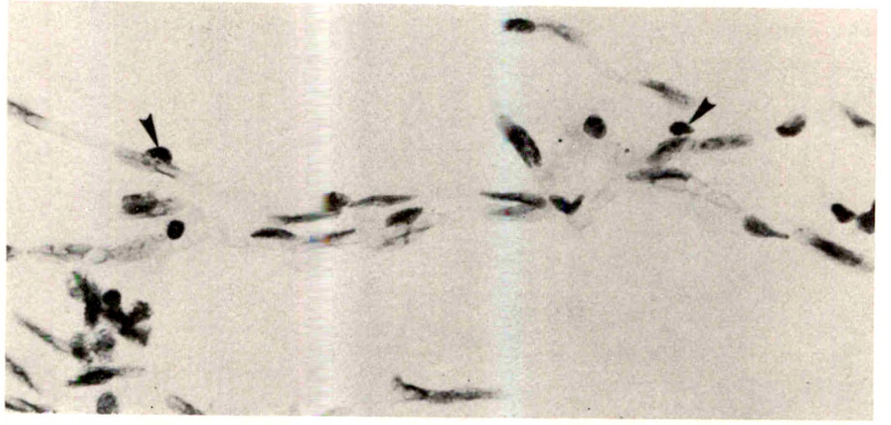
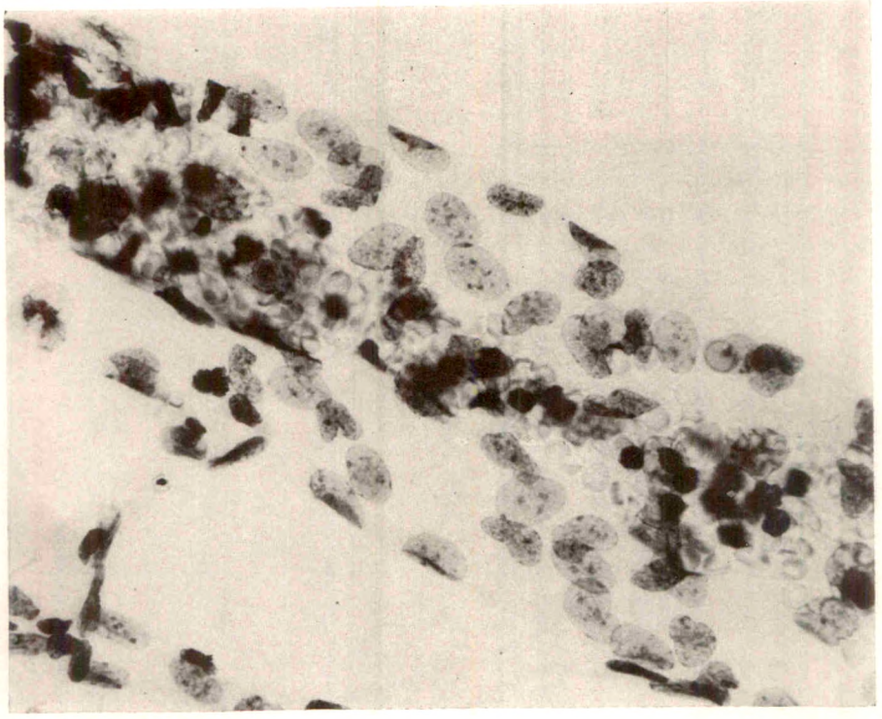
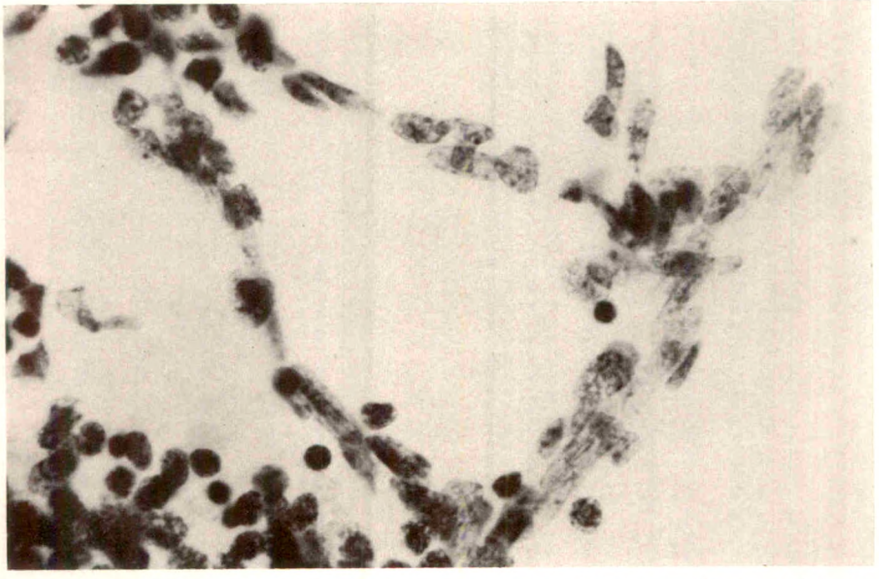




Figs. 1 and 2 (Naidoff, Kenyon, and Green). Figure 1 (top): The hemangioma (arrow) is situated at the iris base in the five o'clock position. Figure 2 (bottom): In the area of the iris hemangioma, notching of the lens is evident upon gross examination (×4).





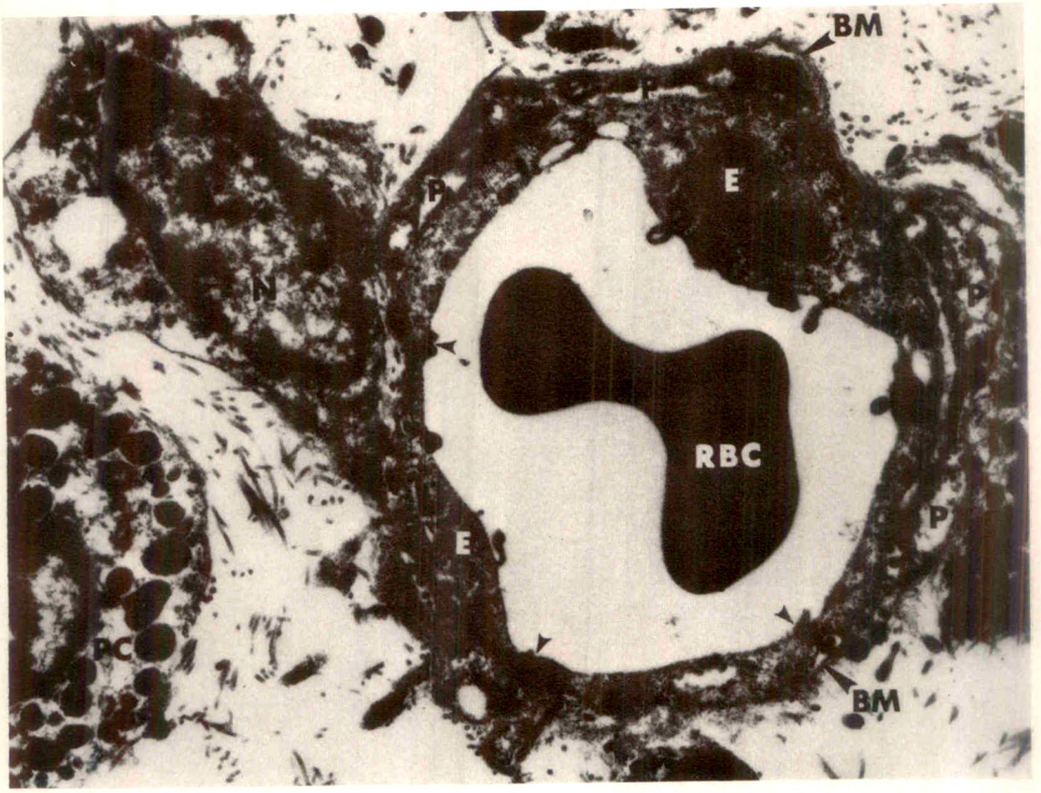
Figs. 3 and 4 (Naidoff, Kenyon, and Green). Figure 3 (top): In histologic section at low magnification, the hemangioma of the peripheral iris stroma is shown occluding the angle and compressing the ciliary body (hematoxylin-eosin, ×135). Figure 4 (bottom): At higher magnification, histologic section of the iris hemangioma reveals dilated vascular channels lined by endothelial cells and traversed by connective tissue septae (hematoxylin-eosin, ×520).

Figs. 5 and 6 (Naidoff, Kenyon, and Green). Figure 5 (top): In histologic sections of the retina, blood vessels are reduced in frequency and appear to consist of endothelial cells only (hematoxylin-eosin, ×550). Figure 6 (bottom): In trypsin digest preparations of the retina, the few remaining retinal capillaries demonstrate a conspicuous reduction of perithelial cells (arrowheads) in association with a prominent or increased endothelial cell population (×550).

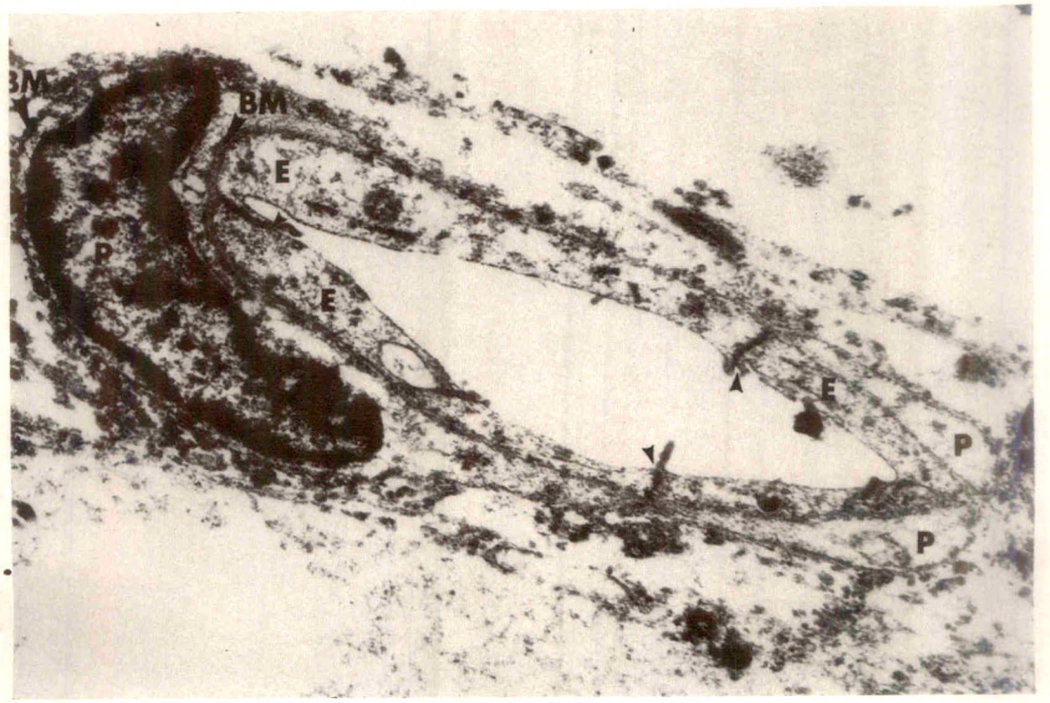
Figs. 7 and 8 (Naidoff, Kenyon, and Green). Figure 7 (top): This larger blood vessel in the trypsin-digested retina appears as a cylinder of pure endothelium which is totally devoid of pericytes (×600). Figure 8 (bottom): In the retina of the fellow eye (os), trypsin digestion discloses similar vascular abnormalities including reduction of vessels, prominence of endothelial cells and deficiency of pericytes (×875).

mentation which was particularly prominent at the five o'clock position. No defects were seen on transillumination. A 3 mm tumor was present at the iris base at five o'clock. After the globe was sectioned vertically, the pigmented iris lesion appeared to be either compressing the ciliary body or infiltrating it and thus obstructing the angle. The lens was notched inferiorly (Fig. 2), and also showed normal posterior umbilication. Small pigment clumps were seen on the zonules. The optic disk was normal. The left eye measured 17.5 × 17 × 17 mm and was normal.

Examination of histologic sections of the right eye revealed a normal cornea. Serial sections numbered 1 through 143 disclosed a lesion composed of large thin-walled vascular structures filled with blood in the inferior iris leaf (Fig. 3). The vascular lesion was located in the iris stroma at the periphery, where it occluded the angle anteriorly, compressed the ciliary body posteriorly and notched the lens superiorly. The channels coalesced to form even larger vascular spaces which were lined by plump and, in some areas, flattened endothelial cells with little or no intervening fibrous tissue (Fig. 4). No muscular tissue was observed in the walls of the vessels by routine and special staining techniques. The iris pigment epithelium was intact and the remaining iris was normal.



The retina appeared normal on routine sectioning except for a decreased number of vessels, which had unusually thin walls and demonstrated endothelial cells only (Fig. 5). Portions of retina from both eyes were subjected to trypsin digestion. This disclosed a curious finding, in that both specimens almost completely disintegrated when exposed to the action of trypsin for short periods of time. In a few areas where the retinal vasculature remained relatively intact, there was a conspicuous reduction or absence of intramural pericytes, with a prominent to increased number of endothelial cells (Fig. 6 and 7). Some totally avascular areas were observed. The optic disk and nerve were normal. Histologic examination of the left eye was normal except for the previously noted retinal vascular abnormalities (Fig. 8).



For detailed study of vascular ultrastructure in the ocular tissues of this patient, the formalin-fixed and paraffin-embedded histologic material was reprocessed for electron microscopy by dissolution of the paraffin with chloroform, rehydration in veronalacetate buffer, dissection into suitably sized specimens, fixation in veronal-acetate-buffered 2% osmium tetroxide, and embedding in Araldite epoxy resin. Thin sections were then cut on a Porter-Blum MT-2 microtome, doubly stained with uranyl acetate and lead citrate, and examined with a JEM 100-B electron microscope.

The cavernous hemangioma of the iris could not be surveyed by electron microscopy because it had been serially sectioned in its entirety for histologic examination. In the unaffected portion of the iris and in the histologically unremarkable ciliary body, however, the capillaries appeared to be entirely normal, as they exhibited a continuous endothelial lining and a normal complement of

Figs. 9 and 10 (Naidoff, Kenyon, and Green). Figure 9 (top): In this electron micrograph, a capillary of the iris is shown to possess a continuous lining of endothelial cells (E) joined by tight junctions (arrowheads). Several pericyte processes (P) are embedded in the basement membrane (BM) of the endothelium. The nucleus (N) of a large perithelial cell is prominent, as are the erythrocyte (RBC) in the vessel lumen and the pigment cells (PC) of the iris stroma (×11,000). Figure 10 (bottom): By electron microscopy, the ultrastructure of this retinal capillary is essentially normal. The endothelial cells (E) are connected by tight junctions (arrowheads). Well-developed pericytes (P) are enveloped by the endothelial basement membrane (BM) (×11,000).

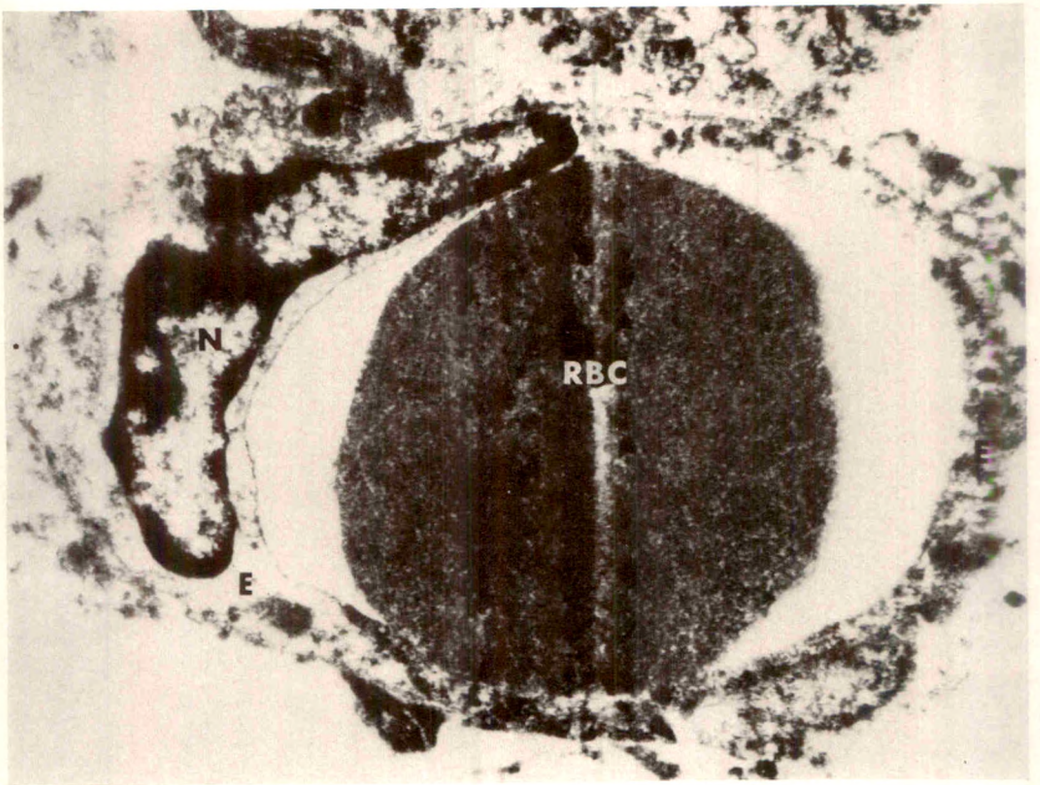
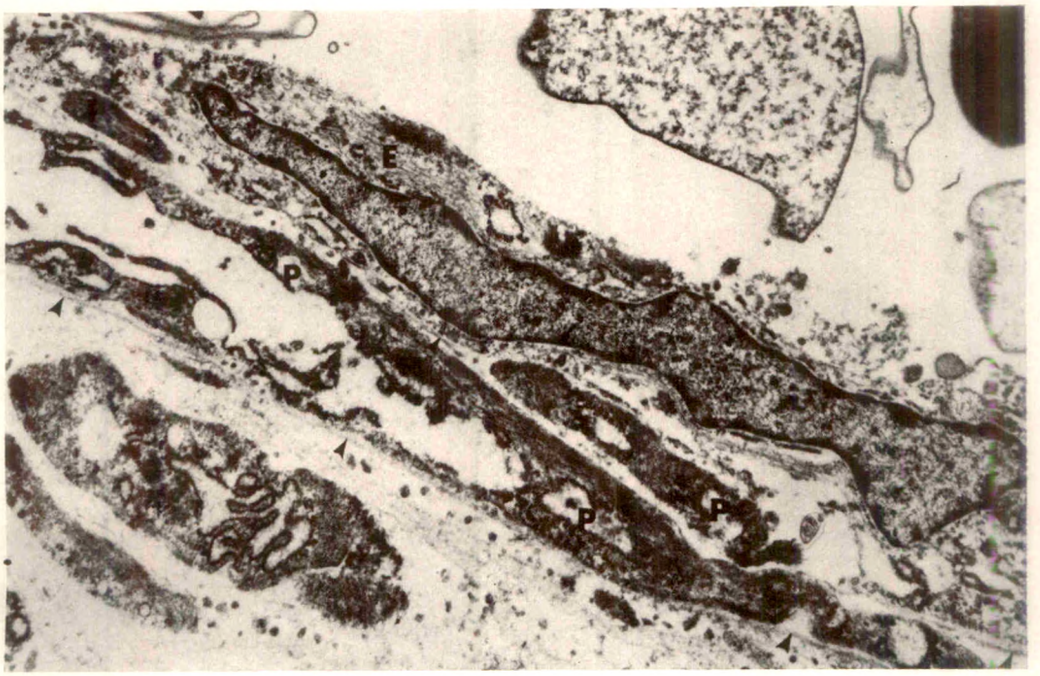
perithelial cells which were enveloped by the basement membrane of the endothelial cells (Fig. 9).

The ultrastructural alterations of the retinal capillaries were generally consistent with the abnormalities evident in the histologic and trypsin digest preparations. In particular, the retinal vessels were found to be markedly reduced in frequency throughout the retina; and in distribution, they were essentially limited to the nerve fiber layer and ganglion cell layer, with virtual absence of capillaries in the inner plexiform and nuclear layers. Whereas the majority of these capillaries displayed the usual ultrastructural appearance of endothelial cells and associated pericytes invested by a basement membrane (Fig. 10), in perhaps one-third of the retinal capillaries, no intramural pericytes could be identified (Fig. 11). The caliber of these vessels was within normal limits and was seemingly unrelated to the presence or absence of pericytes.

In the choroid, the endothelial and perithelial cells of the choriocapillaris appeared normal. No abnormalities of the retinal pigment epithelium or Bruch's membrane could be demonstrated by electron microscopy.



*Other tissues*—The histologic appearance of the cutaneous and visceral hemangiomas varied from capillary to cavernous types, which consisted of dilated thin-walled channels lined by a single layer of endothelial cells, without obvious endothelial proliferation or arteriovenous connections. A particularly interesting finding was that no pericytes could be demonstrated by Bodian silver stain.[1]



In an attempt to establish the significance of this latter finding, hemangiomas from the liver, kidney and heart tissues were studied by electron microscopy. (These specimens, which had been formalin-fixed but had not been embedded in paraffin, were prepared for electron microscopy by the previously described techniques.) In the cavernous hemangiomas of the liver parenchyma, the pericytes could be identified with certainty, as they were closely associated with the endothelial cells and were clearly invested by a well-developed basement membrane (Fig. 12). In the hemangiomas of the renal cortex and superficial endocardium, however, pericytes could not be demonstrated with certainty. Although cells of the appropriate ultrastructural type were apparent in the collagenous tissue surrounding these hemangiomas, such cells were not always in close apposition to the endothelium and, more important, they lacked a clearly defined basement membrane by which they might have been distinguished from connective tissue cells (Figs. 13 and 14). Review of histologic sections from these same specimens were generally consistent with the electron microscopic findings.

## Discussion

All eight reported cases of congenital diffuse hemangiomatosis have resulted in death of the infants before one year of age, the mean survival time being 71 days.[1] The most common cause of death has been heart failure associated with a large liver hemangioma. The cause of death in this patient was attributed to hydrocephalus and meningitis. The unique features of this case were the generalized involvement of the spinal cord,

Figs. 11 and 12 (Naidoff, Kenyon, and Green). Figure 11 (top): Electron microscopy of the retina also reveals abnormal capillaries which are without definite evidence of pericytes despite the presence of a complete endothelial lining (E). (N) nucleus, (RBC) erythrocyte (×19,000). Figure 12 (bottom): In this cavernous hemangioma of the liver parenchyma, electron microscopy permits identification of at least three pericytes (P) which are closely associated with the flattened endothelial cells (E) and are invested by a well-defined basement membrane (arrowheads) (×11,000).

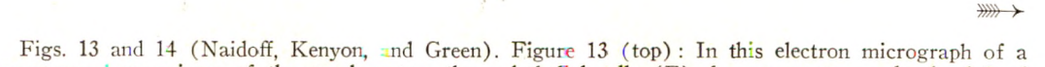
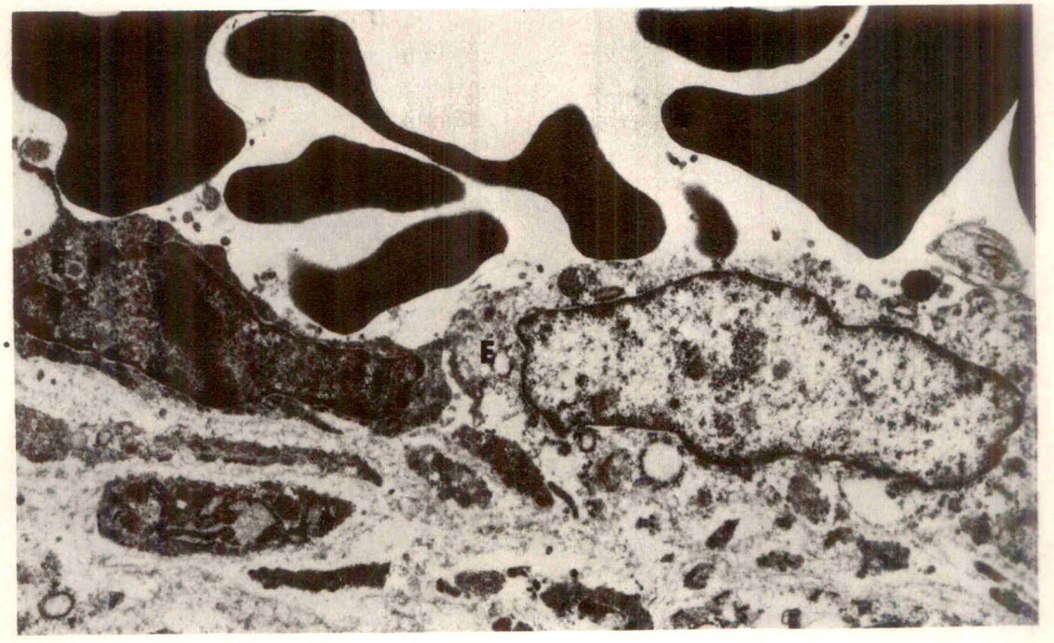
thymus, uterine cervix, skeletal muscle, and iris, none of which was reported in the previous cases.

Both cavernous and capillary hemangiomas of mixed types have been noted at birth or shortly thereafter and tend to enlarge for three to six months. Reduction in size of these angiomas usually begins by one year of age. The capillary type is usually gone by five years of age; the cavernous type is more variable, less predictable, and more often requires surgical intervention. Zarem and Edgerton[3] reported that the use of oral steroid therapy led to the rapid cessation of growth and partial resolution of capillary and cavernous hemangiomas in children. They postulated that the immature vascular tissue in these hemangiomas was responsive to the anti-anabolic effect of the steroids, usually within two weeks of treatment. However, no beneficial effects of this treatment were noted in the present case.

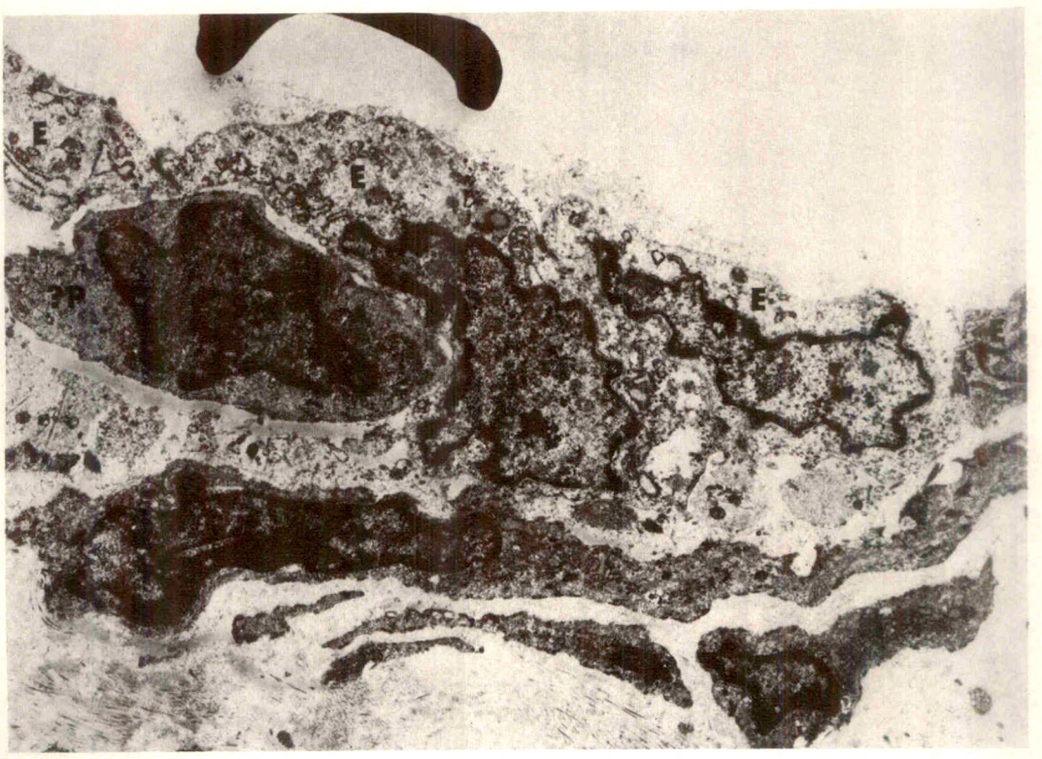


Hemangiomas of the iris are rare. In a series of 145 primary tumors of the iris, Ashton[4] found only three angiomas, an incidence of 2%.

Many cases reported to be iris hemangiomas in the past[5-7] on re-examination have proven to be juvenile xanthogranulomas or malignant melanomas.[8] Reese[9] and Ashton attributed the first histologically proven case of iris hemangioma to Rodin[5] (1929), who also reviewed the nine cases present in the literature at that time and accepted only three as correctly diagnosed. He considered the other six to be granulomas, granulation tissue, or spindle cell sarcomas. However, Rodin's case has now been reclassified as juvenile xanthogranuloma by Dr. Lorenz Zimmerman at the Armed Forces Institute of Pathology.[8]



It was not until 1949 that Blank, Eglick, and Beerman[10] showed that juvenile xanthogranuloma could affect the iris and ciliary body. In this condition, the lesions show infiltrates of pale-staining, mononuclear histiocytes replacing the normal iris stroma and leading to focal or diffuse thickening; Touton giant cells and eosinophils are also present. In many cases, multiple thin-walled capillaries are seen, rupture of which accounts for the spontaneous hyphemas seen in this disease. Associated skin lesions are not always present.



Hogan and Zimmerman[11] state that in iris melanomas, "cystic degeneration, bleeding in the cysts, and hemorrhage into the anterior chamber" may lead to a mistaken diagnosis of iris hemangioma. Moreover, the sometimes marked vascular proliferation in iris melanomas may tend to be more prominent histologically than the melanoma itself.[12] Baghdassarian and Spencer[7] stated that a case reported to be iris hemangioma by Spencer[6] in 1963 was subsequently found to be a melanoma on further sectioning. The important point is that the study of serial sections of suspected iris hemangiomas may instead reveal other entities.

Clinical information in the cases reported as iris hemangiomas is scanty in many instances. These lesions have usually presented with a history of hyphema, though there was no intraocular hemorrhage in our patient. These iris lesions have appeared in patients as young as two months, though most appear in adults. They are usually located near the pupillary border and have a

Figs. 13 and 14 (Naidoff, Kenyon, and Green). Figure 13 (top): In this electron micrograph of a cavernous hemangioma of the renal cortex, the endothelial cells (E) do not possess a clearly defined basement membrane. The cells within the underlying collagenous connective tissue cannot be characterized as pericytes (×8500). Figure 14 (bottom): In the endocardium, electron microscopy demonstrates hypercellularity of the endothelial lining (E) of this cavernous hemangioma. No basement membrane is evident, and pericytes (?P) cannot therefore be unequivocally identified (×6300).

variable history concerning size, with some enlarging gradually and others rapidly. They are described as being red to reddish-white in color and may be present from short to long periods of time. In the recent reports of Ashton,[4] Cashell,[13] and Stallard,[14] the specimens have been obtained by iridectomy.

Histologically, the iris hemangiomas have varied from the capillary type to more cavernous types with delicate fibrous stroma and varying amounts of hemorrhage.

An especially interesting aspect of this case is the histologic and electron microscopic finding of a deficiency of vessel wall pericytes in many of the ocular and visceral tissues. In the eye, although the capillaries of the iris and ciliary body were ultrastructurally unremarkable, the strikingly decreased number of retinal vessels and the extreme fragility of these vessels following trypsin digestion seemed to correlate with the marked reduction in intramural pericytes. In the visceral tissues, the unequivocal presence of pericytes in the cavernous hemangiomas of the liver was in contrast to the lack of identifiable pericytes in the renal and endocardial hemangiomas.

In their discussion of the present case, Holden and Alexander[1] postulated that the hemangiomas may have enlarged secondarily by dilatation of true capillaries in which the absence of pericytes resulted in a loss of tone. And conversely, Kuwabara and Cogan[15] have indicated that the structural integrity of retinal capillaries is dependent upon intact pericytes rather than endothelial cells. Whatever the pathogenesis of these hemangiomatous lesions, it is evident that the observed deficiencies of vessel-wall pericytes points to a generalized congenital defect in capillary structure.

## Summary

Hemangiomas of the iris are rare and have been confused in the past with melanomas and juvenile xanthogranulomas. In a neonate with cavernous hemangioma of the iris, this was associated with generalized cutaneous and visceral hemangiomas, another uncommon phenomenon. Routine and special histologic techniques, plus electron microscopy, disclosed a marked reduction in the number of pericytes in these lesions; the trypsin-digested preparations of the retina showed an almost total absence of intramural pericytes.

### Acknowledgments

We thank Drs. A. E. Maumenee and John Yardley for critical review of this manuscript, and Mr. David Andrews for helpful editorial suggestions.

## NEW SURGICAL LIGHT

THOMAS J. WALSH, M.D.
*New Haven, Connecticutt*

Fiber optic illumination has the unique advantage of bringing adequate light to areas that larger light sources cannot. An operating light source was constructed which combined both specific as well as general field illumination. For specific illumination, we attached a fiber bundle divided into four segments onto a Maumenee eyelid speculum (Fig. 1).

The advantages of using this arrangement are several: The light energy that is delivered is cool and not hot, which is important for a light source this close to the eye. The direction of the light can be altered individually for each case by adjusting the eyelid blade and tightening the clamp. The amount of light is governed by a rheostat on the light source box. The fiber bundles are extremely light and flexible so no added tension or weight is placed on the eye. The brightness of these four ports, as well as the size of the field covered has proved more than adequate (Fig. 2).

For general illumination with this instrument, we used a full-sized fiber bundle with a condensing lens and goose-neck carrier. The goose-neck allows the light to be properly directed and to remain in that position after the bundle is attached to the drape. The condensing lens concentrates the light in an area more nearly approximating the operative field.

The combination of the two lights gives

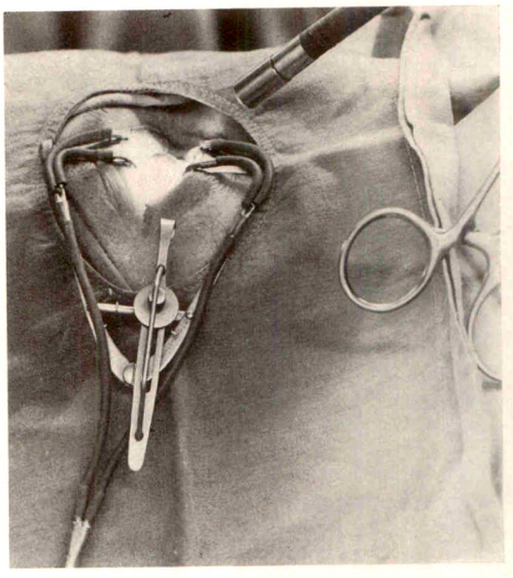

Fig. 1 (Walsh). Lighting of operative field with both types of illuminators.

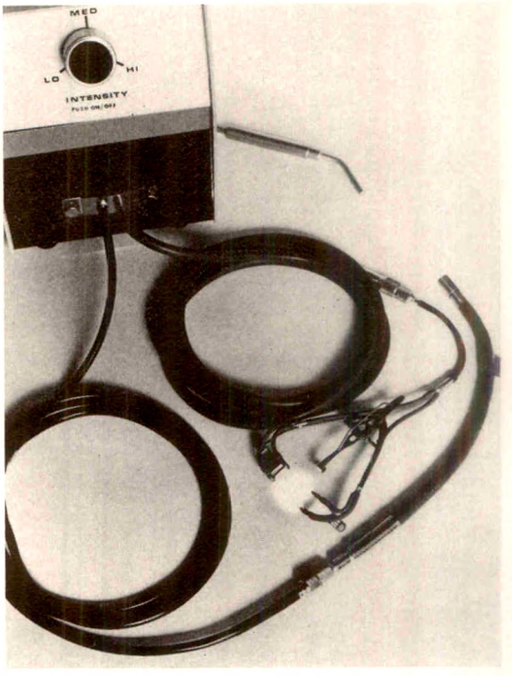

Fig. 2 (Walsh). Light source and all three attachments, including the focal illuminator.

Reprint requests to Thomas J. Walsh, M.D., Department of Ophthalmology, Yale School of Medicine, 333 Cedar Street, New Haven, Connecticutt.

excellent illumination without shadows and without getting in the surgeon's way as he operates. The entire unit can be sterilized in the autoclave or by gas and cold sterilization methods. The unit comes with a standard third component also—a transilluminator (Fig. 2).

Additional fiber optic attachments are under consideration and development and can be added to the basic unit in the future. The instrument is called Lumi-Trac (Instrumentation for Medicine, Inc.).

## Summary

A new fiber optic surgical light incorporates both general field lighting and focal illumination of the specific operative area. It casts bright illumination without shadows, and is constructed in such a way that it is adaptable to each individual case; the brightness may be adjusted to individual requirements. It is light in weight and causes no traction on the globe, and the whole unit can withstand autoclaving, or it may be sterilized by gas or cold sterilization methods.

---

## Ophthalmic miniature

The eye is the most sensitive of all body organs. Therefore it is proper that one drip medications into it extremely gently after having slightly raised the upper eyelid. One should dissolve these medications in liquids that are usually nonirritating. Ancient physicians found egg albumen to be of great benefit as a base for eyedrops.

# MEETINGS, CONFERENCES, SYMPOSIA

EDITED BY THOMAS CHALKLEY, M.D.

## THE IOWA EYE ASSOCIATION

The annual meeting of the Iowa Eye Association was held in Iowa City on May 12-14, 1971. Three half-day sessions were devoted to clinical papers by present and former residents and staff members. Workshops were offered on vertical muscle imbalances, macular lesions, infectious diseases, and glaucoma. The highlight of this year's meeting was a dinner dance which honored two professors who will soon retire from the University of Iowa faculty, Drs. Hermann Burian and Paul Boeder. The unique contributions of each gentleman to the University of Iowa and to world ophthalmology were recalled, and gifts symbolizing the affection and esteem of their students were presented. Special recognition was given to Dr. Burian by the American Association of Certified Orthoptists.

Frederick Mausolf described the hyperviscosity syndrome in a patient with multiple myeloma. Waxing and waning of retinopathy (hemorrhages, microaneurysms, venous dilatation, and slowed retinal circulation) were correlated with plasmaphoresis-induced changes in plasma viscosity and protein levels.

H. Stanley Thompson discussed the value of pilocarpine in distinguishing atropine-induced mydriasis from paralytic mydriasis. Particular emphasis was placed on Jimson weed toxicity. The Jimson weed, containing belladonna alkaloids, is a common invader of crop fields and causes the "corn picker's pupil." Richard Falter reported pharmacologic and pupillographic studies of the mechanism of the initial mydriasis caused by topical guanethidine.

Paul Rutkowski reported that increased intraocular pressure in humans, produced by a suction cup ophthalmodynamometer, causes mydriasis. Impairment of the iris sphincter can be demonstrated by pupillography. Iris fluorescein angiography shows no apparent filling of iris vessels at intraocular pressures above the diastolic ophthalmic artery pressure.

Richard Ulrich gave a progress report on a method originally developed by Donald Greif for recording electroretinograms and occipital lobe electrical responses after stimulation of isolated retinal areas. This technique may become useful for objective visual field examination.

Adnan Halassa reviewed the effect of glaucoma on the blood supply to the optic disk. Fluorescein angiography demonstrated an improvement in circumpapillary choroidal filling following lowering of ocular hypertension by osmotic agents.

Bruce Spivey discussed new methods of teaching ophthalmology to medical students, including self-instruction units and teaching mannekins. Ronald Zahoruk demonstrated the use of television as a teaching aid for external, slit lamp, and fundus information in neuro-ophthalmology.

Karel Maertens, visiting from the Lovanium University in Kinshasa, Democratic Republic of the Congo, portrayed the vicissitudes of practicing ophthalmology in the Congo and described parasitic eye diseases which are virtually unknown to American ophthalmologists.

Bruce Bedell reviewed current research being conducted by the Army Laser Safety Team in Philadelphia. Ogden Frazier and Lee Allen described experiments in filter combinations for color fluorescein fundus angiography.

Philip Knapp described several useful techniques for strabismus surgery when there are extensive adhesions from previous surgery. Particular emphasis was placed on marginal tenotomies, bare sclera technique,

and use of Supramid Extra sleeves and sheets between muscle and sclera to prevent reformation of adhesions.

Robert Watzke presented several cases of intraocular tumors which had defied usual clinical dictums. Larry Wood described the clinical and pathologic findings in a case of Wegener's granulomatosis involving the eyes.

Thomas Burton studied how long it took to freeze the ciliary body of a normal human eye which was subsequently removed as part of an orbital exenteration specimen. By indenting the sclera with the freezing probe he could directly observe blanching of the ciliary processes. Although freezing began with equal rapidity at probe temperatures of −45° and −75° C, the colder temperature proved much more destructive when the lesions were examined histologically; 60 seconds was the optimal freezing time.

Donald Doughman reviewed the Stevens-Johnson syndrome and described the management of its late ocular effects, especially deficiency of mucus in the tears. A scleral contact lens combined with artificial tears is the most successful treatment.

James Allen reviewed the treatment of chronic facial nerve paralysis and described a temporalis muscle-facial transplant to restore eyelid closure.

Frederick C. Blodi presented a review of current department activities and described plans for future expansion. He also presented a series of clinical-pathologic mystery cases which tested the wit and acumen of the audience.

At a brief business meeting, President Joseph Dvorak turned the association's leadership over to new President Arthur Wise. Landis Stewart is the new President-Elect and Charles Phelps the new Secretary-Treasurer, replacing Bruce Spivey, who resigned after nine years of faithful service.

Charles D. Phelps

## UNIVERSITY OF TORONTO ANNUAL RESEARCH MEETING

The 13th annual research meeting and clinical day of the Department of Ophthalmology of the University of Toronto was held May 13-14, 1971. The guest speaker on Research Day was Matthew Alpern, professor of physiological optics in the department of ophthalmology at the University of Michigan. The Clinical Day guest speaker was Arnold Forrest, clinical professor of ophthalmology at Presbyterian Hospital, New York City. Abstracts of the papers presented are as follows:

### AVIAN MACROPHTHALMOS WITHOUT OCULAR HYPERTENSION

Drs. K. Axmith and J. D. Morin (Toronto)—After 128 domestic chickens were reared in continuous incandescent light for 16 weeks, beginning at one week of age, random assignment was made to seven equal groups—six treatment groups and a control group. Surgical treatment comprised unilateral optic nerve section and thermal sclerectomy. Others received atropine 1%, epinephrine 1% drops to the right eye, or epinephrine drops plus acetazolamide in the feed. A control group received no medication. At the end of the treatment period intraocular pressure (IOP) and outflow facility (C) were determined manometrically, using a constant infusion pressure technique. Mean IOP was 7.59 mm Hg. Mean C was 0.05 ml/minute/mm Hg. Mean eye weight was 4.6 g. There was no difference between right and left eye parameters in any group. The only significant difference seen was in IOP between the control group and those submitted to optic nerve section. In no case was there microscopic evidence of pressure-induced pathology. Medical and surgical treatment did not alter the course of eye enlargement. Bilateral eye enlargement occurred with lowered C but without increased IOP in any eye. It was concluded that so-called avian buphthal-

mos does occur in continuous light, but this phenomenon is not related to raised intraocular pressure.

### Role of platelets in corneal graft reaction

Drs. J. J. Hurwitz and P. K. Basu (Toronto—Platelet concentrations in the systemic and limbal circulations and in the aqueous humor were studied in rabbits receiving interlamellar corneal xenografts. A new technique was described for obtaining platelets from the limbal circulation. Results showed that after a rise during the "latent period" there is a marked fall of platelets coincident with the onset of graft rejections.

When heparin was used intramuscularly every 12 hours, the onset of graft rejection was delayed and the severity of reaction diminished.

### Enzymatic zonulolysis using fibrinolytic enzyme

Drs. I. Melnyk and L. D. J. Chisholm (Toronto)—It is well recognized that alpha chymotrypsin will not dissolve the lens-vitreous attachments in children or young rabbits. To determine its effects on intracapsular lens extractions in rabbits, a fibrinolytic enzyme, CA-7, was used in three different concentrations for enzymatic zonulolysis in the same manner as alpha chymotrypsin is used. Operative results showed that while vitreous loss was inevitable without CA-7; with it, however, lens extraction was performed in many of the eyes without vitreous loss. Clinical observations were continued for six weeks postoperatively, and pathologic studies were conducted.

### Effect of vitamin A deficiency on the incorporation of glucosamine in the rat retina

Drs. R. D. Merritt and Y. Matuk (Toronto)—The incorporation of radioactive glucosamine into the protein of subcellular portions of retinas (smooth, rough microsomes, rod outer segments) was studied in vitamin A deficient rats and pair-fed controls. The results suggest that the incorporation of glucosamine is increased in vitamin A deficiency. Although the function of vitamin A in the synthesis of proteins in the retina—and indeed in the body as a whole—is unknown, it was hypothesized that with vitamin A deficiency an abnormal glycoprotein is produced in excess. In the rod outer segments, where opsin is responsible for the structure of the outer segments, the abnormal protein apparently does not have the structural capabilities of opsin; hence, the well-documented histologic breakdown of the rod outer segments occurs.

### Fluorescein angiography in evaluation of diabetic retinopathy

Drs. P. Migasena and C. B. Mortimer (Toronto)—A numerical classification of changes seen on fluorescein angiography in this disease has been developed as an aid to evaluation. This method is used to compare findings in two groups of patients, both treated and untreated.

### The physiology of rod adaptation

Dr. M. Alpern (Ann Arbor)—To evaluate the role of pigment bleaching, rhodopsin kinetics in living human rods is investigated, using Stiles and Crawford's concept of the equivalent background of bleaching and its modus operandi, the automatic gain control model. Rushton's equation for foveal red and green cone pigment kinetics (with appropriate changes in constants) satisfactorily describes the kinetics of rhodopsin bleaching and regeneration over a fair range of experimental conditions. This allows a quantification of the amount of rhodopsin bleached by different exposure durations and intensities so that the relation between rhodopsin bleaching and threshold recovery can be analyzed within this range. Limitations of the general kinetics equation were discussed and the influences of bleaching and back-

grounds on psychophysical thresholds, pupil responses, and the á and b-waves of the ERG were analyzed.

### A CLINICAL TRIAL OF APPLANATION TONOGRAPHY

Drs. R. F. Stevenson and R. K. MacDonald (Toronto)—Applanation tonography was performed by a method wherein the corneal indentation is effected by an annular "thruster." When intraocular pressure readings are taken through the center of the thruster by the Goldmann applanation tonometer, and since this tonometer's movement is independent of the annular thruster, aberrations in ocular rigidity therefore do not influence the accuracy of the $P_0$ and $P_t$ readings. In the 22 normal and 18 hypertensive eyes analyzed, this method proved as reliable as regular tonography in assessment of aqueous flow, whether the pressure decrement quotient, or other method of assessment is used. This simple attachment to the biomicroscope will permit the clinician to perform the test in his own office.

### FREQUENCY SPECTRAL ANALYSIS OF THE DARK ADAPTED ELECTRORETINOGRAM

Drs. J. W. Waisberg and J. A. Parker (Toronto)—An electroretinography laboratory was set up and the equipment further adapted with an FM tape recorder for recording selected responses. Thirteen normal subjects were then tested and their responses recorded and statistically analyzed for four parameters (a-amplitude, b-latency, b-culmination, b-amplitude). Results showed no significant difference between the two eyes of normal subjects. A typical fully dark adapted ERG response was then presented to a set of active analogue filters and analyzed with respect to its wave-frequency content. This demonstrated that the basic ERG response is made up of low frequency waves (below 50 cps) and that the higher frequency components add the fine structure to the basic low frequency response.

### CHANGES OF LOWER EYELID APPOSITION PRESSURES WITH AGE

Drs. J. C. Walters and J. C. Hill (Toronto)—Looking for factors contributing to the development of senile entropion and ectropion, the "apposition pressure" of the lower eyelid on the globe was studied by placing two small fluid-filled balloons behind the lower eyelid, using topical anesthesia. One was placed behind pretarsal and the other behind preseptal orbicularis muscle fibers. These were connected to two pressure transducers and simultaneous tracings obtained, from which were taken the following readings: (1) resting pressure, (2) spontaneous blink-peak pressure, (3) reflex blink (only in some cases by glabella tap), (4) voluntary blink, and (5) squeeze. In the same individual variations were considerable. Between individuals, "pretarsal" and "preseptal" could be reversed, probably indicating unreliable anatomical relationships with the balloons. In the limited number studied no characteristic age pattern emerged.

### SCANNING ELECTRON MICROSCOPY OF THE TUNICA VASCULOSA LENTIS

Dr. M. J. Hollenberg and Mr. D. H. Dickson (London)—This instrument was used to study the vascular pattern and surface topography of the vessels forming the tunica vasculosa lentis in the fetal and neonatal rat in situ. On the final day of gestation, the vitreal surface of the lens was almost totally obscured by a rich, interwoven network of capillaries radiating from the central hyaloid vessel. On the corneal surface of the lens, a much less dense vascular pattern was formed by capillaries converging centrally from a series of short parallel vessels at the lens equator. During the first two weeks of neonatal life interconnecting capillary links disappeared on both lens surfaces, and the remaining main vessels became straighter and narrower. On the 16th day after birth, the only remaining capil-

laries, forming an incomplete, sparse, vascular tree, were on the vitreal lens surface.

THE PATHOPHYSIOLOGY OF NIGHT BLINDNESS

Dr. M. Alpern (Ann Arbor)—Some congenital abnormalities of the retina are characterized by poor night vision as revealed, for example, in defective rod dark adaptation. A small number of patients with abnormalities of this kind have been analyzed by psychophysical, electrophysiologic, and pupillographic tests, in addition to retinal densitometry, with a view to specifying the locus of the defects. The work so far permits a distinction to be drawn between defects of the rhodopsin system and defects of the automatic gain control. Furthermore, it allows a decision to be reached as to whether, in the normal subject, rhodopsin bleaching signals enter the automatic gain control through the input (according to Barlow) or through the feedback (according to Rushton).

COLOR VISION CAPABILITIES OF THE LEGALLY BLIND

Dr. P. K. Kaiser (Toronto)—Six legally blind subjects were tested for color vision by two procedures. Three of the subjects responded normally to the first, the HRR pseudoisochromatic color vision test. One subject was diagnosed as a mild protan, and the remaining two were unable to take the test. The second procedure involved having the subjects view three monochromatic lights at a 15-degree visual angle. The three who responded normally to the first test, as well as the one who responded as a mild protan to the HRR test, all responded normally on the color-naming task. The two remaining subjects gave clear indications of being able to correctly perceive colors towards the ends of the visible spectrum. This study suggests the possibility that colors near the end of the spectrum, reds or oranges and blues, might be used for color coding with the low vision population, but more important, this study demonstrates that a color-naming task would seem to be a more sensitive measure of color vision in persons with low vision than the standard color vision tests.

DISTURBANCES OF ROD THRESHOLD DUE TO TEMPOROSPATIAL PATTERNS OF BACKGROUND LIGHTING

Dr. P. E. Hallett (Toronto)—At the limits of rod vision a small subtense, brief duration signal can be detected if it excites a few retinal rods. The threshold energy of the signal must be increased if luminous backgrounds are present and if these show temporal or spatial changes in intensity, then there are also corresponding changes in the threshold energy of the superimposed signal. Analysis of such experiments involves signal/noise theory and spread functions and points to the importance of lateral inhibitory interactions at rod levels of illumination.

MICROTUBULAR DEGENERATION AND ALTERED GANGLION CELL ELECTRICAL ACTIVITY

Drs. D. R. Crapper and J. A. McLean (Toronto)—Colchicine is known to dissociate neuronal microtubules and block fast axonal transport in rabbit ganglion cell axons. Following 50 μg of intraocular colchicine, electronmicrographs show an increase in ganglion cell neuronal filaments and a decrease in microtubules. The optic tract photic-evoked electrical response progressively declines in amplitude following colchicine while the cortical response to electrical stimulation of the optic tract remains virtually unchanged when monitored by chronically implanted electrodes in unanesthetized rabbits. The ERG is not altered and supports the ultrastructural observation than the receptor, bipolar, and Müller cells are not affected by colchicine. The probable site of conduction failure is the postsynaptic membrane of the ganglion cell. These observations are in agreement with central nervous system observations that dendritic microtubular degeneration associated with neurofi-

brillary tangles is accompanied by a loss of synaptic receptor sensitivity.

LIGHT AND ELECTRON MICROSCOPIC RADIOAUTOGRAPHY OF TRITIATED GLUCOSE INCORPORATION IN THE RETINA OF THE ADULT NEWT

Mr. D. H. Dickson and Dr. M. J. Hollenberg (London)—When tritiated glucose was administered to fasted newts, incorporation of glucose into glycogen throughout the retina commenced at 30 minutes after injection. The first silver grain concentrations were observed over the photoreceptor myoid at two hours. Incorporation of glucose into glycogen reached a maximum at six hours, with grains concentrated over photoreceptor paraboloids, the apices of Müller cells and the inner and outer plexiform layers. By 24 hours there was a reduction of the label in glycogen, but silver grains were now visible over mitochondria in the photoreceptor ellipsoids and in increased amounts in the outer and inner plexiform layers and the nerve fiber layer. After three weeks, most radioactive material was observed over the photoreceptor cell outer segments.

INTERACTION BETWEEN NEAR ULTRAVIOLET LIGHT AND OCULAR PROTEINS

Dr. S. Zigman (Rochester)—A mechanism whereby the near ultraviolet (UV) portion of sunlight can alter physicochemical properties of ocular proteins after penetrating the cornea is suggested by in vitro experiments. Such light has been found to photooxidize aromatic amino acids and other aromatic substances (i.e., p-aminobenzoic acid) in buffers, physiologic solutions, and unaltered aqueous humor into colored compound which combine with lens and aqueous humor proteins.

Irradiation of tryptophan (5nm) in neutral aqueous buffers at 22°C for 24 hours with 3000 to 5000 $\mu w/cm^2$ of 340-380 nm light induced the formation of a yellow-brown oxidation product having twice the molecular weight of tryptophan, no free $\alpha$-amino groups, and altered absorption and fluorescence spectra. This product combined firmly with amino and sulfhydril groups of lens crystallins and many other proteins, coloring them, and appreciably altering their light absorption and fluorescence properties, their solubilities, and their electrophoretic mobilities. Human lenses incubated in physiologic media containing 5 mM tryptophan, and irradiated with near ultraviolet (UV) light as described above, became more intensely yellow-brown and absorbed blue light more efficiently. Uncolored rabbit lenses, irradiated for 72 hours in unaltered bovine aqueous humor also became yellow-brown as did the aqueous.

Our thesis is that aromatic compounds are photo-oxidized in the aqueous humor and lens by the near UV components of sunlight entering the eye. These substances combine with lens proteins leading to an increased browning with aging, and may result in brunescent cataracts. Other chemical changes in lens proteins, such as diminished solubility, may interfere with lens transparency. Alteration in the chemistry of aqueous humor proteins may result in the blockage of aqueous drainage channels, allergic manifestations, and altered eye tissue membrane permeabilities.

Practical application to eye health is suggested. Crystallin lens absorption protects the eye from harmful near UV energy, and aphakic persons should have near UV absorbing spectacles instead of ordinary optical glass. Xenon arc photocoagulators emit near UV energy potentially harmful to the aqueous humor and lens, suggesting a need for filtration of these wavelengths.

BIOSYNTHESIS OF PROTEINS BY THE RETINA

Dr. Y. Matuk (Toronto)—when the incorporation of $^{14}C$-leucine into TCA precipitable material from cell-free systems consisting of pH 5 fraction and pH 5 fraction-ribosomal preparations obtained from beef

retina was studied, optimum concentrations of ATP, phosphocreatine, $Mg^{++}$, and $K^{+}$ were determined. In every case concentrations of these substances that were higher than the optimum were inhibitory. Retinol and retinal had no effect on incorporation of $^{14}C$-leucine but puromycin and ethanol inhibited the incorporation. Inhibition by cycloheximide was found to be dependent on the concentration of pH 5 fraction used.

EXPERIMENTAL OCULOMYCOSIS

Mr. S. M. Hasany and Drs. J. J. Kazdan and P. K. Basu (Toronto)—To study the possible mechanisms by which opportunistic fungi may become harmful to the cornea, rabbit eyes were pretreated locally with corticosteroids (Depomedrol and Decadron) for 10 days prior to fungal spore inoculation into the cornea. In another experiment, fungi were cultivated in media containing corticosteroid (Decadron) and then extracts and filtrates of the fungi were prepared. These were inoculated into normal untreated rabbit corneas.

The result of the first experiment showed that the pretreatment of the external eye with corticosteroids enhanced the frequency and severity of corneal ulcer formation as compared to control eyes which were inoculated by an identical method, but not treated with corticosteroid. The result of the second experiment showed that the fungi had enhanced metabolic activity (increase of dry weight, increase of optical density of the media) when corticosteroid was added to the media, and also that extracts and filtrates prepared from these fungi were more harmful to the cornea as compared to those produced from fungi which were not cultivated in corticosteroid-containing media.

P. K. Basu

## KRESGE EYE INSTITUTE ALUMNI 1971 CLINIC DAY PROGRAM

The 1971 Kresge Eye Institute Alumni Clinic Day program was presented at the David Whitney House, Wayne County Medical Society Auditorium, Detroit, Michigan, on Saturday, May 22, 1971.

Dr. Robert S. Jampel, Professor and Chairman of the Wayne State University Department of Ophthalmology, and Director of the Kresge Eye Institute, opened the program with a presentation of the floor plans and architectural drawings for the new Kresge Eye Institute Building, scheduled for completion in 1973. The new facility will provide space for basic research in the fields of pupillography, neurophysiology, biochemistry, and physiologic optics, as well as clinical facilities for electroretinography, ultrasonography, and fluorescein angiography. The pathology department will be expanded to three times its present size, and a large library and a lecture room for the basic science ophthalmology course is planned. In addition, there will be complete photography, contact lens, and prosthetic departments, along with clinical examining rooms provided for in the plans. The alumni were most appreciative of the effort put forth by Dr. Jampel to make the new facility an outstanding teaching center.

H. Saul Sugar reported on further developments in the use of deep lamellar resection of the cornea and sclera to remove epithelial cysts of the anterior chamber and ciliary body tumors. The final visual results were excellent, as were the clinical photographs.

William Sallee spoke on the advantages and disadvantages of soft contact lenses. Although the hydrophilic lenses are relatively easily tolerated, the disadvantages include maintaining continuous hydration, sterilization of the lenses, imperfect refraction correction, and limitation of astigmatic tolerance. The use of silicone or other "soft" gel materials may overcome these deficiencies.

Daniel T. Weidenthal presented his results in retinal detachment surgery. Reattachment was obtained in 90% of the cases. Approximately one-third of the cases obtained vision 20/50 or better; another third obtained vision of 20/50 to 20/200; and a third obtained only 20/200 or less. After successful reattachment surgery, there was a moderately good outlook as to treatment and final visual result of new holes.

Raymond R. Margherio spoke on the value of using an implant material (Gelfilm) in retinal detachment surgery. Because this material is absorbed gradually, there is less myopia following detachment surgery, and less likelihood of infection and extrusion of the implant.

Delbert P. Nachazel illustrated the use of radioactive $^{32}P$ in the diagnosis of intraocular masses. By exposing the sclera and performing selective counts in specific loci after an appropriate lapse of time, this test proved significantly valuable in differentiating hemorrhagic, inflammatory, and neoplastic lesions.

Ronald Goldman presented a series of orbital floor fractures corrected by the Caldawell-Luc approach. The use of maxillary antral packs was effective, and prevented the extrusion of orbital floor implants.

James A. Olson presented two cases of congenital anterior staphyloma, one bilateral. The corneas were grotesquely enlarged and bulged outwards through the palpebral fissures. Blindness was due to glaucoma following perforation of the cornea. Corneal infection, ulceration, and perforation appeared to be the dominant factor and congenital malformation of the anterior chamber angle was of secondary importance.

Craig W. George presented a case of a congenitally cystic globe. Repeated orbital surgery was required to eliminate the cystic mass during this patient's childhood; however, there was no direct communication of the cyst with the subarachnoid space.

Hugh Beckman discussed the use of lasers to perform iridectomies. After thorough testing in pigmented rabbits, the laser is now considered acceptable for clinical application in selected cases. The use of special intravenous dyes to concentrate specific wavelengths of laser light may aid in the use of laser surgery for lightly pigmented irides.

Ronald G. Agresta presented slides featuring the annual "smorgasbord" of interesting cases treated at Detroit General Hospital in the past year. This included a case of malignant melanoma with orbital extension and metastases to the breast in a young black woman, maxillary sinus carcinoma with a fulgating lesion the size of a fist which displaced the globe upwards and outwards, and the Meyer Schwickerath syndrome of bilateral microphthalmos and microcornea with bilateral acute congestive glaucoma.

Daniel R. Barr reported on the unusually high number of shotgun blast eye injuries seen at Detroit General Hospital. The clinical triad of hyphema, hypotonym, and chemosis usually indicates ocular perforation, and exploration of the orbit is indicated. The shotgun pellets may come to rest outside the globe; however, knowing the point of entry and the final resting place of the pellets enables the surgeon to plot their trajectory and determine whether the globe may have been perforated.

Henry Hirschman presented a three-year follow-up of 150 cataract operations using the intraocular iris-clip lenses. His success rate was high, and with the few complications encountered, this procedure may be more widely used in the near future.

Windsor S. Davies reported on the incidence of unsuspected uveal melanoma in evisceration contents submitted to the pathology laboratory. The ease of removing the scleral shell when malignant melanoma is found in evisceration contents lends support to the continued use of evisceration in indicated cases.

Michael Wainstock demonstrated the use of ultrasonography in the detection, localiza-

tion, and removal of intraocular foreign bodies, retinal detachment, intraocular masses and retrobulbar tumors.

Gerald T. Davies reported on the use of Dacron tape in frontalis sling operations. The material is easy to handle, stable, and ties well, causing little reaction at the knot site.

David Barsky reported on a fungus endophthalmitis occurring after perforation of a corneal ulcer. This elderly cardiac patient had undergone cataract surgery and had been maintained on topical antibiotic-corticosteroid drops for a long period. The need to suspect fungus infection in indolent corneal ulcers was emphasized.

The clinic ended following a brief business meeting and plans were made to schedule Saturday, May 20, 1972, for the next Alumni Clinic Day.

David Barsky

---

OPHTHALMIC MINIATURE

Molenaer tended towards crowded scenes, while his early warm, clear colors gave way to overall brown tones. Perhaps in Molenaer's case—as in the case of Degas, whose bright palette gradually changed towards a predominance of monotonous reds and browns as he grew older—this evolution in coloring was due to slowly developing cataracts, a theory that has been convincingly suggested by the London ophthalmologist and art connoisseur, Patrick Trevor-Roper.

## THE SECTION IS DEAD. LONG LIVE THE SECTION COUNCIL!

Many individuals within and without the AMA have been predicting the demise of the Section on Ophthalmology. However, the 91-year-old "adult" was alive and well at the recent meeting in Atlantic City. Over 250 guests registered attendance during the two-day scientific program. Algernon B. Reese, Distinguished American Guest, spoke on pigmented lesions in and about the eye as culled from his vast personal experience. Hans-Walther Larsen, Distinguished Foreign Guest, discussed angioid streaks in patients with and without pseudoxanthoma elasticum as studied in a series of patients that he has been following in Copenhagen. A highlight of the meeting was a symposium on the management of common uveitis syndromes chaired by David L. Knox of Baltimore.

In addition, 21 short presentations were offered. These covered the spectrum of medical and surgical aspects of clinical ophthalmology. As seen and heard from the podium it is difficult (and dangerous) to select those papers which stood above the others, but from a biased standpoint a few come to mind.

Electric cataracts described by Hanna and Fraunfelder was an electrifying presentation. Aphakic pupillary block treated with vitriotomy by Cotlier and Herman and discussed by Scheie provided food for thought. A young ophthalmologist, Guggino, a masterful discussion of the home measurement of intraocular pressure. This evoked much discussion from the audience, one of the unique features of the AMA meeting. Best and Galin made careful clinical studies of fluorescein angiography in glaucomatous patients using suction-cup ophthalmodynamometry. Levene of New York City and Rieser and Schwartz of Boston provided new insight into the problem of malignant glaucoma. The surgical treatment of eyelid retraction was well presented by Putterman and Urist. Solar retinopathy resulting from sun gazing while under the influence of LSD stimulated considerable comment. In the discussion it was noted that the sun cannot produce a photocoagulation burn, which was news to some of us.

In order to prove that ophthalmology is not unrelated to general medicine Christensen and Pettit discussed optic nerve involvement in ulcerative colitis. Roth and Foos likewise presented a superb study of eye findings in hemochromatosis, and their paper was selected as the most deserving of the Knapp Fund award for 1971.

Ten ophthalmic exhibits were of high caliber. Televised fluorescein angiography in the human fundus by Van Heuven, Schaffer, and Mehu of Albany was selected for the Knapp award. This method bids fair to add a new dimension to angiography, since the light input is minimal and analyses can be made instantaneously.

In keeping with the dictates of the AMA at large, the 91-year-old Section on Ophthalmology passes out of existence at the end of the current year. It will be replaced with a new Section Council consisting of representatives from the various large ophthalmic societies. Chosen to lead this new venture is Bernard Becker, as chairman, and Joseph M. Dixon, as vice-chairman. Falls and Jaeckle will continue to represent ophthalmic interests in the AMA House of Delegates as Delegate and Alternate Delegate, respectively. Davis will continue as representative for exhibits and Duane will serve as secretary and representative for programs.

The Section is dead. Long live the Section Council!

Thomas Duane

## THE INTERNATIONAL EYE FOUNDATION

### A Decade of Progress*

In 1960, the late Doctor Thomas A. Dooley, who had committed his brief life's work to the developing countries of Southeast Asia, discussed with me the need for more and better eye surgical care among his patients. He particularly emphasized the large number of blind persons suffering from corneal scarring or disease. Tom was told that efforts would be made to organize trained eye surgeons to survey these areas with a view to attempting to offer some help.

On Tom Dooley's last trip to the Orient, he was hospitalized in Hong Kong for a back ailment which later proved to be metastatic melanoma. Upon his return to the United States, he stated that he had promised the ophthalmologists there that a team would be forthcoming to aid them in establishing an eye bank and in learning the techniques of cornea grafting. In early 1961, the International Eye Bank (IEB) was formed, and ironically, Tom Dooley's eyes were among the first to be donated to the bank. He died on January 18, 1961.

The IEB was organized as a facet of Medico, Dooley's dream, and the medical arm of Care. Donor eye tissues were shipped to other countries where they were des-

*Abstracted by the author from his presentation before members and guests attending the Foresight luncheon during the First Congress of the Society of Eye Surgeons, Washington, D.C., May 27, 1971.

perately needed but were not available because of religion, custom, or law.

At the request of the Hong Kong Ophthalmological Society, a team of three ophthalmic surgeons (the late John M. McLean, Charles E. Iliff, and I) went to the British Crown Colony in the Fall of 1961. The number of blind persons in Hong Kong was large—greatly disproportionate to the total population. Many of these were refugees who had been "dumped" by Communist China. A large number suffered from curable corneal blindness. The local eye surgeons were well trained, but had little knowledge of grafting because of a total lack of donor materials. The first teaching mission was successful beyond every expectation—35 demonstration operations were performed, and the Chinese ophthalmologists organized an effective eye bank.

Fresh donor eyes and glycerine-preserved corneas were sent by air to numerous countries, and more teaching teams were requested. It became obvious that eye tissues alone were not the answer—teaching in all aspects of ophthalmic surgery was desired. Voluntary teams were sent to many countries, and an 80-bed eye unit was established in Algiers, manned by Johns Hopkins University. Virtually every area of the world was visited by a volunteer or a team, and assistance was given in forming eye banks where requested.

In 1965, the International Eye Bank became a branch of the IEF, and in maintaining its primary purpose of teaching, the functions of the IEF, were expanded far beyond corneal surgery. By 1968, the IEF had outgrown the financial support available from CARE-MEDICO and reluctantly left this organization to become an independent foundation. It adopted the slogan, "The promotion of peace through the prevention and cure of blindness worldwide." Perhaps this was an exaggerated ambition, but it provided challenge to ophthalmologists of the "have" nations to help those in the developing and "have not" nations. The IEF was not designed as a missionary effort, however, and it continued to offer a self-help, people-to-people program with every effort geared to teaching. Each program was time-limited, planned as a cooperative mission with the host country, and intended to be terminated when a developing nation became self-sufficient with trained ophthalmologists.

Exchange fellowships were established with the donations of generous laymen, and the Bunker, Carrigan, Clagett and Hermann fellowships became well known. Funds were raised through social affairs; private foundations were established, several industries associated with ophthalmology gave generously, as did many individual ophthalmologists who became members of the IEF's Foresight Club. Programs were expanded as more funds were forthcoming, but within a very few years, we found we had a "tiger by the tail"—only a small number of the many requests could be implemented.

The sponsorships of ophthalmologists volunteering their services and the support of the Eye Bank Association of America made the IEF a progressive teaching organization, attempting to fulfill an urgent need in international ophthalmology, concentrating upon clinical aspects.

During the past 10 years, 323 fellowships have been sponsored—170 from this country and 153 from other countries. These are short-term, limited to a maximum of six months. Junior fellowships are offered to ophthalmology residents in their last three months of formal training and senior fellowships are granted to those who have completed residencies.

At six universities or large government hospitals in other countries, units have been established in which fellows from the United States are rotated, while the young ophthalmologists from other countries are sponsored for short-term general or sub-specialty ophthalmic training in the United States. Student ophthalmologists from other countries are selected by the ophthalmic Societies in their homelands to be given training in

facets of ophthalmology sometimes lacking in their own teaching hospitals. An increasing number of young ophthalmologists in this country are requesting these assignments abroad in order to obtain more surgical experience, especially since the advent of Medicare and Medicaid, which has seriously reduced surgical training in some areas of the United States. In addition, these volunteers have the satisfaction of knowing they have added "pair of hands" to reach some of the curable blind in a country where there are too few ophthalmologists and too many persons without sight. While our young men serve in institutions abroad, they are responsible to the Director of the Department of Ophthalmology, a highly trained and capable individual dedicated to teaching.

The International Eye Bank has shipped over 6000 corneas to 55 countries during the past decade. These have come from virtually every eye bank in the United States. In addition, this most important branch of IEF has assisted in the establishment of 29 eye banks in 26 countries.

Visiting full-time professors are sponsored for teaching tours abroad. Visiting surgeons, in private practice and with clinical teaching posts at universities, are partly sponsored, usually for longer tours.

The Pan American Association of Ophthalmology has sponsored 30 fellows from 13 Latin American countries to the excellent basic science courses given in Spanish at the University of Puerto Rico. They return home to complete training and then to treat their own people.

The urgent need for teaching units in countries such as Indonesia, where there are many blind persons, has been partly answered by a small grant from USAID, pinpointed to certain areas.

A much-needed, new and exciting program has recently been established. Short courses are being instituted for the training of ophthalmic assistants in Indonesia and in Pakistan. As a result of this program, the few ophthalmologists now practicing in these countries will be able to examine and treat more patients; thus, their skills will be directed where they are most needed. A full-time ophthalmic technician on the IEF staff is in charge of these programs. United States-trained technicians have volunteered to assist with courses on short-term tours.

The Society of Eye Surgeon (SES), established in 1969 as the medical facet of the IEF, has given much impetus to IEF's progress. A report of its first meeting is given elsewhere in this journal. Its membership is worldwide. Funds derived from the SES are applied solely to the support of exchange fellowships and to units abroad—none are used for administration.

The IEF is a unique organization—a small, public foundation, non-sectarian and non-governmental, volunteering its abilities to upgrade eye surgical care throughout the world. Established ophthalmologists give their services, and at the same time donate money, to sponsor young ophthalmologists who need further surgical training and experience. This is a "two-way road"; it is not only a humanitarian effort by our specialty, it also makes ophthalmology a potent worldwide diplomatic force.

We are deeply involved in teaching and in trying to help others. The IEF has become well known and highly respected over the past 10 years. With the continued assistance of our lay donors and ophthalmologists of all nations, it will do more during the next decade.

The supporters of the International Eye Foundation could well have written these words of Louis Pasteur, a scientist dedicated to helping the unfortunate of all nations: "One does not ask of one who suffers, 'What is your country and what is your religion?' One merely says, you suffer; this is enough for me. You belong to me and I shall help you."

J. H. King, Jr.
*Washington, D.C.*

## CORRESPONDENCE

### Eye pad flammability

Editor,
American Journal of Ophthalmology:

Authors Weiss and Skalka recently reported the dangerous flammability of eye pads (Am. J. Ophth. 71:1344, 1971). I would like to re-emphasize their concern. A 48-year-old patient, on whom I had performed an uneventful cataract extraction five weeks previously, called to say that 10 hours earlier this eye pad covering his operated eye had caught on fire while he was attempting to light a cigarette over a gas stove. He sustained second and third degree burns of the face and eyelids with tremendous swelling of the eyelids. Fortunately, the eye itself was not injured, and the burns responded to antibiotics and compresses applied in the hospital. Several weeks later his eye was back to normal, with 20/30 corrected vision.

We should caution smokers, especially those who we know to combine this with heavy alcoholic intake, as to this potential danger.

Frank J. Weinstock
*Canton, Ohio*

---

### Transpupillary cyclophotocoagulation

Editor,
American Journal of Ophthalmology:

In Figures 3, 4, 8, and 9 of the article entitled "Transpupillary cyclophotocoagulation of rabbit eye," by myself and Oleg Pomerantzeff (Am. J. Ophth. 71:911, 1971), the structure labeled *cb* is the iris and the structure labeled *s* is corneal stroma. In Figures 3 and 4, the iris and ciliary body were displaced toward the cornea, while in Figures 7 and 9, the sections were equatorial and the calotte cut unevenly so that some corneal tissue remained. I regret the inconvenience caused by this error.

Pei-Fei Lee
*Boston, Massachusetts*

## BOOK REVIEWS

Ultrastructure of the Peripheral Nervous System and Sense Organs. Atlas of Normal and Pathologic Anatomy. By Jean Babel, Albert Bischoff, and Heinrich Spoendlin. St. Louis, C. V. Mosby, 1970. Clothbound, 452 pages, table of contents, index, 203 black and white figures. $45.25.

This is an atlas of electron microscopic pictures concerned with the peripheral nerve, the auditory, vestibular, olfactory, and gustatory organs, as well as the retina.

The first part is written by Bischoff, a neurologist in Zurich. He covers especially the normal anatomy and the general pathology of peripheral nerves. This is a most instructive introduction to the ultrastructure of these organs and the coverage seems to be quite complete. In the chapter on special pathology, Bischoff concerns himself mainly with metabolic diseases affecting the peripheral nerve. The chapter on motor end plate is illuminating.

The second part of the book deals with various sensory end organs and is by Spoendlin, an otolaryngologist in Zurich.

Ophthalmologists will be mainly interested in the third part of this book which is concerned with the retina. It is written by J. Babel, professor of ophthalmology at Geneva. Dr. Babel discusses the normal anatomy of the retina first and illustrates it mainly with specimens from the rabbit which are fixed much more quickly than human material. The pathologic considerations of the retina center around toxic damage to this organ; damage produced by monoiodacetate, sodium iodate, chloroquine, and iron are especially well covered. The presentation is lucid and instructive.

The pictures are of superb quality and reproduced in an exemplary manner. It is indeed an esthetic pleasure to look at this book and study it. The accompanying text is short, but to the point. The references are most helpful.

F. C. Blodi

# ABSTRACT DEPARTMENT

EDITED BY DAVID SHOCH, M.D.

## ANNALES D'OCULISTIQUE

INTOLERANCE TO SILICONE SPONGES IN SURGERY OF DETACHMENT OF THE RETINA. (French) Rouchy, J. P. (11, avenue Elisee-Reclus, Paris-7e), Ann. Ocul. 204: 55-65, Jan., 1971.

There were no infections in 140 cases in which silicone sponges were used as either implants or explants for retinal detachment surgery. However, nine caused irritation severe enough to require removal. In none of these cases did a retinal detachment follow.—David Shoch

## ARCHIV FÜR KLINISCHE UND EXPERIMENTELLE OPHTHALMOLOGIE

THE FINE STRUCTURE OF THE SO-CALLED OUTER LIMITING MEMBRANE IN THE HUMAN RETINA. (German) Spitznas, M. (Dept. Ophth. Univ. of Cal., San Francisco, Cal. 94122), Arch. Klin. Exp. Ophth. 180:44-56, 1970.

The outer limiting membrane is not a true membrane but appears under the electron microscope as a layer of intracellular, cytoplasmic densities which should be considered as zonulae adhaerentes. The latter are a special type of intracellular junction which have primarily a mechanical function. (8 figures, 22 references)—Walter Segall

PRACTICAL SIGNIFICANCE OF THE PROVOCATIVE TESTS IN GLAUCOMA. (German) Makabe, R. (Univ. Augenklinik, D-6000 Frankfurt a.M., Germany), Arch. Klin. Exp. Ophth. 180:193-203, 1970.

At least three of the five provocative tests (Priscol, water drinking, darkroom, mydriasis and caffeine test) were performed in 100 eyes with incipient simple glaucoma. The results of these tests showed significant positive relationship to simple tonometry and diurnal variations of intraocular pressure. (10 tables, 15 references)—Walter Segall

THE IMPROVED EVALUATION OF PROVOCATIVE TESTS IN GLAUCOMA. (German) Makabe, R. (Univ. Augenklinik, D-6000 Frankfurt a.M., Germany), Arch. Klin. Exp. Ophth. 180:204-210, 1970.

In 231 patients with incipient chronic simple glaucoma three out of five provocative tests (darkroom, mydriasis, caffeine, Priscol and water drinking) were performed. The percentage of pathologic results is as follows: water drinking test 52.5%, Priscol test 48.2%, mydriasis, darkroom and caffeine test 20.0% (3 figures, 16 references)—Walter Segall

COMPARISON OF THE PROVOCATIVE TESTS FOR GLAUCOMA WITH EACH OTHER. (German) Makabe, R. (Univ. Augenklinik, D-6000 Frankfurt, Germany), Arch. Klin. Exp. Ophth. 180:211-216, 1970.

In 231 patients with incipient chronic simple glaucoma three out of five provocative tests were performed (Priscol, water drinking, mydriasis, darkroom and caffeine test). There was no significant relationship between the results of the water drinking test and the Priscol test. However, the results of the Priscol test showed relationship to those of caffeine, the darkroom and the mydriasis test; there was also a significant relationship between mydriasis and darkroom test. (1 table, 18 references)—Walter Segall

ELECTRON MICROSCOPIC STUDIES OF THE CHANGES DUE TO AGE IN THE ZONULA ZINNII OF THE HUMAN EYE. (German) Gaertner, J. (Univ. Augenklinik, D-6500 Mainz, Germany), Arch. Klin. Exp. Ophth. 180:217-230, 1970.

Eight human eyes were studied from patients 9 months to 78 years old. The fibrils and the cement substance of the zonular fibers are produced by fibroblasts located in the region of the Zonula Zinnii especially close to the pars plana. The cilio-zonular basement membrane consists of one layer in juveniles; in adults it forms a multilayered meshwork with granular and lamellar deposits, probably lipids. With increasing age the zonular fibril bundles

show degenerative changes. (7 figures, 23 references)—Walter Segall

VASCULITIS OF THE MARGINAL ZONE OF THE RETINA. (German) Slezak, H. (Augenklinik der Universitat Wien), Arch. Klin. Exp. Ophth. 180:267-272, 1970.

Sometimes sheathed vessels can be seen in the periphery of the retina in eyes with dust-like opacities of the vitreous body; it can be differentiated from peripheral uveitis and from the peripheral form of Eale's disease by biomicroscopic examination and fluorescein angiography. (6 figures, 14 references)—Author's abstract

STUDIES ON THE ALTERED ETIOLOGY OF HYPOPYON ULCER. (German) Bock, J. and Flamm, H. (Augenklinik und Hygiene-Institut), Arch. Klin. Exp. Ophth. 180: 299-316, 1970.

As Ps. pyocyanea and Staph. aureus become more resistant to antibiotics, these germs seem to replace the previously dominant Pneumococcus as the main cause for hypopyon ulcer of the cornea. The cause of this shift seems to lay not only in the propagation of these germs by air humidifiers, contaminated eye-drops, contact lenses etc., but also by the widespread use of antibiotics in ophthalmology. Experimental results show that the primary resistance of the rabbit cornea against Ps. pyocyanea can be reduced by local application of chloromycetin drops. This fact should warn ophthalmologists to reduce the often unnecessary and uncontrolled use of antibiotics as much as possible. (2 tables, 117 references)—Authors' abstract

EXAMINATIONS OF TENSILE STRENGTH OF GLUE AND SUTURED ISOLATED CORNEOSCLERAL STRIPS. (German) Giessmann, H. G., Schlote, H. W., Tuchscherer, V. and Zeller, R. (Augenklinik der Medizinischen Akademie Magdeburg), Arch. Klin. Exp. Ophth. 181:17-24, 1970.

The tensile strength of 10 mm wide corneoscleral strips from cow-eyes was measured using sutures and glue wounds. Glued strips showed at least an equal tensile strength to sutured ones, and in several cases it was significantly higher. (10 figures, 1 table, 16 references)—Authors' abstract

## ARCHIVES D'OPHTALMOLOGIE

CONCERNING 17 CASES OF RETINAL DETACHMENT IN CHILDREN. (French) Farnarier, G. and Alessi, F. (C.H.U., Hopital Nord, 13-Marseilles, XV$^{e}$, France), Arch. Ophtal. 30:277-290, Apr., 1970.

Cases reported stress the frequency of trauma as the etiology, with poor prognosis in high myopia and with prolonged duration of detachment. (3 tables)—Maurice Kadin

ROLE OF THE CORNEA AND LENS IN BIOMETRY OF THE NORMAL ANTERIOR CHAMBER. (French) Delmarcelle, Y., Collignon-Brach, J. and Luyckx-Bacus, J. (Clinique ophtalmologique, Hopital de Baviere, 66, boulevard de la Constitution, Liege, France), Arch. Ophtal. 30:291-300, Apr., 1970.

Utilizing optical biometry and ultrasonography, the authors studied the influence of the cornea and lens on the anterior chamber depth. The anterior depth of the anterior chamber depends on corneal radius of curvature, diameter, thickness and peripheral flattening. The posterior portion depends on the position of the lens insertion and its thickness, and can be measured by ultrasonography. This is the most variable factor, and determines the degree of the opening of the chamber angle. (5 figures, 1 table, 9 references)—Maurice Kadin

PHOTOCOAGULATION OF ANGIOID AFTER FLUORESCEIN ANGIOGRAPHY. (French) Offret, G., Coscas, G. and Orsoni-Dupont, C. (16, rue Logelbach, Paris (XVIIe), France), Arch. Ophtal. 30:419-422, May, 1970.

The authors present two cases in which photocoagulation of angioid streaks was done following fluorescein angiography with the object of preventing extension into the macular area and chorioretinal hemorrhages. (4 figures)—Maurice Kadin

CHROMATIC VISUAL DISTURBANCES IN CENTRAL SEROUS CHORIORETINOPATHY. (French) Coscas, G. and Legras, M. (192 bis, rue de Vaugirard, 75-Paris, XV$^{e}$, France), Arch. Ophtal. 30:491-496, June-July, 1970.

Disturbances of color vision, usually yellow-blue dyschromatopsia, occur in central serous retinopathy before visual loss. (1 figure, 1 table, 15 references)—Maurice Kadin

REFSUM'S DISEASE. (French) Rougier, J. (4, rue de la Charite, 69-Lyon (2e), Arch. Ophtal. 30:665-672, Oct., 1970.

Refsum's disease described in 1945 comprises a neurological syndrome with chronic polyneuritis and cerebellar ataxia, an ophthalmological syndrome with hemeralopia, a shrinking of the field of vision and atypical pigmentary retinitis and a biological syndrome consisting in the presence of phytanic acid in serum. The author reports on the observation of a family in which the father and the mother present no lesions. Elder brother and sister present a complete Refsum's disease and the younger brother has only modifications of the adaptometric curve. The last child shows no clinical or biological signs. (5 figures, 8 references)—Author's abstract

CAN RETINOPATHY BE PREVENTED BY A MORE PHYSIOLOGICAL TREATMENT OF DIABETES? (French) Tutin, M., Tchobroutsky, G. and Guyot-Argenton, C. (7 bis, rue Lesueur, Paris (XVIe), Arch. Ophtal. 30:697-700, Oct., 1970.

In all aspects of diabetes mellitus there exists an inadequate insulin secretion which explains the development of retinopathy. Therapy should aim towards a closer approximation to physiological conditions and multiple insulin injections are proposed. (4 references)—Authors' abstract

HYPERLIPIDEMIA AND DIABETIC RETINOPATHY. (French) Moreau, P. G. and Pichon P. (10, boulevard de la Trémouille, 21-Dijon), Arch. Ophtal. 30:757-768, Nov., 1970.

After a surgey of the different lipids of the body we can understand the five groups of hyperlipidemia described by Fredrickson. We have summarized by easier and most valuable laboratory analyses. Hyperlipidemic retinopathy in fact is frequent and proofs are statistical and experimental; the ophthalmoscopic disorders are described and are correlated with the five groups of hyperlipidemia of Fredrickson. Consequently diabetic retinopathy appears like a kind of hyperlipidemic retinopathy and some arguments verified this proposal. Triglycerides seem to be of great importance in the disease. (10 figures, 16 references)—Authors' abstract

ULTRASTRUCTURAL STUDY OF CORNEAL THICKENING IN THE COURSE OF CHLORPROMAZINE TREATMENT. (French) Pouliquen, Y., Graf, B., Bisson, J., Feuvrier, Y.-M. and Delattre, A. (22, rue Henri-Heine, 75-Paris (XVIe), Arch. Ophtal. 30:769-782, Nov., 1970.

A fragment of the cornea of a patient with corneal thickening due to phenothiazine was examined under electron microscope. A stimulation of melanogenesis at the level of the epithelium and a diffuse excess of anterior stroma due to the drug or its metabolites were observed. The keratocytes react phagocytically to this thickening. (16 figures, 5 references)—Authors' abstract

PROSTAGLANDINS IN OPHTHALMOLOGY. (French) Demailly, P., Saindelle, J. and Saindelle, A. (71, avenue Kleber, 75-Paris (XVIe), Arch. Ophtal. 31:53-62, Jan., 1971.

Prostaglandins E and R have been isolated by chromatographic methods from the iris of various species. This tissue is also able to synthetize prostaglandin in vitro. Injected into anterior chamber of the eye, prostaglandin induces a long-lasting miosis, which is not modified by atropine. (7 figures, 21 references)—Authors' abstract

OPHTHALMIC HERPES ZOSTER: ISOLATION OF A VIRUS STRAIN FROM THE AQUEOUS HUMOR. (French) Denis-Lassalle, J., Clay, C., Cherardi-Bakalova, M. and Offret, G. (Hotel-Dieu, place du Parvis Notre-Dame, Paris), Arch. Ophtal. 31:109-118, Feb., 1971.

A patient had severe ophthalmic herpes zoster and at the end of the second month of the disease a virus was isolated from the aqueous. This may account for the associated uveal inflammation seen in this disease. The characteristic histologic lesion appears to be leukocytic infiltration around ciliary vessels and nerves similar to that seen in a hypersensitiv-

ity phenomenon. (1 figure, 39 references)—David Shoch

THE ELECTRO-OCULOGRAM. (French) Dorne, P. A. and Espiard, J. F. (Lyon, France), Arch. Ophtal. 31:217-224, Mar., 1971.

The most interesting use of the electro-oculogram is the fact that its extinction is pathognomonic of vitelliform degeneration of the macula. It helps to confirm this diagnosis at any ophthalmoscopic stage and also helps to find gene carriers with normal fundi. (4 figures, 1 table, 5 references)—David Shoch

A CLINICAL STUDY OF COLOR SENSE DISTURBANCES DURING OPACIFICATION OF THE CRYSTALLIN LENS AND AFTER CATARACT EXTRACTION. (French) Karantinos, D. (26, rue de l'Universite, Athens, Greece), Arch. Ophtal. 31:235-244, Mar., 1971.

Color sense disturbances begin as soon as the opacification of the lens starts and discrimination becomes worse as the cataract progresses. Postoperatively there is a great color sense disturbance for the first few days after the operation. Six months later most of the cases have a normal color sense. Cyanopsia and erythropsia were observed in a few patients. The Farnsworth 100-Hue test gives the most reliable results and the Ishihara pseudoisochromatic plates the least reliable. (2 figures, 5 tables, 32 references)—David Shoch

DIABETIC RETINOPATHY. (French) Adle, E. H. and Samii, F. (293, avenue Takte-Jamshid, Teheran, Iran), Arch. Ophtal. 31:259-262, Mar., 1971.

In the authors' series of 100 patients with diabetic retinopathy a very strict control of the diabetic state with diet and insulin resulted in an improvement in the retinal changes. Recurrences were observed when diabetic control was lost. The addition of anabolic steroids, Vitamin C, P, and K did not improve the results. (1 table, 2 references)—David Shoch

## ARCHIVES OF OPHTHALMOLOGY

KERATOMYCOSIS. Polack, F. M., Kaufman, H. E. and Newmark, E. (College of Medicine, University of Florida, Gainesville, Florida), Arch. Ophth. 85:410-416, Apr., 1971.

Since the increased use of topical steroids there has been a parallel increase in the incidence of corneal mycotic infections. The authors discuss a series of 33 patients, in 17 of whom there was a previous history of injury with vegetable matter. Eight of the patients had been treated with steroids and antibiotics. Twenty-two of the patients required surgical procedures to control the infection. This included keratectomies, conjunctival flaps and penetrating keratoplasties. (9 figures, 2 tables, 19 references)—David Shoch

PSEUDOPAPILLEDEMA OF JUVENILE DIABETES MELLITUS. Lubow, M. and Makley, Jr., T. A. (Ohio State University Hospitals, Means Hall 25, Columbus, Ohio 43210), Arch. Ophth. 85:417-422, Apr., 1971.

Optic disc edema with neovascularization, peripapillary hemorrhages, and exudates mimicking true papilledema occurred in three teenaged patients with long-standing juvenile diabetes mellitus controlled by insulin. Despite the appearance of papilledema, the unusual signs, symptoms, and course of this syndrome suggest that it is an ischemic manifestation of diabetic microangiopathy within the optic papilla in the absence of adequate collateral circulation. This report confirms the existence of a diabetic optic neuropathy, and discusses its vascular pathogenesis and management. (13 figures, 11 references)—Authors' abstract

INTRAOCULAR PRESSURE IN DIABETES. Bouzas, A. G., Gragoudas, E. S., Balodimos, M. C., Brinegar, C. H. and Aiello, L. M. (59 Skoufa, Athens 135 Greece), Arch. Ophth. 85:423-427, Apr., 1971.

The intraocular pressure of 101 unselected diabetics was correlated to the presence of retinopathy, the blood glucose level, and various clinical factors. The following conclusions were drawn: (1) The mean intraocular pressure in unselected diabetics is not different from that of the general population. There is no difference in mean pressure between juvenile and maturity-onset diabetics. (2) Sex, present age, duration of diabetes, blood pressure, blood glucose level, and type of antidiabetic therapy showed no relation to the intraocular pressure. (3) The presence or absence of retinopathy was not related to the intraocular pressure in these patients with pressures still within normal limits. These essentially

negative results support several earlier studies. They differ from some reports originating mainly from ophthalmological clinics, in which differences have been reported. (2 figures, 2 tables, 35 references)—Authors' abstract

MEDRYSONE HYPERSENSITIVITY. Smolin, G. (Francis I. Proctor Foundation, University of California, San Francisco Medical Center, San Francisco 94112), Arch. Ophth. 85:478-479, Apr. 1971.

A patient treated for an inflamed pinguecula with 1% medrysone (HMS) developed a typical delayed hypersensitivity reaction. This was established as a reaction to the medrysone rather than to any of the substances in the vehicle. (6 references)—Author's abstract

## BRAIN

ACQUIRED LESIONS OF THE FOURTH CRANIAL NERVE. Burger, L. J., Kalvin, N. H. and Smith, J. L. (Department of Ophthalmology, University of Miami School of Medicine, Miami, Florida), Brain 93:567-574, 1970.

Thirty-three cases were included in this study of isolated acquired fourth nerve palsy. The three commonest causes were injury, vascular disease, and diabetes. The subjective red glass Bielschowsky test and observation of the patient's head posture are simple methods for diagnosis of superior oblique weakness. (14 references)—Joel G. Sacks

## BRITISH JOURNAL OF OPHTHALMOLOGY

KERATINOID CORNEAL DEGENERATION. Garner, A. (Institute of Ophthalmology, Judd Street, London, England), Brit. J. Ophth. 54:769-780, Dec., 1970.

Globular hyaline deposits in the superficial stroma and epithelium of the cornea have been recognized under a variety of names for many years. Sometimes seen as an isolated phenomenon, they are usually observed in association with other corneal disorders, and the present report is concerned with their occurrence in three cases of lattice dystrophy, one of subepithelial corneal fibrosis, and one of post-traumatic scarring . . . . Histochemical analysis indicates that the deposits are composed essentially of protein and suggest that they may be related to keratin, possibly as a precursor or incomplete form. In the absence of an existing satisfactory terminology, it is proposed that the process wherein the sulphur-rich globular deposits are formed be referred to as keratinoid corneal degeneration. The multiplicity of the corneal disorders in which the abnormal material is formed implies that the keratinoid deposits do not constitute a separate disease entity so much as a special type of response which may be stimulated in a variety of ways. (15 figures, 1 table, 27 references)—Author's abstract

PARTIAL EVULSION OF OPTIC NERVE. Hart, J. C. D. and Pilley, S. F. J. (Western Ophthalmic Hospital, London), Brit. J. Ophth. 54:781-785, Dec., 1970.

A case of partial evulsion of the optic nerve is presented in which fluorescein angiography was performed. The study demonstrated that, in spite of the extensive nature of the injury, the major retinal vessels were minimally affected with transit of dye through both arteries and veins. The only vessels significantly affected were small vessels in the region of the disc. The field loss was due to rupture of nerve axons at the margin of the disc. (4 figures, 9 references)—Authors' abstract

INTRAOCULAR PRESSURE REDUCTION AND VITREOUS MASS. Robbins, R., Obstbaum, A. S., Best, M. and Galin, M. A. (New York Medical College, New York), Brit. J. Ophth. 54:801-804, Dec., 1970.

Retrobulbar anesthesia and the use of acetozolamide reduce intraocular pressure in the undisturbed rabbit eye, but do not alter vitreous weight. The former technique may be beneficial in lens extraction procedures in that it counteracts the mechanical forces which tend to extrude vitreous. The use of acetazolamide is of no value in preventing vitreous loss. (3 tables, 8 references)—Authors' abstract

FLAT ANTERIOR CHAMBER AND CHOROIDAL DETACHMENT IN APHAKIA. Shah, R. R. (Rajkot, Gujarat, India), Brit. J. Ophth. 55:48-49, Jan., 1971.

In 500 cases of cataract extraction the incidence of choroidal detachment was 2.6% and that of shallow anterior chamber was 13.5%, and there was no regular relationship between

the two conditions. The eyes were treated conservatively and these complications did not affect the ultimate visual acuity or intraocular pressure. (4 references)—Author's abstract

ISCHEMIC OPTIC NEUROPATHY IN CHRONIC SIMPLE GLAUCOMA. Begg, I. S., Drance, S. M. and Sweeney, V. P. (Department of Ophthalmology, 2550 Willow Street, Vancouver, Canada), Brit. J. Ophth. 55: 73-90, Feb., 1971.

The occurrence of discrete, recurrent, and sometimes bilateral hemorrhages in sectors of the disc, in the region of the arcuate nerve fibers, associated with fresh absolute field defects in the Bjerrum area was thought to characterize symptomless ischemic optic neuropathy. These changes were observed in three patients with ocular hypertension, marking the transition to chronic simple glaucoma. A similar sequence marked the progression of field loss in four patients with chronic simple glaucoma. The general neurovascular assessment of the patients, their level of intraocular pressure at the time of the field loss, and the ophthalmodynamometric findings suggested that the ischemic optic neuropathy in this group of patients was probably due to small vessel disease, producing inadequate perfusion of the optic nerve head. Adverse perfusion pressures were seen in only some of this group of patients, which suggests that there are many causes for poor perfusion at the optic nerve head. An imbalance between intraocular pressure and vascular pressure, while common, is not the only cause of a nerve fiber bundle infarction indistinguishable from that found in chronic simple glaucoma. (1 table, 18 figures, 22 references)—Authors' abstract

EXPERIMENTAL OCULAR SCHISTOSOMIASIS. Abboud, I. A., Hanna, L. S. and Ragab, H. A. A. (Cairo University, Egypt), Brit. J. Ophth. 55:106-115, Feb., 1971.

The injection of suspensions of cercariae subconjunctivally in animals did not cause ocular lesions, but produced generalized schistosomiasis. The instillation of cercariae on to the eyelids and conjunctiva also produced generalized schistosomiasis. Injection of cercariae into the anterior chamber of guinea-pigs resulted in an aqueous flare, keratic precipitates, and hypopyon, but generalized schistosomiasis did not develop. The eyes of animals previously infected with cercariae of S. mansoni through the intraperitoneal route revealed no ocular lesions. The eyes of 150 patients suffering from schistosomiasis showed subconjunctival hemorrhages in twelve and flame-shaped retinal hemorrhages in three. It is concluded from the experimental results that the theory of the local route of infection through the eye cannot account for ectopic schistosomal ocular lesions. Generalized schistosomiasis can be produced by cercarial penetration through either the eyelids or the conjunctiva. It is also concluded that schistosomiasis does not affect the ocular structures, except in the form of rare ectopic lesions. (6 tables, 5 figures, 25 references)—Authors' abstract

LACTIC DEHYDROGENASE ACTIVITY OF AQUEOUS HUMOUR IN RETINOBLASTOMA. Dias, P. L. R., Shanmuganathan, S. S. and Rajaratnam, M. (Dalrymple Hall, 22 Bellhaven Terrace, Glasgow, W.2., Scotland), Brit. J. Ophth. 55:130-132, Feb., 1971.

LDH activity in the aqueous humour of 46 patients with non-malignant intraocular disorders ranged from 0 to 350 units/100 ml. The four cases of retinoblastoma studied gave values of 1800, 2100, 1600, and 3250 units/100 ml. Since LDH activity in the aqueous humour is greatly elevated in retinoblastoma, it seems likely that the estimation of LDH activity in the aqueous humour may be of value in the diagnosis of intraocular malignancy. (2 tables, 7 references)—Authors' abstract

## BULLETIN DE LA SOCIETE BELGE D'OPHTALMOLOGIE

THE OCULAR MANIFESTATIONS OF CONGENITAL ERRORS OF METABOLISM. (French) Goux, J. P. and Kallay, O. (Clinique ophtalmologique de l'Universite de Louvain), Bull. Soc. Belge Ophtal. 157:9-319, 1971.

This excellent monograph begins with an introduction on the relationship of enzyme biochemistry to genetics. The various congenital anomalies are then considered under various headings. The first chapter is on carbohydrate defects such as galactosemia and galactokinase deficiency. The second chapter is on amino acid metabolic problems. The third chapter is on lipids and the fourth chapter is on Wilson's disease. The last two chapters are on specific tissue disorders, diseases of the conjunctiva and bone and epithelial transport disease. (84 figures)—David Shoch

## JAPANESE JOURNAL OF OPHTHALMOLOGY

PORES OF THE TRABECULAR WALL OF SCHLEMM'S CANAL: FERRITIN PERFUSION IN ENUCLEATED HUMAN EYES. Segawa, K. (Ophthalmological Clinic, Shinshu University, Matsumoto-shi, Japan), Jap. J. Ophth. 15:1-8, Jan.-Mar., 1971.

A small quantity of ferritin was injected into the anterior chamber of freshly enucleated human eyes. After a half-hour wait, thin sections were made for electron microscopic study. The ferritin was found to have passed through the trabecular meshwork and the endothelial pores of Schlemm's canal. There was no evidence of an active transport mechanism. (10 figures, 5 references)—Paul A. Hein, Jr.

MACULAR ERG IN CENTRAL SEROUS RETINOPATHY. Nagata, M. and Honda, Y. (Department of Ophthalmology, Tenri Hospital, 200 Mishima-cho, Tenri-city, Nara, Japan), Jap. J. Ophth. 15:9-16, Jan.-Mar., 1971.

Compared with the fellow eye, the eye with central serous retinopathy shows a diminished macular ERG. In thirteen patients with central serous retinopathy treated by photocoagulation, the ERG returned to normal in only two, although all had return of normal visual acuity and loss of the central scotoma. (4 figures, 15 references)—Paul A. Hein, Jr.

EYE INJURY BY ORGANIC PHOSPHORUS INSECTICIDES. Ishikawa, S. (Department of Ophthalmology, University of Tokyo School of Medicine, Tokyo), Jap. J. Ophth. 15:60-68, Jan.-Mar., 1971.

Seventy-one children from an area of Japan heavily treated by helicopter with organic phosphorus insecticides developed eye abnormalities, consisting of narrowed visual fields, reduced visual acuity, optic neuritis, pupillary abnormalities, and altered ocular motility. Treatment with atropine and PAM was efficacious. (5 figures, 11 references)—Paul A. Hein, Jr.

## JOURNAL OF PEDIATRICS

INFANTILE NYSTAGMUS: A PROSPECTIVE STUDY OF SPASMUS NUTANS, CONGENITAL NYSTAGMUS AND UNCLASSIFIED NYSTAGMUS OF INFANCY. Jayalakshmi, P., Scott, T. F., Tucker, S. H. and Schaffer, D. B. (Univ. of Pennsylvania School of Medicine), J. Pediat. 77:177-187, Aug., 1970.

Prospectively collected data on 52 study and 56 control children were used to analyze the diagnostic and prognostic criteria commonly applied to infants with nystagmus. Compared with control children, the affected children had a higher incidence of electroencephalographic abnormalities, strabismus, other neurologic abnormalities, and family history of nystagmus. Except for a higher incidence in multiparous women, no environmental pre- or perinatal circumstances differentiated the study children from control children. Cessation before the fifth year occurred in 70% of those without and in 30% of those with associated strabismus or other neurologic abnormalities. (4 tables, 35 references)—Authors' abstract

RETINAL CHANGES PRODUCED BY PHOTOTHERAPY. Sisson, T. R., Glauser, S. C. Glauser, E. M., Tasman, W. and Kuwabara, T. (Temple Univ. School of Med. and Harvard Univ. School of Med.), J. Pediat. 77:221-227, Aug., 1970.

Phototherapy is used to treat hyperbilirubinemia in the newborn. The potential hazard of retinal damage under such therapy was evaluated using newborn piglets. With electron microscopy, changes in the visual receptors were observed in exposed eyes which were not observed in shielded eyes. Therefore, utmost care would seem to be required to shield the eyes of infants exposed to bilirubin phototherapy units. (6 figures, 7 references)—Joel G. Sacks

SIMULTANEOUS OCCURRENCE OF CONGENITAL ANIRIDIA, HAMARTOMA, AND WILMS' TUMOR. Haicken, B. N. and Miller, D. R. (New York Hospital-Cornell Medical Center, New York), J. Pediat. 78:497-502, Mar., 1971.

The syndrome of Wilms' tumor associated with aniridia consists of congenital nonfamilial aniridia, Wilms' tumor developing before 3 years of age, eye lesions associated with aniridia, mental and growth retardation, microcephaly, genitourinary anomalies and deformities of the pinna. The twenty-fifth case of this syndrome is presented and demonstrates new findings not seen previously: congenital li-

poma and spina bifida with meningocele. This case provides an important link between the Wilms' tumor-aniridia syndrome and disorders of growth control (hemihypertrophy, hamartoma, and visceral cytomegaly syndrome). The array of overlapping congenital malformations occurring with Wilms' tumor, aniridia, and disorders of growth control suggest common teratogenic and oncogenic mechanisms. (1 figure, 1 table, 28 references)—Authors' abstract

## JOURNAL OF NEUROSURGERY

BILATERAL TRAUMATIC ABDUCENS PALSY. Schneider, R. C. and Johnson, F. D. (University of Michigan Medical Center, Ann Arbor), J. Neurosurg. 34:33-37, Jan., 1971.

Two patients with bilateral abducens palsy are presented. A study of the associated injury to the cervical spine suggests that a severe blow to the head in an upward and posterior direction may produce contusion or avulsion of the abducens nerve by the rigid petrosphenoidal ligament under which it passes. (3 figures, 12 references)—Authors' abstract

## KLINISCHE MONATSBLATTER FÜR AUGENHEILKUNDE

EXPERIMENTAL PRODUCTION OF GIANT RETINAL TEARS AND THEIR TREATMENT BY INTRAOCULAR AIR TAMPONADE. (German) Machemer, R., Aaberg, T. and Norton, E. W. D. (Bascom Palmer Eye Institute, University of Miami, Florida), Klin. Mbl. Augenh. 157:1-12, July, 1970.

Giant retinal tears between 90° and 360° could be produced experimentally in the owl monkey eye. After correct positioning of the animal, air was injected into the vitreous cavity to replace all of the vitreous and subretinal fluid and to unfold the retina, and diathermy or cryo was applied to the sclera. Utilizing this technique eight eyes with giant tears between 180° and 350° were successfully reattched. This experimental intraocular air tamponade is hoped to serve as a model for similar human detachments that are not complicated by vitreous strands. (13 figures, 2 tables, 12 references)—Authors' abstract

ANTAGONISTIC EFFECT OF MYDRIATICS AND MIOTICS ON THE OUT-FLOW RESISTANCE OF THE AQUEOUS HUMOUR. (German) Makabe, R. (6 Frankfurt/Main 70, Ludwig-Rehn-Str. 14), Klin. Mbl. Augenh. 157: 30-38, July, 1970.

Tonography was performed in open angle glaucoma suspects after local application of parasympathicolytic, sympathicomimetic and parasympathicomimetic drugs. A significant correlation was observed between the increase in outflow resistance produced by parasympatholytics and a decrease in outflow resistance produced by pilocarpine. However a similar correlation could not be found, when a sympathomimetic and pilocarpine were used. (3 figures, 49 references)—Helmut Buettner

CATARACT AFTER EXTRACORPORAL DIALYSIS. (German) Straub, W. and Freund, J. (355 Marburg/Lahn, Univ. Augenklinik), Klin. Mbl. Augenh. 157:50-52, July, 1970.

A 39-year-old woman with uremia developed bilateral mature cataracts during weekly extra corporal dialysis, which had been going on for several months. The authors suggest that these cataracts are probably caused by osmotic changes during hemodialysis. (2 figures, 4 references)—Helmut Buettner

FLUCTUATIONS OF INTRAOCULAR TENSION DURING HEMODIALYSIS. (German) Reisner, W., Schmidt, P. and Kotzaurek, R. (A-1090 Wien, Alserstr. 4, A-1090 Wien, Lazarettgasse 14, 1. Med. Klinik der Univ. Wien), Klin. Mbl. Augenh. 157: 53-60, July, 1970.

Intravenous injection of hypertonic solutions (i.e. urea) can lower the intraocular pressure (IOP). Lowering the osmotic pressure of the serum, on the other hand, can result in a rise of IOP, due to a delayed reduction of the urea concentration in the aqueous humor and the vitreous. During 25 hemodialysis procedures in seven patients (with normal IOP) the IOP increased significantly. No quantitative correlation between the increase in IOP and the change of osmotic pressure in the serum could be evaluated. However there exists an indirectly proportional correlation between the initial IOP and the degree of increase of the IOP during hemodialysis. (6 figures, 4 tables, 23 references)—Helmut Buettner

DOES THE SCHIØTZ TONOMETER HAVE TO BE DISMANTLED AFTER EACH MEASUREMENT OF INTRAOCULAR PRESSURE? Leydhecker, W. and Sixt, B. (Univ.-Augenklinik Wurzburg), Klin. Mbl. Augenh. 157:65-69, July, 1970.

By means of physical and clinical methods the authors investigated what errors arise, if a Schiøtz tonometer is not dismantled and the tonometer rod not cleaned after each use. Two new methods for the measurement of the friction between the rod and the cylinder have been developed. After five measurements without dismantling the tonometer one error of scale reading already occurs. After 13 measurements, there are two errors in scale readings. Therefore, the tonometer must be dismantled and cleaned after each measurement. (1 figure)—Authors' abstract

THE EFFECT OF PILOCARPINE AND PROSTIGMINE MIXED WITH PILOCARPINE ON THE INTRAOCULAR PRESSURE IN GLAUCOMA SIMPLEX. (German) Stelzer, R. (A-1090 Wien/Österr., Alserstr. 4, II. Univ. Augenklinik), Klin. Mbl. Augenh. 157:74-79, July, 1970.

In 30 eyes with glaucoma simplex pilocarpine (1%) reduced the intraocular pressure (IOP) by 20.7% while the facility of aqueous outflow (C) was increased by 70%. A mixture of pilocarpine (2%) and prostigmine (3%) lowered the IOP by 30.9% and increased the C-value by 150%. (2 figures, 5 tables, 14 references)—Helmut Buettner

FLUORESCEIN ANGIOGRAPHIC FINDINGS IN RETINITIS PUNCTATA ALBESCENS. (German) Makabe, R. (6 Frankfurt, a. M. 70, Ludwig-Rehn-Strasse 14 West-Germany), Klin. Mbl. Augenh. 157:114-118, July, 1970.

An 18-year-old white woman complaining about progressive loss of night vision presented the typical fundus changes of retinitis punctata albescens. She had a decreased visual acuity, concentrically constricted visual fields with a ring scotoma, a diminished and retarded dark adaptation, impaired color perception and no ERG response. Fluorescein angiography showed early fluorescence of the white spots in the fundus, suggesting that these are areas with a defect of the pigment epithelium. (5 figures, 14 references)—Helmut Buettner

RUBELLAR EMBRYOPATHY OF THE EYE. (German (Töndury, G. (CH-8006 Zürich, Schweiz, Anatom. Univ.-Institut), Klin. Mbl. Augenh. 157:141-164, Aug., 1970.

Fifty-four of 102 embryos and fetuses whose mothers had rubella during the first trimester of pregnancy, showed heart lesions (46) and cataracts (38). The combination of cataract and cardiac lesions was present in 30 cases. The chronic process of destruction of the lens, even persisting in the postnatal period due to continuous presence of the rubella virus in the affected structures, begins 10 to 12 days after manifestation of the disease in the mother. The primary lens fibers swell and later disintegrate. The same happens to the newly formed secondary lens fibers at the equator, which are continuously added in the periphery. This results in a lens with a liquified embryonal nucleus and a thin cortical layer of secondary lens fibers.

More rare findings were: atrophic and abnormally short iris with poorly developed sphincter muscle and atrophic ciliary body (in 4 cases) and microphthalmos combined with lenticular and corneal malformation (in 4 cases). There were no inflammatory signs (i.e. iridocyclitis) in all these cases. Up to the seventh month, embryos and fetuses cannot respond with cellular reaction. The only response to a virus infection is a necrosis of the affected cells. (18 figures, 1 table, 44 references)—Helmut Buettner

DIAGNOSIS OF OCULAR MYASTHENIA IN CHILDREN. (German) Manz, F. and Schmidt, D. (78 Freiburg, Hansastr. 9, Neurol. Klinik mit Abt. f. Neurophys.; 78, Freiburg, Killianstr., Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 157: 173-182, Aug., 1970.

Ocular symptoms of myasthenia gravis are very common and often the earliest manifestation of this disease. About 10% of all cases of myasthenia have their onset before the age of 15. Therefore this disease should be considered in all children with paresis of the extraocular muscles. The tensilon- and prostigmine- test, which can be performed as an office procedure, provides a decisive diagnosis in most cases. In doubtful cases or when more subtle examinations are desired, stimulation electromyogra-

phy, needle electromyography or registration of the opto-kinetic nystagmus before and after administration of cholinesterase inhibitors may be performed. (9 figures, 3 tables, 39 references)—Helmut Buettner

THE EFFECT OF CATAPRESAN (R) ON THE INTRAOCULAR PRESSURE (IOP). (German) Heilmann, K. (8 München 80, Ismaningerstr. 22, Augenklinik der Techn. Hochschule, West-Germany), Klin. Mbl. Augenh. 157:182-192, Aug., 1970.

2-(2,6-dichlorphenyl amino) 2-imidazoline-hydrochloride (Catapresan (R)), an antihypertensive drug, lowers the IOP significantly, when applied locally. It is free from local side-effects and does not produce miosis. However, general side effects such as a considerable decrease in blood pressure, a dryness of mucous membranes and a sedative effect still prevent the routine use of this drug in the treatment of glaucoma. A comparative study of the effects of a 0.5% and a 0.25% solution of Catapresan (R) in 17 patients with primary glaucoma showed more general side effects when using 0.5% Catapresan (R) locally, while the IOP was lowered to the same extent by both concentrations. (4 figures, 3 tables, 4 references) —Helmut Buettner

SERUM GLYCOPROTEID LEVEL AND DIABETIC RETINOPATHY. (German) Langness, U., Thiel, H. J. and Moog, E. (23 Kiel, Hegewischstr. 2, Univ. Augenklinik; 23 Kiel, Metzstr. 53/57, II. Med. Klinik u. Poliklinik der Univ. West-Germany), Klin. Mbl. Augenh. 157:202-208, Aug., 1970.

The serum level of protein-bound amino sugars (glycoproteids) is known to be elevated in diabetics and especially so in diabetic angiopathy. Of 121 diabetics (19 to 60 years of age) 11 had diabetic microangiopathy of the retinal vasculature; four years later eight more had developed diabetic retinopathy, regardless of whether the diabetes had been well treated or not. All 121 patients had a significantly elevated serum glycoproteid level, even before changes of their retinal vessels were detected. The authors think that it might be possible to predict the onset of diabetic retinopathy by determining individual glycoproteid fractions in the serum. (3 tables, 36 references)—Helmut Buettner

MALIGNANT CHOROIDAL MELANOMA AND THE CILIARY NERVE. (German) Vogel, M. H. (43 Essen, Hufelandstr. 55, Univ. Augenklinik, Klinikum Essen, West-Germany), Klin. Mbl. Augenh. 157:215-224, Aug., 1970.

In 17 out of 20 malignant melanomas of the choroid, a ciliary nerve was found in the area of the tumor base on histological examination. This nerve was covered by a more or less thick layer of nevus cells which showed a gradual transition into the tumor tissue. Choroidal nevi have been designated as the site of origin of the malignant melanomas of the choroid. The idea is advocated that the nevus cells are proliferated Schwann's sheath-cells of the ciliary nerves. This interpretation is in accordance with the opinions of the neurogenic origin of malignant choroidal melanoma which have been propagated in the literature. It also would explain the frequency of malignant choroidal melanomas at the posterior pole of the eye. (8 figures, 16 references)—Author's abstract

FUNDUS AND HISTOLOGICAL FINDINGS IN INFANTS WITH PACHYMENINGEOSIS HAEMORRHAGICA INTERNA. (German) Schmidt, B. and Trojan, H. J. (355 Marburg/Lahn, Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 157:239-244, Aug., 1970.

Multiple subhyaloid hemorrhages, sometimes associated with papilledema, point to the diagnosis of pachymeningiosis hemorrhagica interna. Three well documented cases of this disease in infants are reported. (6 figures, 4 references)—Helmut Buettner

LYMPHATIC TUMORS OF THE EYE AND ADNEXA. (German) Stärk, N. and Thiel, H. J. (6000 Frankfurt/Main, Ludwig-Rehn-Str. 14, Univ. Augenkl.; 23 Kiel, Hegewischstr., Univ. Augenkl. West-Germany), Klin. Mbl. Augenh. 157:308-326, Sept., 1970.

Primary lymphatic tumors may be divided into three groups: 1) reactive hyperplasias 2) sarcomas of the lymphoreticular tissues and 3) progressive autonomous hyperplasias, which have all the sarcoma characteristics except for the extensive and destructive growth of sarcomas. The histological diagnosis of these tu-

mors is often very difficult or even impossible, especially as to determination of malignancy or non-malignancy. However, the treatment of choice seems to be early irradiation, as shown by an evaluation of 36 cases of ocular lymphomas. (12 figures, 5 tables, 34 references)—Helmut Buettner

TONOGRAPHIC INVESTIGATIONS DURING TREATMENT WITH LOCAL INJECTION OF DEXAMETHASONE. (German) Neumann, M. and Hiller, H. (X 69 Jena/DDR, Bachstr. 18, Univ. Augenklinik East-Germany), Klin. Mbl. Augenh. 157:334-342, Sept., 1970.

Tonography—performed in 15 patients, who received subconjunctival (2.5 mg) or retrobulbar (5 mg) dexamethasone injections for treatment of uveitis—revealed a significant increase in intraocular pressure (IOP) and aqueous humor secretion, while the resistance to aqueous out-flow was unaffected. The elevated IOP was transitory and never reached pathological values (more than 26 mm Hg). (4 tables, 22 references)—Helmut Buettner

THE DEBRÉ-LAMY-LYELL SYNDROME. (German) Reich, H. and Jünemann, G. (44 Münster i. W., v. Esmarchstr. 56, Univ. Hautklinik; 44 Münster i. W., Westring 15, Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 157:358-365, Sept., 1970.

Lyell's syndrome (toxic epidermal necrolysis) was first described by the French pediatricians Debré, Lamy and Lamotte in 1939, prior to Lyell's publication in 1956. It is characterized by extensive necrolytic dermal lesions combined with ocular involvement such as conjunctival scarring, symblepheron formation and corneal infiltration or ulceration, often followed by perforation. This disease has a mortality of 30%. In addition to a certain predisposition, drugs (sulfonamides, pyrazolone derivatives, antibiotics and barbiturates), viruses and bacteria (Staphylococcus pyogenes) can cause this dangerous disease. Five case reports are included in this paper. (5 figures, 19 references)—Helmut Buettner

REGENERATION OF DARK ADAPTATION IN SURGICALLY REATTACHED RETINAS. (German) Hammerstein, W. (4 Düsseldorf, Moorenstr. 5, Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 157:385-388, Sept., 1970.

Twenty-four out of 25 eyes with retinal detachments showed progressive normalization of the dark adaptation curve postoperatively. One eye, which did not recover, had a detachment of several years duration. This suggests, that recovery of retinal function depends on the duration of the retinal detachment. (1 figure, 1 table, 27 references)—Helmut Buettner

ERG AND EOG POTENTIALS AFTER LONG TERM RESOCHIN ADMINISTRATION. (German) Svěrák, J., Erbenová, Z., Peregrin, J. and Salavec, M. (582 Hradec Králové Königgrätz/CSSR, Univ. Augenklinik), Klin. Mbl. Augenh. 157:389-392, Sept., 1970.

Of 32 patients, receiving Resochin for at least six years (average total dose 572 g.) for treatment of chronic polyarthritis, 87% had a significant decrease of the b-wave amplitude of the ERG and 47% had a pathologically low EOG activity. All patients had normal appearing fundi. (2 figures, 33 references)—Helmut Buettner

CHANGES OF THE STANDING POTENTIALS OF THE EYE (EOG) IN CHOROIDAL DETACHMENT. (German) Alexandridis, E. (69 Heidelberg, Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 157:395-399, Sept., 1970.

In three eyes with choroidal detachments the EOG-amplitudes were markedly reduced or even extinguished, depending on the size of the detachments. Following surgical reattachment of the choroid the EOG recovered rapidly and 10 to 11 days later it was absolutely normal. (3 figures, 15 references)—Helmut Buettner

PERIPHERAL IRIDECTOMY WITH CAUTERIZATION OF THE SCLERAL (SCHEIE'S PROCEDURE). 3. COMPLICATIONS. (German) Polychronakos, D. J. and Chryssafis, B. (Thessaloniki/Griechenland, Aristoteles Str. 10), Klin. Mbl. Augenh. 157:463-475, Oct., 1970.

Five hundred Scheie's procedures are analyzed with regard to their complications. The

incidence of synechia, cataract, vitreous prolapse and loss, flat anterior chamber and malignant glaucoma is almost the same as in any other fistulating operation. Sympathetic ophthalmia has so far never been observed after a Scheie's procedure. The incidence of late infections, however, has been unexpectedly high, 2.2% in this study. (4 tables, 20 references)—Helmut Buettner

A NEW METHOD FOR THE FILM FIXATION OF THE KERATOPROSTHESIS IN THE HOST TISSUE. (German) Faulborn, J. (78 Freiburg/Br. Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 157:476-487, Oct., 1970.

After implantation of a keratoprosthesis into subcutaneous tissue, a capsule of connective tissue is formed around the prosthesis. On transplantation into the eye, the connective tissue behaves like an autotransplant, into which the prosthesis is firmly embedded. The first clinical and histological observations in four rabbit eyes have shown that two and four months after the transplantation of the autoallotransplant into the eye, a firm connection exists with the host tissue. (12 figures, 6 references)—Author's abstract

TENSILE STRENGTH OF RABBIT CORNEA AFTER PERFORATING INJURY AND ETHYL-DEOXYURIDINE (EDU) ADMINISTRATION. (German) de Decker, W. (23 Kiel, Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 157:487-492, Oct., 1970.

In 1967 another virostatic agent, EDU, was introduced into therapy of corneal herpes. It is as effective as iodine-deoxy-uridine (IDU), but better tolerated by the corneal tissue. Comparative measurements of tensile strength of corneal scars after perforating injuries treated with and without EDU showed, that the administration of EDU improved wound healing. (2 figures, 1 table, 12 references)—Helmut Buettner

PHOTOCOAGULATION IN INFLAMMATORY DISEASES OF THE FUNDUS. Heydenreich, A. (Univ.-Augenklinik Jena), Klin. Mbl. Augenh. 157:610-617, Nov., 1970.

Photocoagulation is a valuable support for conservative drug therapy in inflammatory diseases of the fundus. In choroiditis, in particular, isolated patches or relapses at the marginal zones of older patches were coagulated. With this procedure, the clinical course of the disease could be shortened and the progressive character of the disease could be brought under control. In retinal periphlebitis, spot coagulation of bleeding vascular areas combined with fluorescein ophthalmoscopy brought about scarring of these areas and thus prevented recurrent hemorrhages in 42% of the cases. In a similar way, focal areas were coagulated in retinitis centralis serosa. In Coats' disease, secondary retinoschisis, secondary retinal detachment and secondary retinal foramen, the pathological areas were sealed by coagulation and spreading of these processes to healthy retinal areas was prevented. (10 figures, 1 table, 15 references)—Author's abstract

ULTRASOUND-ECHOGRAPHY—AN IMPORTANT AUXILIARY EXAMINATION IN RETINAL DETACHMENT SURGERY. (German) Freyler, H. (A-1090 Wien, Spitalgasse 2, I. Univ. Augenklinik, Schweitz), Klin. Mbl. Augenh. 157:617-633, Nov., 1970.

Echography can provide pertinent pre-, intra- and post-operative information in retinal detachments. Especially in eyes with opaque media, this method has proven to be very valuable in retinal detachment surgery. (8 figures, 29 references)—Author's abstract

DEVELOPMENT OF CHOROIDAL VESSELS IN THE MACULAR AREA. (German) Heimann, K. (5 Köln-Lindenthal 41, Univ. Augenklinik West-Germany), Klin. Mbl. Augenh. 157:636-642, Nov., 1970.

The authors studied in embryos and fetuses the development of the choroidal vessels by means of indian ink- and neoprene-injection. In the macular area the short ciliary arteries form a dense and well anastomosing network of choroidal arterioles, emphasizing the particular hemodynamic conditions of this area. This pattern of choroidal vessels differs markedly from the rest of the choroid and can explain the predilection of the posterior pole for inflammatory and degenerative lesions, for example congenital toxoplasmosis. (5 figures, 15 references)—Helmut Buettner

FAMILIAL INCIDENCE OF THE BLOCH-SULZBERGER-SYNDROME (INCONTINENTIA PIG-

MENTI) WITH OCULAR INVOLVEMENT. (German) Benedikt, O. and Ehalt, H. (A-8036, Graz, Auenbruggerplatz 4 Univ. Augenklinik,), Klin. Mbl. Augenh. 157: 652-663, Nov., 1970.

Papulo-macular and vesicular changes with streak-like deposits of melanin pigment in the skin (incontinentia pigmenti) can be associated with ocular anomalies, such as corneal opacifications, congenital cataracts, iris malformations, persistent hyperplastic primary vitreous, pseudoglioma, uveitis, chorioretinitis with subsequent optic atrophy, retinal folds, hydrophthalmus, nystagmus and strabismus. This disease starts in early infancy and is predominently found in females. The authors report two cases of Bloch-Sulzberger syndrome in one family (mother and daughter) with ocular involvement. The daughter's left eye was removed under the assumption of an existing retinoblastoma. Histological examination revealed persistent hyperplastic primary vitreous with a persistent hyaloid artery and retinal dysplasia. The authors assume, that this syndrome represents a sex-linked hereditary disease. (9 figures, 33 references)—Helmut Buettner

IRRADIATION THERAPY OF LYMPHOMAS IN THE OCULAR REGION. (German) Stärk, N. and Pánek, V. (6000 Frankfurt/Main, Ludwig-Rehn-Str. 14, Univ. Augenklinik; 6000 Frankfurt/Main, Univ. Klinik f. Strahlentherapie, West-Germany), Klin. Mbl. Augenh. 157:693-697, Nov., 1970.

In seven cases of localized lymphomas (three histological proven malignant) beta-irradiation proved to be very effective. Therefore irradiation should always be preferred to mutilating radical surgery. (1 table, 13 references)—Helmut Buettner

ELECTRON MICROSCOPIC FINDINGS IN KERATOCONUS. (German) Göttinger, W. and Auböck, L. (A-8036 Graz, Univ. Augenklinik; A-8036 Graz, Path. Univ. Inst.), Klin. Mbl. Augenh. 157:762-772, Dec., 1970.

Phagocytizing stromal cells and large amounts of collagen fibril precursor material were found in six corneas of patients with keratoconus. These changes may be the expression of an enzymatic defect in fibrillogenesis, resulting in the malformation of the cornea. The theory of an enzymatic defect fits well with the interpretation of keratoconus being a hereditary disease. (9 figures, 19 references)—Helmut Buettner

## LANCET

HEADACHE AND THE EYE. A COMMUNITY STUDY. Waters, W. E. (Dept. of Social Medicine, Oxford University, England), Lancet 7662:1-4, 1970.

Groups of individuals with headache, unilateral headache, or migraine, and a group who had not had a headache in the previous year, were identified by questionnaire in a random sample of a general population. Four hundred and fourteen individuals were examined for visual acuity and ocular-muscle imbalance. These tests gave little evidence that visual defects were more frequent in those with headache or those with migraine compared with individuals without headache in the same population. The only statistically significant difference found between the four groups was that hyperphoria with near vision was more frequent in the migraine group. It is concluded that, in the general population, headaches are seldom caused by defects in visual acuity or ocular-muscle imbalance. (3 figures, 4 tables, 11 references)—Author's abstract

## NEW ENGLAND JOURNAL OF MEDICINE

NORRIE'S DISEASE—AN X-LINKED SYNDROME OF RETINAL MALFORMATION, MENTAL RETARDATION AND DEAFNESS. Holmes, L. B. (Massachusetts General Hospital, Boston), N. Eng. J. Med. 284:367-368, 1971.

A family in which six males in four generations were affected with Norrie's disease (an X-linked syndrome of retinal malformation, mental retardation and deafness), the initial diagnoses of retrolental fibroplasia, pseudoglioma, and congenital toxoplasmosis had been suggested. The general lack of awareness of this syndrome is probably responsible for these incorrect diagnoses. Because of the devastating nature of the syndrome and the lack of any effective treatment, some parents may seek prenatal sex identification in all subsequent pregnancies and plan to abort all unborn

males. (2 figures, 5 references)—Joel G. Sacks

## TRANSACTIONS OF THE AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARNGOLOGY

COLOR ENHANCEMENT OF BRAIN AND ORBITAL SCANS IN PROPTOSIS. Kramer, S. G., Archer, D. D., Polcyn, R. E., Charleston, D. B. and Yasillo, N. (University of Chicago, 950 E. 59th St., Chicago, Illinois), Tr. Am. Acad. Ophth. Otolaryng. 74: 1240-1248, Nov.-Dec., 1970.

Thirty-three patients with orbital disease were evaluated by radioisotope scanning of the brain and orbits with sodium pertechnetate-99m (NaTc04)—a technique virtually unattended by hazard or morbidity. Ordinary interpretation of such scans is frequently difficult because of high background activity in the orbital regions which obscures orbital detail. This study utilized an electronic color enhancement technique to increase the ease and accuracy of scan interpretations. No scan of a patient with an intra-orbital mass was interpreted as negative, and no scan of a patient without a mass was interpreted as positive by this technique. Masses were correctly localized with respect to the globe in 13 of 14 positive scans. Radioisotope scanning of the orbits particularly when aided by color enhancement, proves to be a simple and accurate diagnostic aid for detecting and localizing intra-orbital masses. (3 tables, 2 figures, 18 references)—Authors' abstract

SUB-TENON STEROID INJECTION FOR OPTIC NEURITIS. Smith, J. L., McCrary, J. A., Bird, A. C., Kurstin, J., Kulvin, S. M., Skilling, Jr., F. D., Acers, T. E. and Coston, T. O. (University of Miami School of Medicine, Florida), Tr. Am. Acad. Ophth. Otolaryng. 74:1249-1253, Nov.-Dec., 1970.

Steroids injected in the sub-Tenon's space have been helpful in the management of optic neuritis. This route of administration is easier, safe, and less painful than retrobulbar injection. We prefer to use aqueous triamcinolone. The clinical response to this drug lasts one to two weeks after a single injection. The effects of the drug, administered as we have described, warrant further clinical study in the treatment of ischemic optic neuritis and congestive thyroid exophthalmos. (1 table, 4 references)—Authors' abstract

LYELL'S DISEASE, THE STEVENS-JOHNSON SYNDROME, AND EXFOLIATIVE DERMATITIS. Ostler, H. B., Conant, M. A. and Groundwater, J. (University of California San Francisco Medical Center), Tr. Am. Acad. Ophth. Otolaryng. 74:1254-1265, Nov.-Dec., 1970.

A case of Lyell's disease has been presented. On the basis of observation and a partial review of the literature, the disease has been compared clinically, histologically, and etiologically with the Stevens-Johnson syndrome and exfoliative dermatitis. Typical Lyell's disease appears to be a clinical and pathologic entity, distinct from other dermatologic disorders. Since there are only a limited number of ways in which skin and mucous membranes can react to disease, it is not surprising that Lyell's disease often resembles other mucocutaneous diseases in one or more respects. (6 figures, 5 tables, 16 references)—Authors' abstract

AUTOMATIC OBJECTIVE REFRACTION: REPORT OF A CLINICAL TRIAL. Safir, A., Knoll, H. and Mohrman, R. (Mount Sinai School of Medicine, New York), Tr. Am. Acad. Ophth. Otolaryng. 74:1266-1275, Nov.-Dec., 1970.

Objective techniques of refraction which are currently used are objective only in the sense that they do not require the subjective response of the patient, but they do require the subjective response of the examiner. A truly objective instrument for determining refractive error has been designed and built. This instrument may be operated satisfactorily by a person untrained in refraction. The result of the measurement of the refractive state of the subject is provided in the form of a written record. An analysis is presented of a clinical test evaluating the performance of the instrument as compared to the results obtained by a panel of practitioners examining the same patient sample. It is concluded that the new instrument provides a measure of refractive error that is equivalent to that obtained by streak retinoscopy. (8 figures, 4 references)—Authors' abstract

MARGINAL (RING) CORNEAL ULCER AS PRESENTING MANIFESTATION OF WEGENER'S GRANULOMA: A CLINICOPATHOLOGIC STUDY. Ferry, A. P. and Leopold, I. H. (Mount Sinai School of Medicine, City University of New York), Tr. Am. Acad. Ophth. Otolaryng. 74:1276-1282, Nov.-Dec., 1970.

Marginal (ring) ulcers of the cornea are frequently symptomatic rather than primary. A case is reported in which a ring ulcer of the cornea was one of the earliest manifestations of Wegener's granuloma. On pathologic examination of the eye, a granulomatous reaction to corneal collagen fibers was found in the walls of the ring ulcer. This observation supports the concept that abnormal immune mechanisms play a major role in the pathogenesis of Wegener's granuloma. Appropriate management by the ophthalmologist of a patient with a ring ulcer includes both care of the corneal lesion and a search for a possible underlying systemic disease. (8 figures, 8 references)—Authors' abstract

A SCLERAL PATCH FOR EXPOSED IMPLANTS. Helveston, E. M. (Indianapolis, Indiana), Tr. Am. Acad. Ophth. Otolaryng. 74: 1307-1310, Nov.-Dec., 1970.

A new procedure has been described which employs human eye bank sclera as a patching material for use in retention or replacement of an extruding or extruded orbital implant. (5 figures, 4 references)—Author's abstract

SIMULTANEOUS BILATERAL UVEAL MELANOMAS RESPONDING TO BCNU THERAPY. Stark, Jr., W. J., Rosenthal, A. R., Mullins, G. M. and Green, W. R. (Wilmer Institute, the Johns Hopkins University and Hospital, Baltimore), Tr. Am. Acad. Ophth. Otolaryng. 75:70-83, Jan.-Feb., 1971.

To our knowledge, this patient is the first to be treated for intraocular melanoma with BCNU. The dramatic therapeutic response to BCNU represents a significant departure from the results usually obtained in the treatment of metastatic ocular melanoma, as seen from a review of the literature. Consequently, we believe further trials with BCNU are indicated in cases of intraocular melanoma that are not amenable to surgery. (12 figures, 31 references)—Authors' abstract

CONSERVATIVE TREATMENT OF INTRAOCULAR MELANOMAS. Long, R. S., Galin, M. A. and Rotman, M. (New York Medical College, New York), Tr. Am. Acad. Ophth. Otolaryng. 75:84-93, Jan.-Feb. 1971.

Choroidal malignant melanomas have been treated with cobalt 60 plaques. A computerized technique is used to assess the duration of treatment and the method for fractionation of the dose. These tumors are responsive to this form of therapy, and ocular function may be preserved while the neoplasm is eliminated. (3 tables, 5 figures, 17 references)—Authors' abstract

EFFECT OF RADIATION THERAPY ON METASTATIC CHOROIDAL TUMORS. Jaeger, E. A., Frayer, W. C., Southard, M. E. and Kramer, S. (Jefferson Medical College of Thomas Jefferson University, Philadelphia), Tr. Am. Acad. Ophth. Otolaryng. 75:94-101, Jan.-Feb., 1971.

This report describes our experiences in the use of irradiation to treat metastatic tumors of the choroid in 21 eyes of 15 patients, and points out several factors of interest. Consideration perhaps should be given to the use of larger doses of initial radiation than was used in this series of patients, and to repeat treatment if a residual tumor is present. It was not possible to correlate the degree of malignancy of the primary tumor and response of the choroidal metastasis to ocular irradiation. While irradiation of these ocular tumors must be considered a palliative measure, this technique does offer preservation of useful vision in some instances. No ill effects were observed from radiation treatment. (2 tables, 4 figures, 10 references)—Authors' abstract

MALIGNANT CELLS IN THE BLOOD OF EYE PATIENTS. Stanford, G. B. and Reese, A. B. (University of Utah Medical School, Salt Lake City), Tr. Am. Acad. Ophth. Otolaryng. 75:102-109, Jan.-Feb., 1971.

At the present time, discovery of malignant cells in the blood of a patient has little prognostic significance. The one exception occurs

when a shower of cells is isolated during surgery. Results from some human clinical studies indicate that the five-year survival rate is cut in half under these circumstances. Theoretically, the natural resistance is impaired by operative stress, and a shower of cells is not as easily destroyed at this time. There is no justification at present for altering or withholding curative therapy on the basis of malignant cells which are demonstrated in a preoperative blood sample taken from a patient with an otherwise potentially curable lesion. After the postoperative period, persistent appearances of malignant cells in the blood of a patient who has undergone a curative-type resection may indicate the need for additional roentgen-ray therapy or chemotherapy. Because an established trend indicates a 50% survival rate in patients who are found to have a shower of malignant cells at the time of surgery, every effort should be made to prevent dissemination at the time of treatment of eye tumors. (6 figures, 16 references)—Authors' abstract

PIGMENTED NEVI OF THE CHOROID. CLINICAL STUDY OF SECONDARY CHANGES IN THE OVERLYING TISSUES. Naumann, G. O., Hellner, K. and Naumann, L. R. (Universitats-Augenklinik, Hamburg, Germany), Tr. Am. Acad. Ophth. Otolaryng. 75:110-123, Jan.-Feb., 1971.

This report describes clinical observations on 124 choroidal nevi in 112 patients who were reexamined periodically for an average of two years . . . The concept that the vast majority of malignant melanomas develop from preexisting nevi is supported by our observations on the location and sex distribution of the lesion, which are quite similar in both, and by the high frequency of choroidal nevi in eyes enucleated at autopsy. The secondary changes in the overlying tissues caused by many choroidal nevi complicate the separation of small malignant melanomas from nevi. Careful long-term follow-up examination, including fluorescein angiography, infrared fundus photography, and perimetry are necessary to rule out malignant transformation. (10 figures, 48 references)—Authors' abstract

EDITED BY THOMAS CHALKLEY, M.D.
*700 North Michigan Avenue, Chicago, Illinois 60611*

For adequate publicity, notices of postgraduate courses, meetings and lectures must be received *at least* three months prior to the date of occurrence.

### FIFTH AFRO-ASIAN CONGRESS OF OPHTHALMOLOGY

The fifth Afro-Asian Congress of Ophthalmology will be held at Nissei Kaikan Hall, Tokyo, Japan, July 9-12, 1972. The main subjects are infection of the eye and management of glaucoma, with symposia on the cornea, cataract surgery, and contact lenses. For further information contact Prof. Akira Nakajima, Secretary General, The Japanese Organizing Committee for the fifth Afro-Asian Congress of Ophthalmology, Department of Ophthalmology, Juntendo University, Hongo, Bunkyo-ku, Tokyo, Japan 113. Prof. Yukihiko Mitsui is president of the local organizing committee and Dr. Yukio Kogure is treasurer.

### FIRST INTERNATIONAL SURGICAL EYE SYMPOSIUM

The First International Surgical Eye Symposium will be held in Bologna, Italy, on April 23-27, 1972. Refined surgical techniques in the management of the chamber angle in glaucoma, congenital and senile cataracts, corneal lesions, prosthetokeratoplasties and plastic surgery of the eyelids and orbit will be demonstrated. Operative sessions will be televised. Papers on these subjects and concerning recent advances in orbitography, ultrasonography, and fluorescein angiography will be presented.

For information contact the Clinica Oculistica, Universita di Bologna via Massarenti, 9—Bologna, Italy.

### PACIFIC MEDICAL CENTER: STRABISMUS CONFERENCE

The Pacific Medical Center, San Francisco, will hold a conference on strabismus October 28-30, 1971. This conference will cover new physiologic information, clinically applicable tests, and surgical approaches. Clinical problems will be emphasized and discussed in a round table format.

The fee is $125. For information: Arthur Jampolsky, M.D., Chairman, Department of Continuing Education, Pacific Medical Center, Clary and Webster, San Francisco, California 94115.

### RESEARCH STUDY CLUB: OPHTHALMOLOGY MEETING

The Research Study Club of Los Angeles will hold their 41st annual mid-winter convention in ophthalmology and otolaryngology, January 23-28, 1972, at the Los Angeles Hilton Hotel, Los Angeles.

The guest speakers on ophthalmology will be Giambattista Bietti, Rome, Italy; Alejandro Salleras, Buenos Aires, Argentina; Marshall M. Parks, Washington, D.C.; Michael J. Hogan, San Francisco, California; Dohrmann K. Pischel, San Francisco, California; and Lester T. Jones, Portland, Oregon. A cadaver course will be conducted at the University of Southern California School of Medicine.

### FDA APPOINTS OPHTHALMOLOGICAL ADVISORY GROUP

The Food and Drug Administration announces the appointment of an Ophthalmological Advisory Group. A. Edward Maumenee, Wilmer Institute, is chairman of the committee. Other committee members are James Allen, Tulane University; Bernard Becker, Washington University; Jerome Goldman, Washington Hospital Center; Peter Laibson, Wills Eye Hospital; Irving H. Leopold, Mt. Sinai Hospital, John McTigue, George Washington Hospital, and Maurice Rabb, Illinois University School of Medicine.

### CALL FOR PAPERS: RADIATION EFFECTS

The National Academy of Sciences invites submission of current data on somatic, genetic, and environmental effects of low-level ionizing radiation, including effects on human growth and development. This material is requested whether or not it has been published, but work in progress, not yet reported, is of particular interest. The request is made in order to assist an advisory committee of the National Research Council in its deliberations concerning ionizing radiation effects on human populations. Please send material to Dr. A. W. Hilberg, Division of Medical Sciences, National Academy of Sciences, 2101 Constitution Avenue, Washington, D.C. 20418.

### LEARNING DISABILITIES CONFERENCE: ORTON SOCIETY

The 22nd annual national conference on language-learning disabilities (dyslexia) of the Orton Society will be held November 4-7, 1971, at the Statler-Hilton Hotel, Boston, Massachusetts. The theme is language disability in the clinic and the classroom. For further information contact the Orton Society, Inc., 8415 Bellona Lane, Towson, Maryland 21204.

### NATIONAL EYE INSTITUTE APPROPRIATION FOR 1972

On August 10, 1971, President Nixon signed into

law the appropriations bill agreed upon by the House of Representatives and Senate, granting the National Eye Institute $37,255,500 for the fiscal year of 1972 (July 1, 1971, through June 30, 1972). This is an increase of $7 million over last year. The scientific fellowship program in ophthalmology was decreased $800,000 from $1.7 million, thus reducing the number of fellows that can be supported from 123 to 52.

### Annual conference: Wills Eye Hospital

The 24th annual conference of the Wills Eye Hospital will be held February 3-5, 1972, at the Bellevue Stratford Hotel in Philadelphia. The Bedell lecture will be given by Lorenz E. Zimmerman, and there will be symposia on cataracts with work shops on retina and refraction. For further information contact Robert D. Mulberger, M.D., Chairman, Conference Committee, Wills Eye Hospital, 1601 Spring Garden Street, Philadelphia, Pennsylvania 19130.

### Society of Military Ophthalmologists

The Society of Military Ophthalmologists annual meeting will be held September 20, 1971, at 6:00 P.M. at the Stardust Hotel, Las Vegas. After the traditional collation, Byron Smith will lecture on oculoplastic rehabilitation. A short business meeting follows. All members are urged to attend.

## Personals

### Robert Machemer

Robert Machemer has been named the first Louis B. Mayer Scholar by Research to Prevent Blindness, Inc. He is thus the recipient of a $25,000 grant under RPB's new Scholars Program. The grant is made possible by an initial three-year $75,000 gift to RPB from the Louis B. Mayer Foundation, Beverly Hills, California. Additional grants of $25,000 will be made to different scientist each year under terms of the Scholars Program.

Dr. Machemer was born in Munster, Germany, in 1933, and received his medical education in that country. He came to the United States in 1966 as a Research Fellow at the Bascom Palmer Eye Institute, University of Miami School of Medicine, and was appointed assistant professor in that school's department of ophthalmology in June, 1970. He has been chief of the ophthalmology section of Miami's Veterans Hospital since 1968.

### Hermann M. Burian

Hermann M. Burian has retired from the University of Iowa as Emeritus Professor of Ophthalmology. He was made Clinical Professor of Ophthalmology at the University of North Carolina School of Medicine, and since July 1, his new home is at 1303 Wildwood Drive, Chapel Hill.

# SYMPOSIUM ON GLAUCOMA

**Friday and Saturday, January 21 and 22, 1972**

## GUEST FACULTY

W. Morton Grant, M.D.
Harvard University

H. Dunbar Hoskins, Jr., M.D.
University of California

David Apple, M.D.
University of Illinois

Robert N. Shaffer, M.D.
University of California

David Walton, M.D.
Harvard University

William H. Coles, M.D.
University of South Carolina

## LOUISIANA STATE UNIVERSITY SCHOOL OF MEDICINE FACULTY

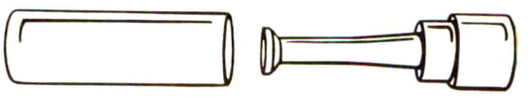
George M. Haik, M.D.
Professor and Head

George S. Ellis

Joel B. Pollard

Howard S. Reitman

Hilliard M. Haik



Luis F. Perez

Robert J. Cangelosi

## TOPICS

Diagnosis and treatment modalities of chronic simple, angle closure, malignant, aphakic, congenital and traumatic glaucoma; tonometry—methods and clinical considerations; complications of glaucoma surgery; trabeculectomy—indications and technique; tonography—its clinical usefulness; osmotic agents; cataracts and glaucoma; corticosteroids—use and abuse; phospholine iodide and cataracts; cryosurgery.

# DMV Contact Lens Remover

ACTUAL SIZE

**The NO STRETCH Method of Contact Lens Removal**

So simple, so far superior to the manual method of stretching the eyelids, that every one of your patients should use this procedure for removing contact lenses. Just the wetting of the cup and a gentle touch to the lens does it. Complete with carrying case, as shown.

Colors: Yellow, Pink, White, Avocado and Aqua

*Available from your contact lens laboratory*

**OVERSEAS OUTLET:**
Willi Ott
Kontaklinsen
Stauffacherstrasse 5
8004 Zurich, Switzerland

## DMV Contact Lens Company

BOX 2829 ZANESVILLE, OHIO 43701

PHONE: (614) 452-4787

*THE TISSUE-FRIENDLY*

# SUPRAMID EXTRA®

**SUTURE.** Polyfilament but neither braided nor twisted. New cable-type construction with several strands enclosed in a perfectly smooth cover of the same material, gives great pliability and superior strength. Strong as steel wire, handles as silk. No stitch irritation, no growth of tissue into suture. Sizes 10-0 to 8.

**SPECIAL NEEDLES:** Our CT needle for cataracts (wire size 0.30mm, length 9mm), CA needle for corneal work (wire size 0.30mm, length 6mm), and EX needle for special keratoplasties (wire size 0.2mm, length 5mm), a flattened reverse cutting needle to prevent "leaking wounds," equal to the smallest hand made eyed needles No. 82F, **and finally the smallest spatula needle on the market, length 5 millimeters, wire size 0.2mm, double armed with 10-0, 9-0 and 8-0 black Supramid Extra. Code Nos. 2SC-100, 2SC-90 and 2SC-80.**

**A NEW PRODUCT:** Implants—Sleeves (Tubes) for preventing adhesions in Eye Muscle Surgery. Method development by Edward A. Dunlap, M.D. Reference: Dunlap, Edward A.: Plastic Implants in Muscle Surgery, Archives of Ophthalmology, 80: 249-257, August 1968.

**TUBING.** *Fully inert because it is made of the same material as the suture;
* Thinnest walls of any surgical tubing, fully transparent and can be *repeatedly* autoclaved;
* Most economical. It is in your interest to compare prices and quality.

**FOIL.** Excellent results with our suture created the demand for Foil for plastic and reconstructive surgery in such cases as orbital fractures, lid reconstruction, etc. Foil is chemically identical with the sutures, thus just as inert when buried in the tissue.

Available in thickness from 0.05mm to 2.00mm, in sheets 15 x 20cm.

Can be steam-autoclaved, cut to size, and carved to shapes and forms.

ACTUAL SIZE

## NO MORE ACCIDENTAL ADHESIONS!

ONCE YOU GRASP THE LENS, AT NO TIME DOES THE IRIS OR ANY OTHER TISSUE ADHERE TO THE PROBE, EVEN WHEN THERE IS DIRECT CONTACT!. THIS EXCEPTIONAL ADVANTAGE IS DUE TO ITS SPECIALLY DESIGNED TIP.

OTHER IMPORTANT ADVANTAGES:

- Thin tip (2.75 mm.) with special shape for better visibility.
- Light weight (11 g.) Just like your ball pen.
- Heat - resistant, so it can be autoclaved repeatedly.
- Durable, it can be used a great number of times.
- Rechargeable, uses gas *"FREON" 12; commercially available.
- Low price.

# *Kowa* SL
## slit lamp microscope

*The new portable approach to ophthalmic examination.*

The Kowa SL has removed all limitations placed on the use of the slit lamp microscope by conventional, bulky, fixed instrumentation.

Hand-held and fully portable, the Kowa SL permits ophthalmic examination at any time, any place: before or after surgery, at the patient's bedside, in the nursery . . . anywhere.

Yet for all its compactness, light weight, moderate price, and remarkable versatility, it has sacrificed nothing in the way of performance or reliability.

The Kowa SL's optics are the finest; its mechanics and electronics are state-of-the-art; it offers an image bright enough for use in a fully illuminated room.

In short, the Kowa SL is one of the most sophisticated slit lamp microscope systems there is . . . and the *only one* that's fully portable.

For the details on the *new portable approach* to ophthalmic examinations, the Kowa SL, contact the representative in your area.

# The crystal drop assures stability

As you may be aware, the first sign of deterioration in a product containing epinephrine is a color change... reddish-brown or "yellowing." Each clear drop of PE* Ophthalmics is its own proof of stability...as also evidenced in clinical studies involving unrefrigerated shelf life, temperature changes and exposed-to-air studies simulating patient use. Proven shelf life, over 3 years (for maximum assurance, vials are date-coded on a 2 year basis). No change in clarity or potency was evidenced in any tests. The crystal clarity of every drop assures your patient full therapeutic effect, first drop to last.

PE* Ophthalmics provide simple *one-solution* treatment of open angle glaucoma... eliminating patient error, assuring the physician exact evaluation of therapy. Available in 5* strengths in 15cc color-coded vials, nationwide and in Canada.

*Pilocarpine Hydrochloride 1%, 2%, 3%, 4%, 6% with Epinephrine Bitartrate 1% (½% Epinephrine Base).

**Contraindication:** Narrow angle glaucoma. **Precautions:** Use with caution in unverified glaucoma and hypertension. If irritation or sensitization occurs, discontinuance may be necessary.

A. Ray Irvine, Jr.
Dharmendra V. Arya — Ralph S. Riffenburg
Robert E. Levine — Alan A. Snyder
Jean Mannagh — T. Rodman Wood
Anthony B. Nesburn — Zolton Yuhasz

Registration Fee: $75.00. Residents, Interns and Fellows $25.00. Fee includes luncheon both days; cocktails, and banquet reservations for registrant and guest. Please register prior to September 1, 1971.

Further information may be obtained by writing to Robert E. Levine, M.D. or T. Rodman Wood, M.D., Program Chairmen, Estelle Doheny Eye Foundation, 272 South Lake Street, Los Angeles, California, 90057.

# SOFT CONTACT LENSES

*A Practical Course Sponsored by University of Florida to be held January 26-29, 1972 in Gainesville, Florida*

(Immediately preceding the Florida Midwinter Seminar)

The course is designed to provide practical instruction in the selection, fitting and use of all types of soft contact lenses. It will consist of lectures, roundtable discussions, demonstrations and workshops on fitting techniques. An outstanding faculty will include:

J. Aquavella
J. Baldone
C. Black
V. Chiquiar Arias
G. Feldman
M. Friedberg
A. Gasset
J. Hartstein
H. Kaufman
S. Mishima
M. Poster
W. Sampson
M. Uotila
K. Whitham

Registration fee will be $100 for the seminar or $300 for the seminar and workshop. Attendance will be limited and the deadline for applications is December 1, 1971. For application forms and additional information please write:

Antonio R. Gasset, M.D.

## INDIRECT OPHTHALMOSCOPY OF THE PERIPHERAL RETINA

Purpose: To teach this new technique—the normal anatomy of the peripheral retina to residents and ophthalmologists.

Contents: Demonstrates and discusses normal anatomy of the equatorial and oral region of the retina as viewed during indirect ophthalmoscopy and scleral indentation. All normal anatomy and variations are discussed, and presented in views of post mortem eyes and shown in scenes taken with the Stenstrom cine. This technique demonstrates the actual views of the fundus as seen during clinical examinations.

Running Time: 41 minutes—16 mm sound

Cost: Rental $25.00 per week
Purchase price $300.00

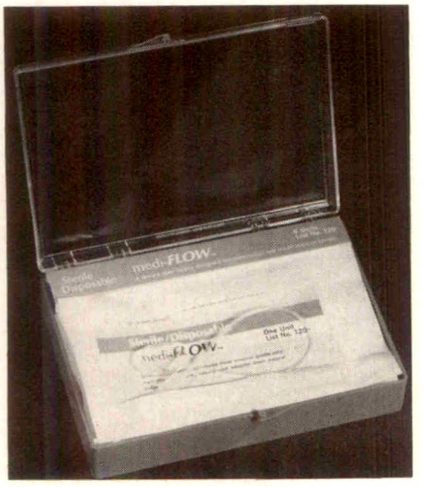
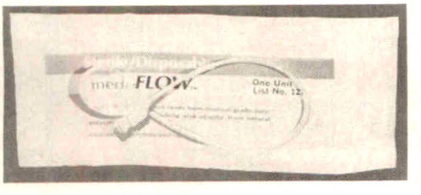
## THE UNIVERSITY OF TEXAS MEDICAL SCHOOL AT HOUSTON BASIC SCIENCE COURSE IN OPHTHALMOLOGY

**January 3 through February 25, 1972**



**Texas Medical Center, Houston, Texas**

This course consists of 270 hours of lectures and demonstrations by an experienced faculty of forty ophthalmologists and basic scientists. It is directed toward the requirements of residents and prospective residents in ophthalmology.



The curriculum includes:

| | |
|---|---|
| Anatomy | Pharmacology |
| Physiology | Optics |
| Pathology | Refraction |
| Biochemistry | Glaucoma |
| Neuro-ophthalmology | Motility |
| Embryology and Genetics | Visual Fields |
| Microbiology | External Disease |
| Medical Ophthalmology | Surgery |

Tuition is $600.00. For further information and application forms please write to Whitney G. Sampson, M.D., Coordinator of Basic Science Programs, Department of Ophthalmology, The University of Texas Medical School, 530 West 20th Street, Houston, Texas 77008.

The medi-FLOW device is available either in a 6-pack or single unit through your usual source of ophthalmic supplies.

## *medi-FLOW*™

battle-proved in Viet Nam* . . . now amplifying the armamentarium of civilian ophthalmology.

The medi-FLOW device delivers controlled medication to the cornea and conjunctiva either rapidly or slowly, as you desire.

It is a uniquely designed clear plastic scleral lens with a polyethylene tube and Luer-lock adaptor for attaching either a syringe or I.V. set. The lens incidentally protects the cornea from eyelid trauma, reduces discomfort rapidly, and aids in the prevention of symblepharon formation—all outstandingly valuable assets of medi-FLOW.

# UNREALISTIC DEMANDS ON SCIENCE AND MEDICINE

To serve the public most effectively, scientists, engineers, and physicians need a friendly, sympathetic environment and one in which their limitations are understood. Until recently such an environment prevailed, but the last few years have brought changes in the public's attitudes. Many adverse changes are involved, but one of the most important is the public's inaccurate estimate of what can be achieved. The public has come to expect miracles from engineering and medicine.

Today medical scientists and physicians are particularly subject to pressures produced by unrealistic demands from the public. Failure to produce miracles is taken as proof of a refusal to be interested in meeting the public's desires. One indignant correspondent wrote me in part as follows:

"It would certainly seem, from the record to date, that basic research scientists are so preoccupied with the exquisiteness of their protocols and the refinements of their research approaches that they have missed entirely the objective and intent of we taxpayers who are funding their 'ivory tower isolationism' . . . we as taxpayers expect something more in return than scientific dialogue between the scientists at seminars and in medical journals."

During a recent discussion concerning the new cancer program, similar remarks were made. If the critics are unwilling to grant humane motives to medical scientists, they should at least recognize the power of self-interest. Anyone responsible for a dramatic advance in the fight against cancer will receive recognition and undying fame.

In some aspects of medicine, physicians can perform today what would have been impossible 40 years ago. Yet there are other aspects in which the practice of medicine has not changed much. For example, little can be done to halt the aging process. Neurologic disorders are another area in which the medical profession cannot deliver as much as people wish.

Physicians find that many patients have unrealistic ideas of what doctors can do for them. Many people seem to think that they can carelessly expend physical resources in any way they wish and that the doctor can always cure them. Patients give no cooperation in the matter of exercise, diet, or abstinence from heavy smoking and yet expect the doctor to make up for their neglect. They want a drug to substitute for self-control and their own efforts. That kind of miracle is not yet available, nor is it likely to be.

Expectations for magical cures are partly responsible for the growing frequency of medical malpractice suits. If a cure is not forthcoming, the patient assumes the doctor must be at fault. Sometimes he is at fault, but often too much is expected of him. So common have malpractice suits become that fear of them is adversely affecting the practice of medicine and is raising the cost of medical care. Today many doctors find it necessary to practice medicine defensively—that is, instead of concentrating only on the well-being of the patient, they must also order a large number of unnecessary test and examinations to answer questions they may be asked in court.

Scientists, engineers, and physicians cannot realistically hope that the favorable climate of 10 years ago will soon be restored. They can foster an improved climate, however, by persistently reminding the mass media and the public of the many limitations of science, technology, and medicine. We are neither witch doctors nor magicians.

This symposium will cover the corneal and ophthalmic plastic field. Multiple lectures will be given with ample time for panel discussion and questions from the registrants.

Afternoons will be set aside for recreation including tennis and golf tournaments. There will be planned entertainment for most evenings.

Tuition will be $175, breakfasts included. Special rate of $75 available for residents upon application from their Department Head. Checks should be made payable to "Bascom Palmer Eye Institute" and mailed to Ophthalmic Plastic and Corneal Surgery Symposium, Bascom Palmer Eye Institute, P.O. Box 875, Biscayne Annex, Miami, Florida 33152.

# Nixon-Kennedy Cancer Plans Fuse

The politicization of cancer took another step this month when President Nixon submitted legislation to set up a "cancer-cure program: at the National Institutes of Health but with a director reporting directly to him rather than to the head of NIH. Mr. Nixon's announcement was viewed as a political co-option of Sen. Edward Kennedy's autonomous "national cancer authority" proposal, which was on the verge of being reported out of committee. The two measures' remarkable similarity shows the effects of compromise negotiations between the Senator and HEW Secretary Elliot Richardson.

Although Mr. Nixon says the program will be "within" NIH, observers quickly discerned —and Richardson later confirmed to MWN —that it would be equal in rank to NIH and FDA. Thus it would absorb the NCI and be independent of NIH, at the same time being administratively tied to NIH and scientifically cooperating with the other institutes.

Many observers speculate that disturbing the makeup of NIH could signal the beginning of its breakup. Although the Administration has tried valiantly to portray the cancer-cure program as a part of the agency, under it NCI would no longer be equal in stature to the eight other NIH arms. Its budget would be made up separately and its grants and contracts would no longer have to be approved by an advisory council.

Other institutes—especially Heart and Lung—seem uptight about the impending change. If Heart and Lung can't compete to its satisfaction for funds within the NIH framework, its outside supporters may agitate for separate status too.

The director of Mr. Nixon's cancer program would be appointed by the President himself, subject to Senate confirmation. Richardson says this director (not yet chosen) "will not report to me, but directly to the President through the Office of Science and Technology." The present NCI director, Dr. Carl G. Baker, would become deputy director.

The reaction from Kennedy's office was swift but mixed. The Senator's health subcommittee immediately halted final processing of his bill, S. 34, and scheduled hearings on Mr. Nixon's proposal next week. A Kennedy spokesman says the President's bill "exceeded anything discussed between the Senator and Richardson." But he admits the two camps were "very close."

Both sides agree on a separate agency, headed by a Presidential appointee to provide over-all coordination and direction for a "moonshot" cancer cure. A spokesman for Kennedy says the only big difference now between the two camps is whether the super-agency stays within HEW. "We still feel that a NASA-type organization separate from HEW is the best approach, and the Administration is going to have to prove its idea is better," he says. Richardson says the agency would definately stay within HEW. The only question, he adds, is whether it would remain in NIH.

Mr. Nixon's new plan differs sharply from the one he described in his health message January 22. He then proposed a program completely within NIH, with its director subordinate to the NIH chief and, in effect, providing a kind of high-visibility leadership for NCI. The shift developed after it became clear that Administration efforts to bottle up S. 34 in the Senate Labor and Public Welfare Committee had failed, thanks largely, the White House concedes, to lobbying headed by philanthropist Mary Lasker.

# SUMMARIES

1. All papers must have summary.
2. Summary must not exceed 250 words in length. Usually summary will be 100 to 150 words in length.
3. Use narrative form. Do not give a list of headings, and do not number various parts of the summary.
4. Do not use abbreviations or references in summary.
5. Do not repeat or paraphrase title.
6. Summary should provide a condensation or abstract of material presented in body of paper. It is intended to inform when main paper is not immediately available.
7. Be specific. Tell age, sex of patient or give specific numerical results when feasible. Indicate experimental method used. Indicate conclusions derived.
8. Do not present material in summary which is not available in body paper.
9. Avoid generalities.

# Meetings

Special advertising rate for all not-for-profit organizations for Announcement of Meetings

Four to six insertions, depending upon availability of space, of one-fourth page black and white advertisement. Copy must be received at least nine months in advance.

**$150 total cost** (no commissions)
**Regular price: $360**

# Apollo Space Flight Veteran: Methulose, for dry eyes!

Methulose artificial tears lubricate sensitive ocular tissues to provide comfortable, soothing relief from eye dryness and irritation without blurring vision. Little wonder it is a big item on Apollo flights where dry eyes could present serious problems.

Meanwhile, back on earth, Methulose might be the simple solution to the dry-eye problems of many of your patients. A non-irritating buffered aqueous solution containing Methylcellulose U.S.P. preserved with Benzalkonium Chloride 1:25,000, it is available in 15cc and 30cc direct application plastic containers. Write for a generous supply of 5cc starter samples.

**PROFESSIONAL PHARMACAL CO., INC.**

P. O. Box 230 300 W. Josephine St., San Antonio, Texas 78206

In an environment of repeated irritation...

## one drop of Albalon™ provides over 190 minutes of the most potent decongestant activity.

In a recent double blind study,* the superior decongestant activity of Albalon™ Liquifilm® was clearly demonstrated. Compared to three of the most familiar vasoconstrictors, just one drop of Albalon™ provided both immediate, effective eye-whitening, and 190 minutes of the most potent protection against repeated ocular insult.

Additionally, Albalon™ comes in the Liquifilm® vehicle to soothe, lubricate and comfort itchy, smarting, red eyes.

*from an independent study conducted on a controlled population; data on file, Allergan Research Department.

**Contains:** naphazoline HCl, 0.1%; Liquifilm® (polyvinyl alcohol), 1.4%; with benzalkonium chloride, disodium edetate, citric acid, sodium citrate, sodium chloride, sodium hydroxide and purified water. **Indications:** For use as a topical ocular vasoconstrictor. **Contraindications:** Hypersensitivity to the components of this preparation. **Precautions:** This preparation should be used only with caution in the presence of hypertension, cardiac irregularities, hyperglycemia (diabetes), hyperthyroidism. **Adverse Reactions:** Pupillary dilatation, increase in intraocular pressure, systemic effects due to absorption (i.e. hypertension, cardiac irregularities, hyperglycemia). **Warnings:** Should not be used in patients with narrow angle glaucoma. If irritation persists, or increases, discontinue use. **Dosage and Administration:** One to two drops instilled in each eye every three to four hours or less frequently, as required to relieve symptoms.

Rx **Albalon**™ LIQUIFILM® Ophthalmic Solution
(naphazoline HCl)

## THE PRECISION MICROSCOPE THAT'S AS MANEUVERABLE AS YOU ARE

Your delicate movements during surgery require you to **move about freely.** So you've passed up table or floor mounted microscopes to retain your mobility.

Now, the XONIX STEREOSCOPE* — the quality binocular microscope **you control like a loupe.** To bring a subject into focus, you merely move your head. A glance below the oculars gives you an unobstructed, unmagnified view of the field. **Your hands are completely free** — no fiddling with adjustments during surgery.

**Self-contained coaxial light system** pinpoints the subject with 1500 foot-candles of **cool illumination,** which you'll find particularly useful when operating in cavities.

Interchangeable oculars provide various magnifications, such as 6X, with exceptional optical clarity and resolution. The optical system was **computer-designed** specifically for this instrument.

Comfortable headpiece is **chamois-lined** to absorb moisture and **foam-padded** to provide a soft cushion. You can even wear the XONIX STEREOSCOPE **with your regular glasses** without sacrificing field size.

**THE XONIX STEREOSCOPE — DESIGNED FOR THE SURGEON WHO WANTS THE SAME MANEUVERABILITY WITH HIS MICROSCOPE AS HE HAS WITH HIS HANDS.**

## GENERAL

Address manuscripts and other scientific communications to Frank W. Newell, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Manuscripts must be original material submitted solely to the AMERICAN JOURNAL OF OPHTHALMOLOGY. Two original typed copies must be submitted. The entire manuscript, including case reports, footnotes and references, must be typed in double space, with wide margins, on 8½ by 11-inch heavy white bond paper. See Suggestions to Authors (Am. J. Ophth. 70: Advertising pages 85–88, December, 1970). Receipt of manuscript is acknowledged immediately.

Author's proofs must be corrected and returned within 48 hours to Manuscript Editor, 160 East Grand Avenue, Chicago, Illinois 60611.

Fifty reprints of each article will be supplied to the senior author without charge. Additional reprints may be obtained from Ophthalmic Publishing Company, 160 East Grand Avenue, Chicago, Illinois 60611, if ordered at the time proofs are returned.

Address news items and society proceedings to Thomas Chalkley, M.D., 700 North Michigan Avenue, Chicago, Illinois 60611.

Exchange copies of medical journals should be sent to David Shoch, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Subscriptions, requests for single issues, notices of changes of addresses, advertising and other communications should be sent to 160 East Grand Avenue, Chicago, Illinois 60611.

Change of address notices must be received at least 60 days in advance and must include both old and new addresses.

Claims for copies lost in the mail must be received within 60 days from the date of issue.

Advertisement insertion orders and copy must be received before the first day of the preceding month for which the advertisement is scheduled.

# There is still nothing like it.

The superb Donaldson* Stereo-Camera is still the standard of quality that all others try to match. None has yet.

And quality means more than precision construction. The Donaldson is simple to use — you concentrate on the subject, not on complicated controls. It is versatile — you can use it for close-up photography as you would an ordinary 35mm camera. It is a complete system — with an available drum viewer, strip viewer, and single slide viewer.

As for processing, we simplify that too — both developing and mounting if you wish. And last but not least, the Donaldson Stereo-System is now available without delay. Write today for a full description and ordering information. Mentor Division, Codman & Shurtleff, Inc., Randolph, Massachusetts 02368.

*David D. Donaldson, M.D., Associate Professor of Ophthamology, Harvard Medical School, Howe Laboratory of Ophthamology and Massachusetts Eye and Ear Infirmary.

*Occupational Vision Studies*
*(From Study #33, Volume II, Guide to Occupational and Other Visual Needs)*

# Trainman

(Engineer)

The lives of many passengers depends on the skill of the engineer who operates the locomotive — and his skill, in turn, is dependent at least in part on his vision while on the rails. Distance vision is of prime importance to the engineer, to see hand and arm signals clearly at varying distances. Intermediate vision must be good to watch his collection of dials and gauges, while near vision demands involve reading orders, timetables and other material.

Volume II of *Guide to Occupational and Other Visual Needs* outlines in detail the vision needs not only of locomotive engineers, but other trainmen as well. In addition, forty-seven other occupations are similarly covered. It belongs in your working library, and you can get it through any Vision-Ease distributor.

That's also where you can get the multifocal lenses with which to fit the trainmen you serve. Any of the usual styles and sizes and some that are pretty unusual. Check your distributor.

*Announcing two new designs*

# CONFORM-A-SPHERIC™ *and* ELLIP-SEE-CON™

## ASPHERIC CORNEAL LENSES

**ARE WE NUTS?** Imagine . . . we're advertising a NEW corneal lens design when everyone's interested in soft lenses!

**WE HAVE OUR REASONS!** First, soft lenses are in a transition phase. (It may be 12 to 18 months before everyone may fit soft lenses.) Also, the new soft lens materials are not expected to solve **all** contact lens needs nor to completely replace the hard lens.

**THE PUBLIC MUST BE SATISFIED!** Aspheric designs will challenge soft materials for future comfort and fitting simplicity. In fact, aspheric lenses will:

1) Eliminate peripheral flare without gimmicks. They furnish a wider, brighter peripheral field of vision.

2) Assured reproductibility! A distinct advantage over convential sperical curves.

3) Their gentle, more evenly distributed bearing areas minimize corneal changes and spectacle blur problems.

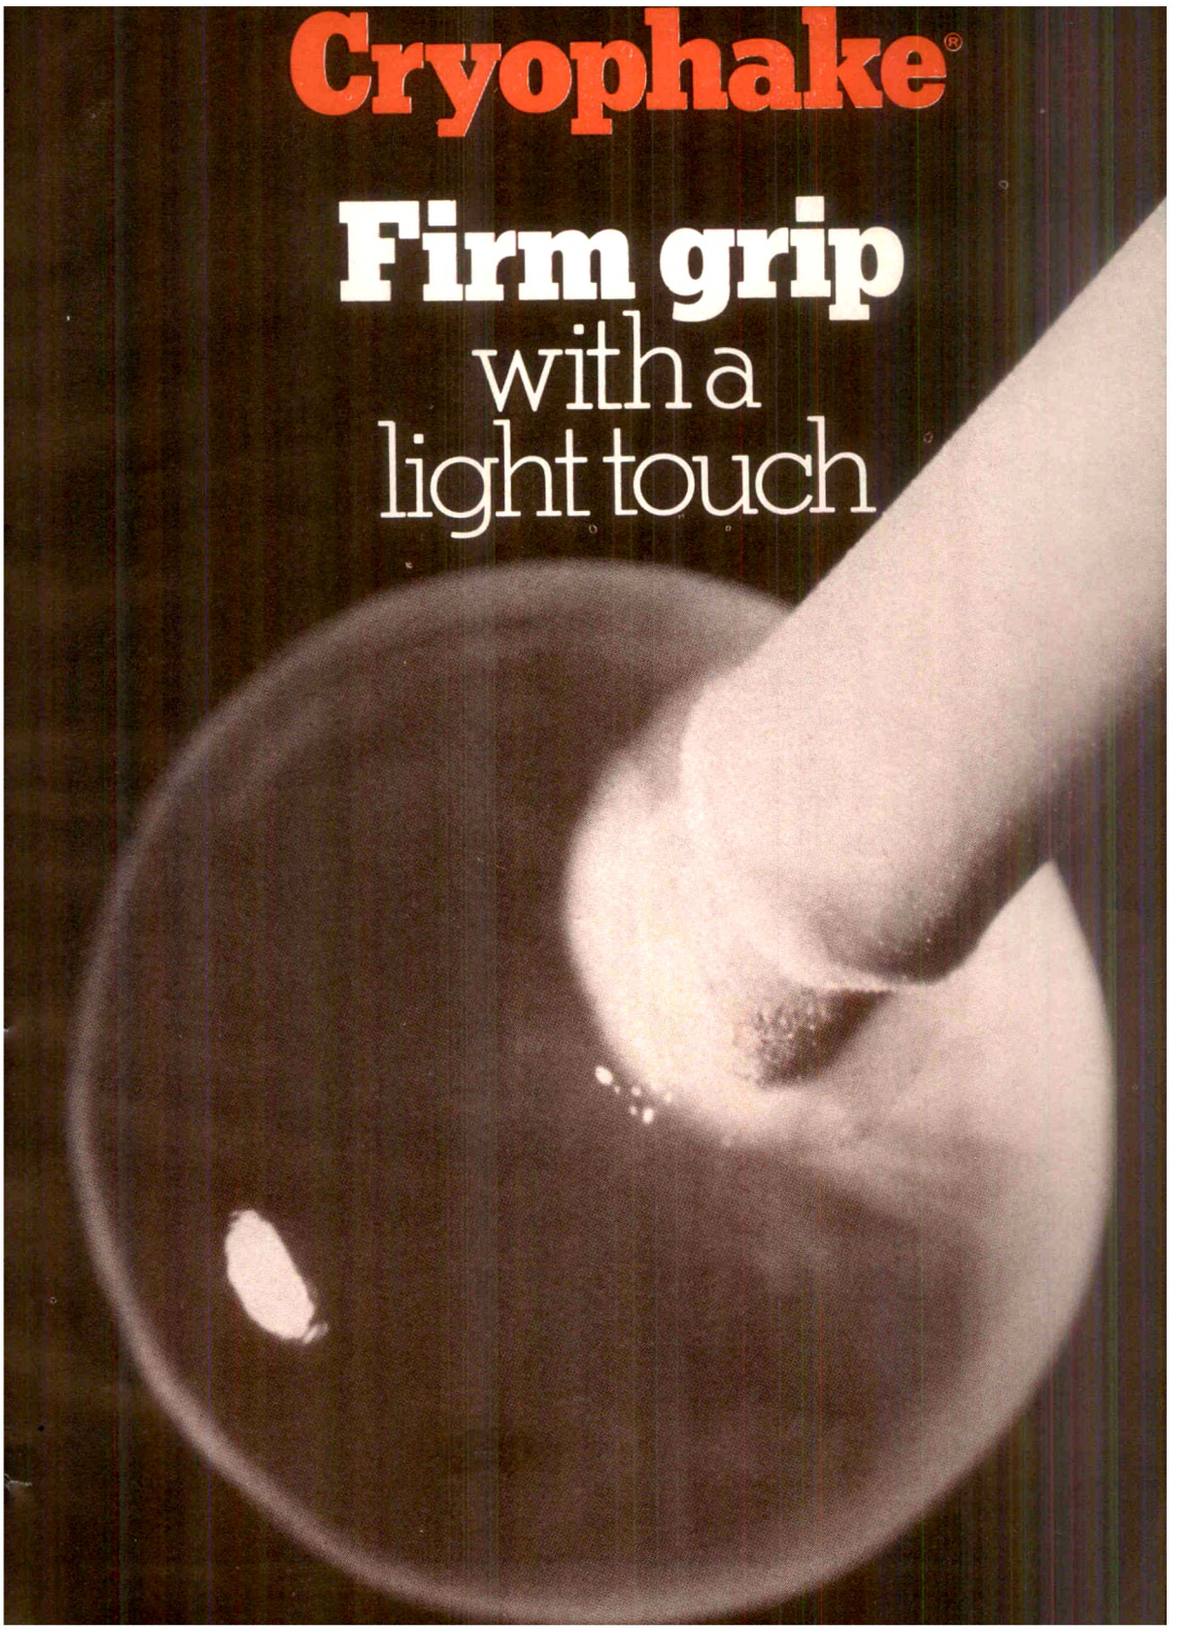
When properly managed, aspheric lenses will increase patient comfort and decrease fitting time.

**ASPHERIC LENSES COST LESS!** Aspheric lenses cost less than soft lenses. And, in these inflationary times, you'd better believe that this is meaningful.

**ASPHERIC LENS VERSATILITY** We have two aspheric corneal lens designs:

1) CONFORM-A-SPHERIC™—aspheric values replace the conventional spherical peripheral curve (s). Can be used with any existing fitting philosophy (spherical or toric base curves).

2) ELLIP-SEE-CON™—an ellipsoidal central curve and an aspheric bevel.



**LEARN HOW** to use Aspheric Corneal Lenses.

Cryophake®
Firm grip
with a
light touch

# Cryophake®

Sterile/Disposable Cryoextractor

Developed by R. David Sudarsky, M.D.

**for a firm grip with a light touch**

**All the advantages of cryoextraction with Cryophake**

Reduces incidence of capsule rupture[1-5]
Facilitates intracapsular extraction[2,3,4,5]
Reduces likelihood of vitreous loss[1,2,5]
Reduces trauma and postoperative complications[1-5]
Permits a wide variety of surgical techniques[3]

**All these surgical benefits with Cryophake**

Selective defrosting . . . accidental adhesions easily freed without loosening bond on lens
Ready for immediate use, self contained, easily activated
Compact, hand-contoured design for 'in use' comfort
Lightweight and maneuverable
Small tip for maximum visualization
Pre-sterilized to minimize chance of infection
Disposable and inexpensive

**Cryophake** . . . for all your cataract surgery

# BY ALL MEANS!

Armorlite originated the world's first hard resin lenses in 1947, and has been perfecting them ever since. We make more types of these modern lenses than any one else, and they have a reputation for unsurpassed quality. We make only hard resin lenses and we do it in earnest; they are not a side-line with us.

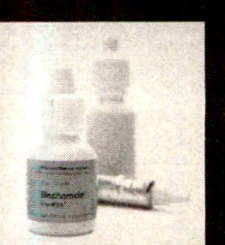
When you think patient care and protection, think Armorlites, by all means.

## ARMORLITE, INC.

# ONE RX CAN PROVIDE ROUND-THE-CLOCK THERAPY

## Blephamide® Liquif lm®

**OPHTHALMIC SUSPENSION**



Sodium sulfacetamide, 10.0%; prednisolone acetate 0.2%; phenylephrine HCl, 0.12%; Liquifilm (polyvinyl alcohol), 1.4%; and antipyrine, 0.1%.

Specifically designed to treat nonpurulent blepharitis. Patient-accepted for routine day and night use.

With Liquifilm®—the advantage, but not the disadvantage...of ointments—prolonged contact with lesions—no greasy appearance—ointments are not required to be sterile.

Dries quickly to a clear, invisible film on lids...so cosmetically acceptable, round-the-clock treatment virtually assured.

One-prescription economy.

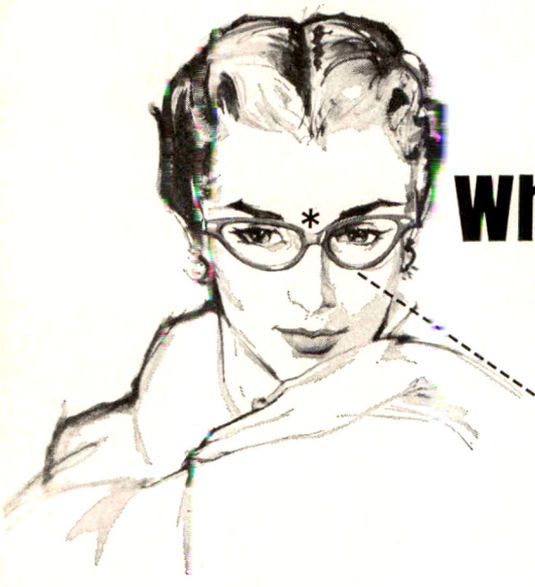
**Why Use Two... When One Will Do!**

With BLEPHAMIDE LIQUIFILM, you provide antibacterial/anti-inflammatory/anti-allergy/anti-seborrheic activity—in a form that has the convenience of drops...the persistence of ointments All of the advantages of both dosage forms...none of the disadvantages.

**Description:** Sodium sulfacetamide, 10.0%; prednisolone acetate, 0.2%; phenylephrine HCl, 0.12%; Liquifilm (polyvinyl alcohol), 1.4%; phenylmercuric nitrate, 0.004%; polysorbate 80, 0.1%; antipyrine, 0.1%; with: disodium edetate; sodium phosphate; dibasic anhydrous sodium phosphate; monobasic sodium thiosulfate; purified water; hydrochloric acid to adjust pH to 6.8.

**Indications:** Nonpurulent blepharitis and blepharoconjunctivitis (seborrheal, staphylococcal, and mixed); nonpurulent conjunctivitis (allergic and bacterial).

**Contraindications:** Acute herpes simplex (dendritic keratitis), purulent untreated infections, vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, ocular tuberculosis and fungal diseases of the eye.



**Warnings:**

1. In diseases due to microorganisms, infection may be masked, enhanced or activated by the steroid.
2. Extended use may cause increased intraocular pressure in susceptible individuals. It is advisable that the intraocular pressure be checked frequently.
3. In those diseases causing thinning of the cornea perforation has been known to have occurre with the use of topical steroids.
4. Use with caution in patients with known or sus pected sensitivity to sulfonamides — if sensitivit or other untoward reactions occur, discontinu medication.
5. Should be used with caution in the presence narrow angle glaucoma.
6. Reports in the literature indicate that posteri subcapsular lenticular opacities have been re ported to occur after heavy or protracted use topical ophthalmic steroids.

**Dosage and Administration:** 1 drop 2 to 4 time daily, depending on the severity of the conditio

**Supplied:** 5 cc. and 10 cc. plastic dropper bottles on prescription only.

ALLERGAN Pharmaceuticals
Irvine, California/Montreal, Canad

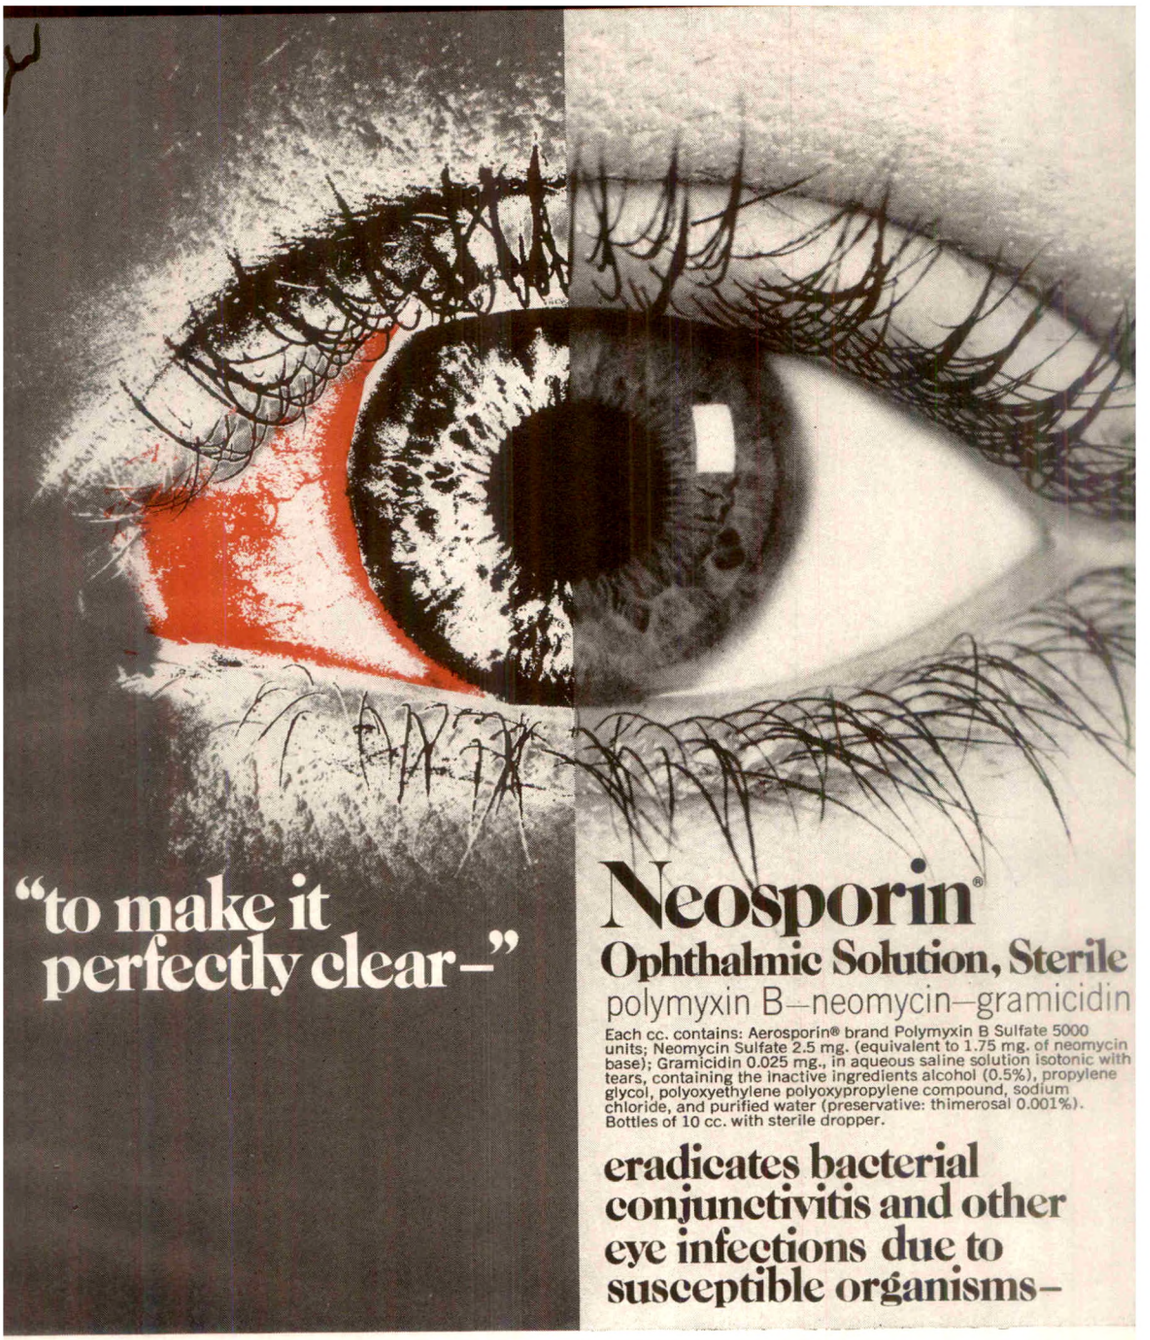
# Why Younger Lenses are also available in hard resin

Younger Seamless Lenses are designed to overcome resistance to ordinary, age-revealing visible bifocals and, especially for women in the change of life, to help allay their psychoneurotic fears of growing old by eliminating an outward sign of their condition.

Persons old enough to require bifocals also are heir to another condition of aging, characterized by a diminishing of fluids in the skin, which causes wrinkles, sagging and tenderness in bony areas. This in turn gives rise to complaints like "these glasses hurt my nose".

While the youth-seeking matron undergoing menopause will put up with a certain amount of minor pain for the sake of her appearance, how much nicer for her if she could enjoy her invisible bifocals in complete comfort!

Frankly, that's why YOUNGER-LITE Seamless Lenses were developed. They're precision-cast from pure CR-39*, the hard resin wonder material equal to and sometimes superior to glass in optical characteristics and second only to glass in physical ways. With only half the weight of glass, YOUNGER-LITEs offer the wearer the combined advantages of comfort and invisibility. What could be better for the patient?



Your next bifocal candidate will appreciate these advantages and thank you for them. What could be better for *you*?

*A PPG Industries trademark

*Younger Lenses are available through most independent labs and all American Optical branches . . . in glass or hard resin.*

YOUNGER-LITE *Seamless*

YOUNGER MANUFACTURING COMPANY 3788 So. Broadway Pl • Los Angeles, Cal. 90007

"to make it perfectly clear–"

# Neosporin®

## Ophthalmic Solution, Sterile

polymyxin B–neomycin–gramicidin

Each cc. contains: Aerosporin® brand Polymyxin B Sulfate 5000 units; Neomycin Sulfate 2.5 mg. (equivalent to 1.75 mg. of neomycin base); Gramicidin 0.025 mg., in aqueous saline solution isotonic with tears, containing the inactive ingredients alcohol (0.5%), propylene glycol, polyoxyethylene polyoxypropylene compound, sodium chloride, and purified water (preservative: thimerosal 0.001%). Bottles of 10 cc. with sterile dropper.

## eradicates bacterial conjunctivitis and other eye infections due to susceptible organisms–

- highly effective against almost all pathogens which invade the eye, including *Pseudomonas* and *Staphylococcus aureus*
- bacterial resistance rarely develops on repeated or prolonged use
- low allergenicity
- also available: Neosporin® Ophthalmic Ointment—Each gram contains: Aerosporin® brand Polymyxin B Sulfate 5000 units; Zinc Bacitracin 400 units; Neomycin Sulfate 5 mg. (equivalent to 3.5 mg. neomycin base) in special white petrolatum q.s. In ⅛ oz. tubes with ophthalmic tip.

*Precaution:* As with other antibiotic preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs. Articles in the current medical literature indicate an increase in the prevalence of persons allergic to neomycin. The possibility of such a reaction should be borne in mind.

*Contraindications:* This product is contraindicated for subconjunctival or intraocular injection, or for irrigation of fistulous tracts. This product is also contraindicated in those individuals who have shown hypersensitivity to any of its components.

Complete literature available on request from Professional Services Dept. PML.

Wellcome

# His efficiency depends on his vision.

You've heard it said that the Guild Optician is expert at his work. Occupational vision, especially for the presbyope, is most efficient when individually prescribed for. Working distances often vary; machine settings must be checked at one distance and work performed at another . . . and possibly a third for reading plans and specs.

To arrive at these requirements is a matter of tedious research in existing manuals and patient questioning of the subject as to his non-occupational activities involving vision (if he were a fisherman, his specialized vocational Rx just wouldn't do).

The Guild Optician is admirably suited to handle these details, given a basic Rx from which to work. In this way his services save the ophthalmologist valuable time. This is one of the ways in which a Guildmember can help both the ophthalmologist *and* his patient.

**Guild of Prescription Opticians of America, Inc.**
**1250 Connecticut Avenue, N.W., Washington, D.C. 20036.**

Most ophthalmic solutions start out sterile. But the OCUMETER® helps this one stay that way.
OCUMETER helps steroid solution stay sterile by eliminating a major cause of contamination —the eye dropper. Sterile, highly stable
Ophthalmic Solution
DECADRON®
Phosphate
(Dexamethasone Sodium Phosphate|MSD)
0.1% Dexamethasone Phosphate Equivalent
for mild acute iritis and nonpurulent conjunctivitis
For prescribing information, please see next page.

## for mild acute iritis and nonpurulent conjunctivitis

Not all steroid ophthalmic solutions stay sterile during the days and weeks of therapy. But this one is more apt to—Ophthalmic Solution DECADRON Phosphate (Dexamethasone Sodium Phosphate, MSD) in the OCUMETER® eliminates a common source of contamination—the eye dropper.

*Uniform dosage, drop after drop*

Each drop of Ophthalmic Solution DECADRON Phosphate contains the same dosage of steroid. And, with a gentle squeeze, the OCUMETER measures out one drop at a time. So your patient can conveniently get the steroid dose you want her to have, wherever she is.

Each cc. contains dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate. Also available as DECADRON® Phosphate Ophthalmic Ointment (0.05%); and as NeoDECADRON® Ophthalmic Solution containing dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base in each cc.; and NeoDECADRON® Ophthalmic Ointment, containing dexamethasone sodium phosphate equivalent to 0.5 mg. (0.05%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base per gram.

Sterile, highly stable
Ophthalmic Solution
**DECADRON®** Phosphate
(Dexamethasone Sodium
Phosphate | MSD)

CONTRAINDICATIONS: DECADRON and NeoDECADRON should not be used in the presence of infectious tuberculous lesions of the eye, chickenpox, early acute herpes simplex, vaccinia, the early acute stages of most viral diseases of the cornea and conjunctiva, acute purulent untreated infections of the conjunctiva and lids, suspected ocular or aural fungal infection, perforated ear drum. Sensitivity to components is also a contraindication.

PRECAUTIONS: DECADRON: Like all adrenal corticosteroids, may sometimes mask, activate, or enhance incipient infection. Whenever possibility of infection exists, suitable antibiotic agents or a steroid-antibiotic preparation (such as NeoDECADRON) should be considered. If infections do not respond promptly, therapy should be discontinued until the infection has been adequately controlled by other measures.

Systemic side effects may occur with extensive use of steroids. Rarely, ocular herpes simplex has been reported in patients receiving adrenocortical steroids systemically or locally in the eye for other conditions.

As with other corticosteroids, increased intraocular tension can follow extended local use (1-2 weeks or more) of dexamethasone sodium phosphate. Since increased intraocular tension can lead to loss of vision, this possibility should be kept in mind and topical administration used only under adequate tonometric supervision, particularly in patients known to have glaucoma, or whose family history includes glaucoma.

In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids. Reports in the literature indicate that, rarely, protracted use of topical corticosteroids in the eye may be associated with the development of posterior subcapsular cataracts. Hereditary and degenerative eye diseases in general do not show any response to treatment with these preparations.

Stubborn cases of anterior segment eye disease may require systemic adrenocortical hormone therapy. When the deeper ocular structures are involved, systemic therapy is necessary.

NeoDECADRON: A few individuals may be sensitive to one or more of the components of NeoDECADRON. If any reaction indicating sensitivity is observed, discontinue use. Sensitivity to neomycin may occasionally develop, especially when it is applied to abraded skin. Some reports in the current literature point to an increase in the number of persons sensitive to neomycin.

Use of any antibiotic agent may result in overgrowth of fungi or other organisms not susceptible to the antibiotic, necessitating prompt medical attention for such new infections.

As the safety of topical steroids during pregnancy has not been confirmed, they should not be used for extended periods during pregnancy.

**For more detailed information, consult your MSD Representative or see the Direction Circular. Merck Sharp & Dohme Division of Merck & Co., Inc., West Point, Pa. 19486**

**MSD** MERCK SHARP & DOHME

soflens™
CONTACT LENS
(polymacon)

Conventional methods of fitting contact lenses do not apply to SOFLENS Contact Lenses (polymacon). For a detailed description of the fitting technique, refer to the SOFLENS Fitting Guide, copies of which are available from: SOFLENS Division, Bausch & Lomb Incorporated, Rochester, New York 14602.

**DESCRIPTION:** The SOFLENS Contact Lens (polymacon) is a hemispherical shell of approximately 13mm chord diameter and 0.1 to 1.0mm thickness. It consists of 61.4% poly (2-hydroxyethyl methacrylate) and 38.6% water by weight when immersed in normal saline. The SOFLENS Care Kit is a package required for lens asepticizing, cleaning, and storage consisting of the following:

| | |
|---|---|
| SOFLENS Carrying Case | Cat. #140301 |
| SOFLENS Aseptor-Patient Unit | Cat. #140302 |
| SOFLENS Squeeze Bottle | Cat. #140304 |
| SOFLENS Salt Tablets | Cat. #140305 |
| SOFLENS Patient Instruction Book | Cat. #140300-100 |

**ACTIONS:** The SOFLENS Contact Lens (polymacon) absorbs water to 38.6% of its dry weight when equilibrated in normal saline solution. In its hydrated state a SOFLENS Contact Lens (polymacon) becomes soft and pliable. When placed on the human cornea the hydrated SOFLENS Contact Lens (polymacon) acts as a refracting medium to compensate spherical ametropias. The material has a refractive index of 1.43 and the lens has a visible light transmittance greater than 97%.

**INDICATIONS:** SOFLENS Contact Lenses (polymacon) are indicated for the correction of visual acuity in persons with non-diseased eyes who have spherical ametropias; refractive astigmatism of 1.50 diopters or less and/or corneal astigmatism of 2.00 diopters or less.

**CONTRAINDICATIONS:** SOFLENS Contact Lenses (polymacon) are contraindicated by the presence of any of the following conditions. (1) Acute and subacute inflammations of the anterior segment of the eye. (2) Any eye disease which affects the cornea or conjunctiva. (3) Insufficiency of lacrimal secretion. (4) Corneal hypoesthesia. (5) Any systemic disease which may affect the eye or be exaggerated by wearing contact lenses. (6) Early stages of pregnancy.

**WARNINGS: Medicants and Eye Drops**—SOFLENS Contact Lens (polymacon) must be stored ONLY in normal saline solution. No ophthalmic solutions or medicants, including conventional contact lens solutions, can be used by SOFLENS Contact Lens (polymacon) wearers prior to or while the lens is in place on the eye. Also, no solutions, including conventional contact lens solutions, other than normal saline may be used on SOFLENS when the lens is off the eye.
**Abrasions and Infections**—If the lenses become less comfortable to the wearer than when they were first placed on the wearer's corneas, this may indicate the presence of a foreign body. The lens should be removed immediately and the patient examined. If any eye abrasion, ulceration, irritation or infection is present, a physician should be consulted immediately.
**Wearing Restrictions**—SOFLENS Contact Lenses (polymacon) should be removed before sleeping or swimming and in the presence of noxious and irritating vapors.
**Visual Blurring**—When visual blurring occurs the lens must be removed until the condition subsides.
**Lens Sanitation**—Patients who would not or could not adhere to recommended daily sanitary care of SOFLENS Contact Lenses (polymacon) should not be provided with them.

**PRECAUTIONS: Storage**—SOFLENS Contact Lenses (polymacon) must be stored ONLY in normal saline solution. If left exposed to air, the lenses will dehydrate, become brittle, and break readily. If a lens dehydrates, it should be soaked in normal saline solution until it returns to a soft, supple state.
**Cleaning and Asepticizing**—SOFLENS Contact Lenses (polymacon) must be BOTH cleaned and asepticized daily. One procedure does not replace the other. CLEANING is necessary to remove mucus and film from the lens surface. ASEPTICIZING with the SOFLENS Aseptor-Patient Unit has been shown to prevent the growth of certain organisms, namely Staphylococcus aureus, Pseudomonas aeruginosa, Bacillus subtilis, Candida albicans, and Herpes simplex, on the lens and in the SOFLENS Carrying Case. Fresh normal saline must be prepared daily for cleaning and storing the lenses. The carrying case must be emptied and refilled with fresh normal saline solution just before asepticizing the lenses. If a SOFLENS Aseptor-Patient Unit is not available for asepticizing the lenses, the lenses must be boiled in their carrying case in a pan of water for 15 minutes.
**Hygiene**—Hands must be washed, rinsed thoroughly, and dried with a lint-free towel before handling the lenses. Cosmetics, lotions, soaps, and creams must not come in contact with the lenses since eye irritation may result. If hair spray is used while the lenses are being worn, the eyes must be kept closed until the hair spray has settled.
**Fluorescein**—Never use fluorescein while the patient is wearing the lenses because the lenses will become discolored. Whenever fluorescein is used, flush the eyes with normal saline solution and wait at least one hour before replacing the lenses. Too early replacement may allow the lenses to absorb residual fluorescein irreversibly.

**ADVERSE REACTIONS:** Serious corneal damage may result from wearing a lens which has been soaked in a conventional contact lens solution containing preservatives. Eye irritation may occur within a short time after putting on a hypertonic lens. Removal of the lens will relieve the irritation. Very rarely a lens may adhere to an eye as a result of the patient sleeping with the lens on or wearing a hypotonic lens. If a lens adheres for any reason, apply normal saline and wait until the lens moves freely before removing it. Clinical studies indicate visual blurring is experienced by less than 5% of SOFLENS Contact Lens (polymacon) wearers. Rainbows or halos around objects or blurring of the vision may occur if the lenses are worn continuously for too long a time. Removal of the lenses and a rest period of at least one hour generally relieves these symptoms. Excessive tearing, unusual eye secretions, and photophobia are not normal; if these symptoms occur, the patient should be examined to determine their cause.

**DOSAGE AND ADMINISTRATION:** There may be a tendency for the patient to overwear the lenses initially. Therefore, the importance of adhering to the following initial daily wearing schedule should be stressed to the patient:

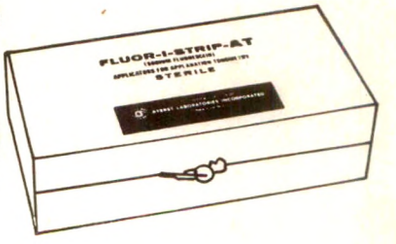
| Day | Wear Time (hours) | Rest Period (hours) | Wear Time (hours) | Rest Period (hours) | Wear Time (hours) |
|---|---|---|---|---|---|
| 1 | 3 | 1 | 3 | 1 | 3 |
| 2 | 3 | 1 | 3 | 1 | 3 |
| 3 | 4 | 1 | 4 | 1 | 4 |
| 4 | 4 | 1 | 4 | 1 | 4 |
| 5 | 6 | 1 | 6 | 1 | 4 |
| 6 | 6 | 1 | 6 | 1 | 4 |
| 7 | 8 | 1 | 8 | | |
| 8 | 8 | 1 | 8 | | |
| 9 | 8 | 1 | 8 | | |
| 10 | 10 | 1 | balance of the waking hours* | | |
| 11 | 12 | 1 | balance of the waking hours* | | |
| 12 | 14 | 1 | balance of the waking hours* | | |

*Lenses should never be worn 24 hours a day.

Care must be taken on the initial visit to assure that the patient is supplied with a SOFLENS Care Kit and fully understands all care and handling instructions for the lenses. As with any contact lens, regular recall visits are necessary to assure patient health and compliance with instructions.

**HOW SUPPLIED:** Each lens is supplied sterile in a glass vial containing sterile normal saline solution. The glass vial is marked with the dioptric power (black for plus power lenses; red for minus) and the manufacturing lot number of the lens. To assure proper lens care and handling, each SOFLENS patient must be supplied with a complete SOFLENS Care Kit.

BAUSCH & LOMB
SOFLENS DIVISION



**When fitting contact lenses: to guard against the risk of infection inherent in the use of sodium fluorescein solutions, stain eyes with sterile Fluor-I-Strip-A.T. No excess fluorescein to stain the patient's face or clothing...water-proof grip to prevent staining of your fingers. Simply retract upper lid, apply dry orange tip of flexible applicator to the bulbar conjunctiva at the temporal side. For all these benefits: Specify Ayerst**

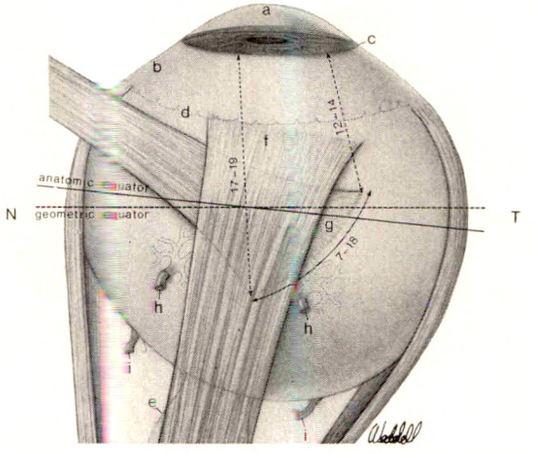
# OpMi 6 lets you see a lot more than you'd expect... and gives you the widest field, too...

**55 mm at 3.6x,**
**20 mm at 10x,**
**11 mm at 18x.**

At all magnifications the new OpMi 6 gives you the widest field of view of any operation microscope. And, within the field, the image quality is truly extraordinary. As you can see above, there is high resolution and contrast, and the graph paper demonstrates the perfectly flat field with no distortion edge-to-edge.

For all microsurgical disciplines, the OpMi 6 offers you features unmatched anywhere: **(1)** The precisely controlled zoom system–fully motorized, 1:5, constant angular zoom. Easy to get the precise magnification you want at any microscope orientation you want—vertical, horizontal or anywhere in between; **(2)** The unique motorized focusing along the optical axis regardless of the angle of the microscope; **(3)** The brilliant and uniform co-axial illumination—external slit and homogeneous illumination also available; **(4)** The working distance is adjustable—from 4" to 16" in steps of 1"—and up to 7' (to carry things to an extreme); **(5)** All the famous Zeiss accessories—the Beam Splitter for photography, television, and supplementary viewing systems through the microscope optics, high-eyepoint eyepieces for spectacle wearers; much more.

Ask anyone who has seen this microscope what they think of it. Better yet, ask us. Write or call Carl Zeiss, Inc., 444 Fifth Ave., New York, N. Y. 10018. (212) 736-6070.



Nationwide Service.

Slit Lamp PE/E with Hruby lens, fixation device, applanation tonometer, beam-splitter, observation tube and camera.

# Why a Zeiss Slit Lamp? Because you get precisely what you pay for.

Precisely means the high resolution that has made Zeiss optics world-famous, and the precision operation that has made Zeiss engineering synonymous with craftsmanship. And, to make sure that the slit lamp you buy will be tailored precisely to you and your work, you can choose from a range of instruments and features unmatched by anyone. There's no reason all slit lamps should be alike (after all, all people aren't), so with Zeiss, even before you consider accessories, your choice is a wide one. For your convenience, we have:

**4 basic models**—manual and motorized, step-wise and zoom. The step-wise magnification system is from 6x to 40x (the widest range of any slit lamp from anyone), the zoom is 8x to 40x. They're called the SM/M, the PM/M, the PE/E, and, of course, the famous Photo-Slit Lamp, the ultimate in sophistication. Standard on the Photo-Slit Lamp, and available also on the other three models, is an extra-long working distance to facilitate surgical intervention.

**The unique Galilean observation system**—it allows the famous Zeiss beam-splitter (used on our Operation Microscopes) to be inserted, letting you attach observation tubes and still, cine, and television cameras—invaluable aids for consultation or teaching purposes—all operating directly through the optics of the microscope. And because it is telecentric, this system lets you work with eyes relaxed, focused on infinity, *sans* strain. It quite literally means fewer headaches.

**The unusual depth of observation**—a result of the combination of the great depth of focus of the biomicroscope and the unmatched depth of the slit image.

**High-eyepoint eyepieces**—for physicians who must wear corrective lenses, these eyepieces offer the same wide field of view enjoyed by non-eyeglass wearers.

**Ease-of-handling**—these light-in-weight instruments are easy to use on a refraction unit or a table, whether you're left- or right-handed, tall or short, or have any kind of special requirements.

For complete details write Carl Zeiss, Inc., 444 5th Avenue, N.Y., N.Y. 10018. (212) 736-6070.

Nationwide service.

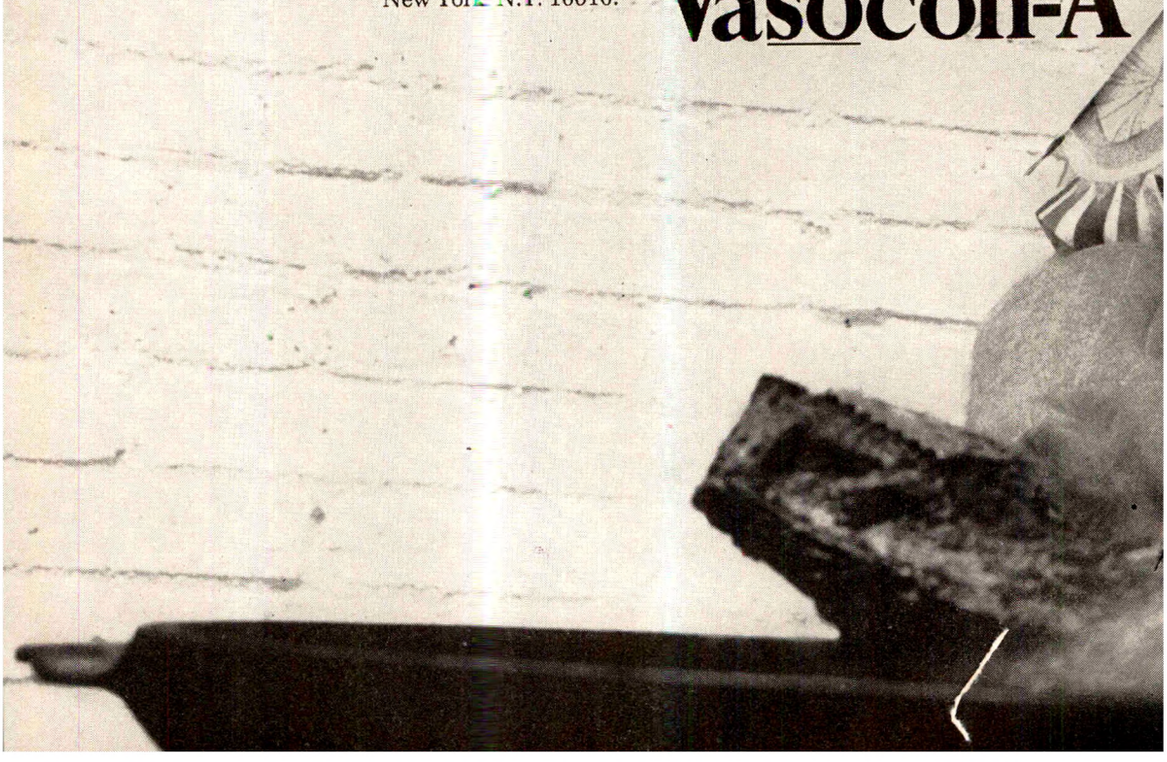
# Coals hot Steak rare Eyes raw

Windblown smoke and heat from cookouts make eyes burn and water. Vasocon-A relieves the discomfort. Long-acting vasoconstrictor-decongestant, antihistamine. Reduces burning and itching. Good after contact lens insertion and removal, too.

CAUTION: Federal law prohibits dispensing without prescription. See package insert before prescribing.

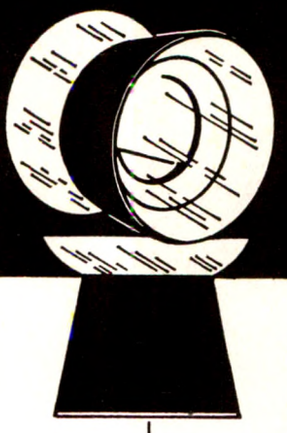
COMPOSITION: Naphazoline HCL, 0.05%; antazoline phosphate, 0.5%; boric acid, 1.2%; sodium carbonate anhydrous; sodium chloride; phenylmercuric acetate (preservative) 0.002%.



SIDE EFFECTS: Except for transitory stinging, side effects have rarely been encountered.

CONTRAINDICATIONS: Should not be used by patients with narrow angle glaucoma. If irritation persists or increases, patient should be advised to discontinue use and return to physician.

SUPPLIED: 15 cc plastic dropper-tip vials.



Smith, Miller & Patch, Inc.,
New York N.Y. 10010.

Area Code 617 • 479-2680

*Diagnostic and Surgical High Intensity Transilluminator*

Extremely flexible fiber optic bundle transmits strong, cold light to a straight or right angle probe or to special lenses for gonioscopy and goniotomy

The High Intensity Transilluminator is particularly useful in the study and management of the following conditions:

**Retinal Detachment**-Determining the shape and position of large choroidal structures such as vortex veins and long ciliary nerves and arteries. This permits the surgeon to avoid these structures with diathermy or perforation.

**Intraocular Foreign Bodies**-Detecting intraocular foreign bodies located close to the ocular wall, even if the transparent media are cloudy.

**Uveal Tumors**-Examining the posterior segment (with or without vitreous hemorrhage) for the presence of a tumor.

**Gonioscopy and Goniotomy**-Direct, illuminated viewing of the chamber angle. The Transilluminator provides internal, retro-illumination for the gonioscopy lens #MW54 (with additional clip-over lens for higher magnification) and the Goniotomy Lens #MW52A (with scleral rim and suturing holes).

The powerful and cold light of the Transilluminator is also suitable for illumination of the anterior segment and illumination of the surgical field when operating near the globe's posterior pole.

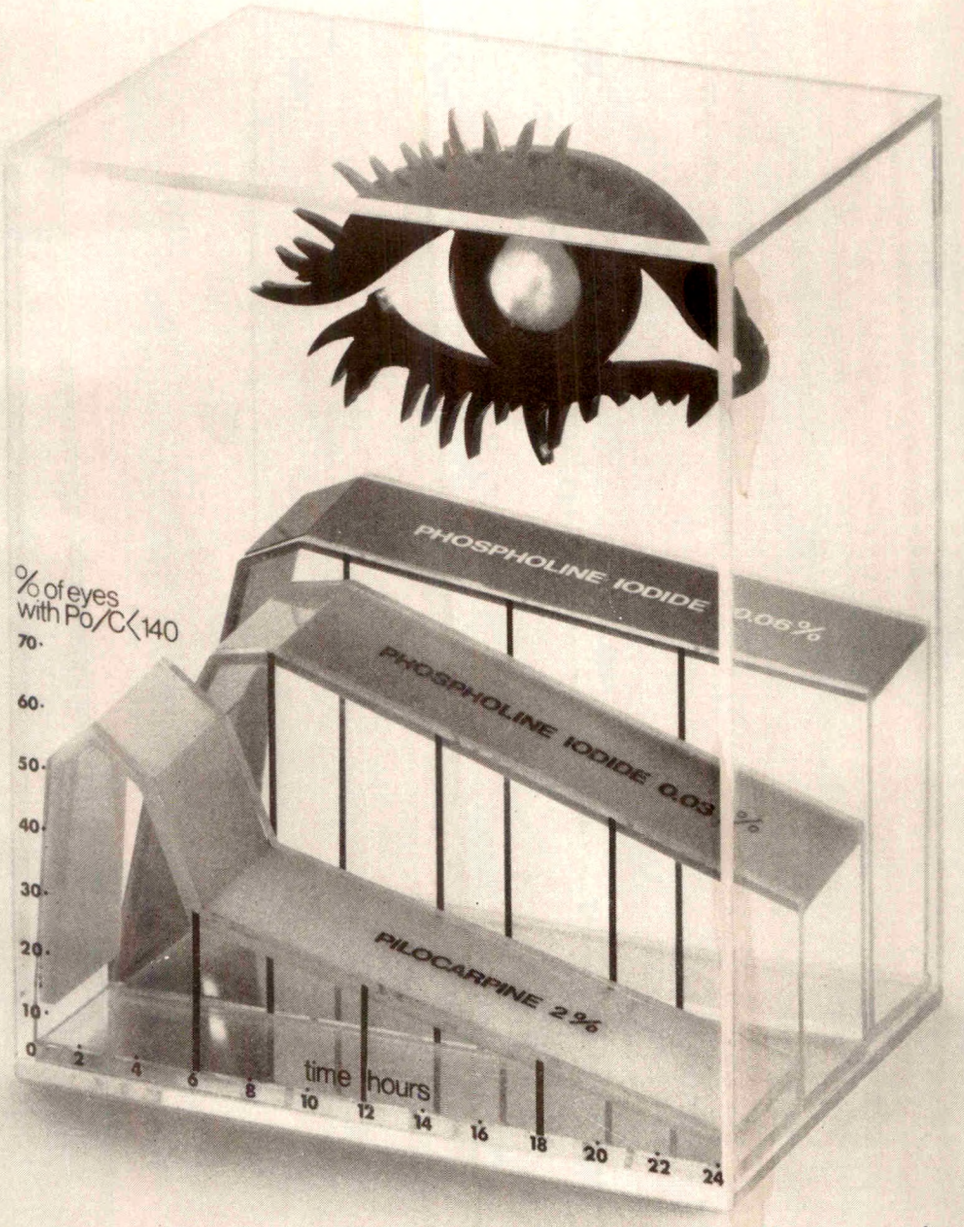
# Not more potent, but longer acting...*

PHOSPHOLINE IODIDE 0.03% and 0.06% were compared with pilocarpine 2% in a study of the time course of changes in outflow facility and intraocular pressure after single dose administration in patients with open-angle glaucoma. While Phospholine Iodide 0.06% showed little diminution in effect on intraocular pressure after 24 hours, the effect of pilocarpine 2% declined markedly in the first few hours, and was almost completely dissipated after 24 hours. The action of Phospholine Iodide 0.03% was intermediate between that of pilocarpine 2% and Phospholine Iodide 0.06%.

## An important consideration in the management of glaucoma



When treated with short acting miotics, the patient with open-angle glaucoma runs the risk of an undetected intraocular pressure buildup during the night—a "silent emergency."

The longer acting Phospholine Iodide® (echothiophate iodide) may protect against this nightly insult. A single instillation of the 0.03% or 0.06% strength before retiring will act through the critical hours, and is especially recommended when you have found pilocarpine to be inadequate.

When initiating therapy... Phospholine Iodide 0.03% can often maintain 24 hour control of intraocular pressure with a single instillation at bedtime. It provides a smooth transition to the higher strengths—0.06%, 0.125%, 0.25% —when necessary. When indicated, epinephrine or carbonic anhydrase inhibitors may be prescribed with any strength of Phospholine Iodide.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide for ophthalmic solution)

Effect of Phospholine Iodide and pilocarpine on intraocular pressure control.

*Adapted from Barsam, P. C., Boston U. School of Med.: Time Curves of the Effect of Miotics on Intraocular Pressure and Outflow Facility, Scientific Exhibit, Annual Convention, American Academy of Ophthalmology and Otolaryngology, Las Vegas, Oct. 5-9, 1970.

See next page for Brief Summary of prescribing information.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide)

## for 24 hour control in chronic simple (open-angle) glaucoma and glaucoma secondary to aphakia

just 1 or 2 instillations a day
- for long lasting effect on ocular tension—
helps protect against a "silent emergency" at night
- may be substituted for the bedtime dose of a short acting miotic
that controls intraocular pressure by day, but
fails to provide adequate control during the night and early morning
- choice of four strengths for individualized therapy—
may be used alone or as a complementary agent

**BRIEF SUMMARY (for full prescribing information, consult package circular)**
**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE (echothiophate iodide) concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

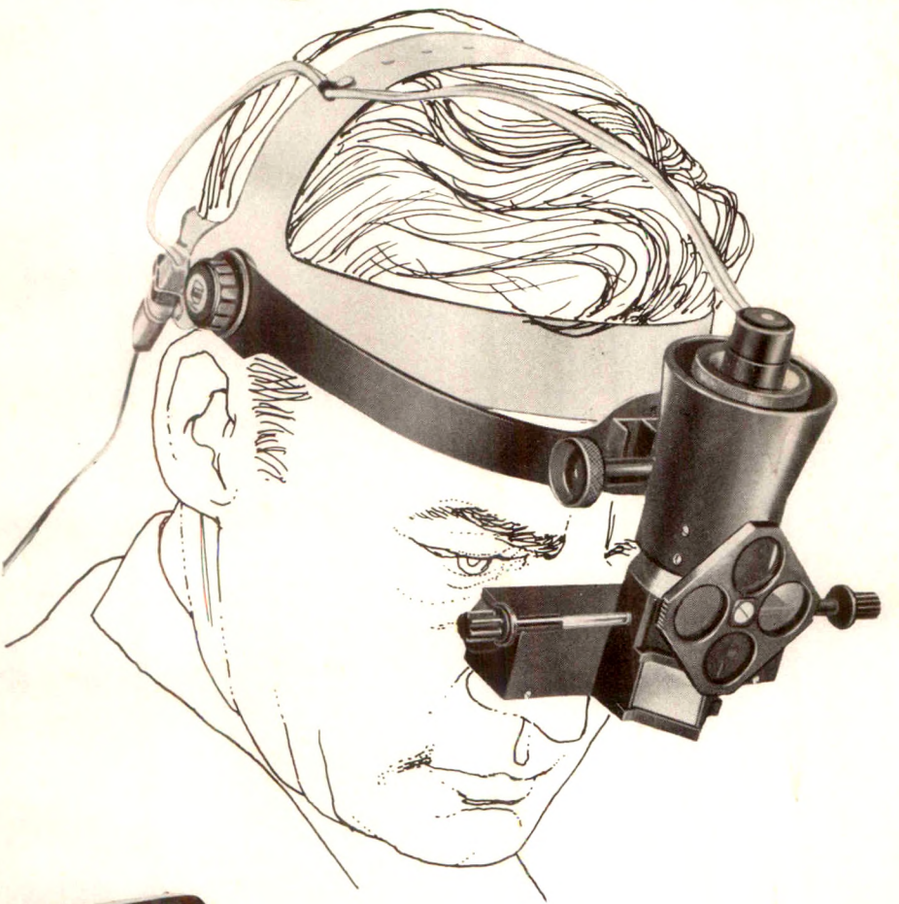
**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, brow-ache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local)* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE (echothiophate iodide) therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.



*(systemic)* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

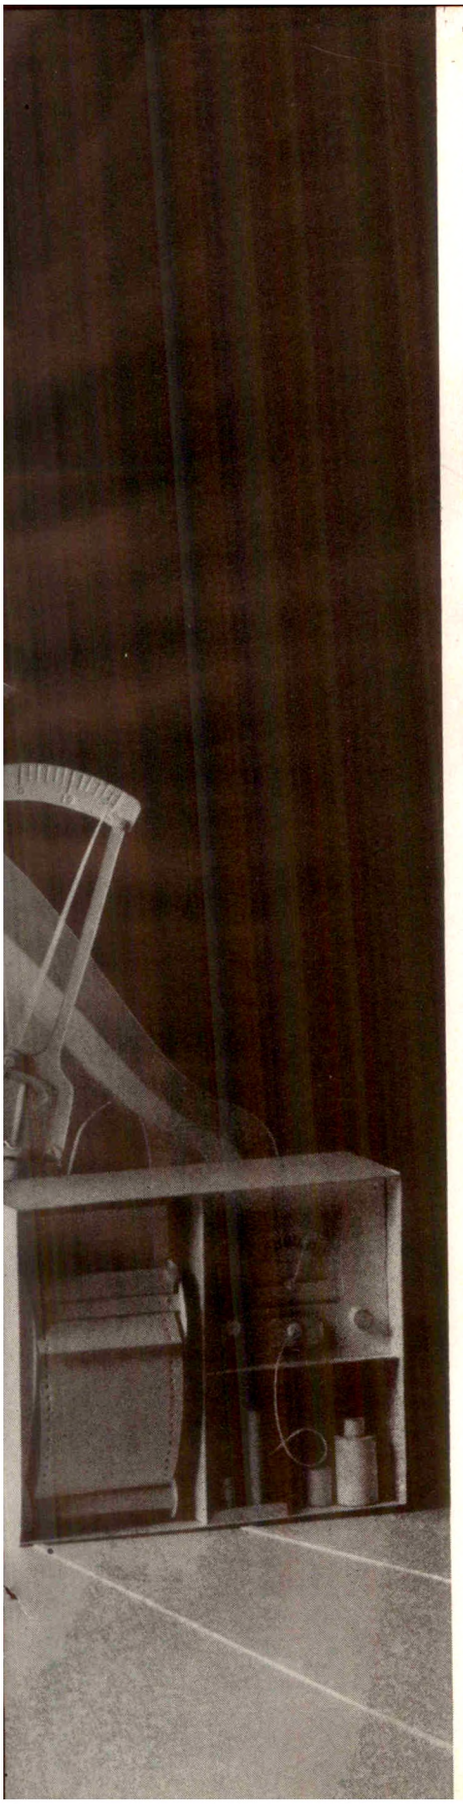
# The Fison indirect ophthalmoscope is an integrated, versatile, system



The Fison binocular ophthalmoscope offers as standard many attachments usually considered as extras ; plus the unique 'bi-mirror' which allows consultation with or instruction of two extra observers, able to view the fundus simultaneously from left and right. The high intensity light source is venturi-section cooled for maximum wearer comfort while the newly-designed vision system combines optical stability with minimum weight. Fully stereoscopic viewing through automatically-aligning lenses in an adjustable P.D. system gives optimum depth perception. The integral but detachable filter wheel is supplied fitted with cobalt and red-free filters ; provision is made for incorporation of special colour filters for specific study and research work. The tough, smart carrying case has a fitted, removable transformer, accessory compartment and pocket for detachment charts and case notes.

**KEELER OPTICAL PRODUCTS INC · 456 PARKWAY, BROOMALL, PA. 19008**

# When epinephrine is indicated for the management of chronic simple (open-angle) glaucoma

# Ayerst Epitrate® BRAND OF epinephrine bitartrate

BRIEF SUMMARY

*(For full prescribing information, see package circular.)*

**Epitrate**® (epinephrine bitartrate)

***For management of chronic simple (open-angle) glaucoma***

**Description:** A sterile aqueous solution of levorotatory epinephrine bitartrate 2% (equivalent to 1.1% base), it is stable, retains its potency throughout use, and requires no refrigeration. It has a low surface tension.

**Action:** Intraocular pressure is lowered by reducing the rate of aqueous formation. Improvement in outflow facility is also observed in certain cases following prolonged therapy.

**Indications:** Useful in management of chronic simple (open-angle) glaucoma, either alone or in combination with miotics. In selected cases, it may also be used with carbonic anhydrase inhibitors.

**Contraindications:** Prior to peripheral iridectomy, an epinephrine preparation is contraindicated in eyes that are capable of angle closure since its relatively weak mydriatic action may, nevertheless, precipitate angle block. Gonioscopy should be carried out on all patients before initiating therapy.

**Warnings:** Topical use of epinephrine in any form should be interrupted prior to general anesthesia with certain anesthetics such as cyclopropane or halothane which sensitize the myocardium to sympathomimetics.

**Precautions:** EPITRATE (epinephrine bitartrate) should be used with caution in the presence of hypertension, diabetes, hyperthyroidism, heart disease, and cerebral arteriosclerosis because of the possibility of systemic action.

**Adverse Reactions:** As with other epinephrine solutions, transitory stinging on initial instillation may be expected. Headache or browache frequently occur on beginning EPITRATE therapy, but usually diminish as treatment is continued. Conjunctival allergy occurs occasionally. Pigmentary deposits in the lids, conjunctiva or cornea may occur after prolonged use of epinephrine eyedrops. In rare cases, maculopathy with a central scotoma may result from the use of topical epinephrine in aphakic patients; prompt reversal generally follows discontinuance of the drug. Systemic effects have occasionally been reported, such as: palpitation, tachycardia, extrasystoles, hypertension, trembling, sweating, and pallor.

**Dosage and Administration:** 1 drop, with frequency of instillation being individualized, from every two or three days to twice daily. More frequent instillation than one drop four times daily does not usually elicit any further improvement in therapeutic response.

**How Supplied:** No. 1015–EPITRATE–ophthalmic solution of epinephrine bitartrate 2% (equivalent to 1.1% base). [Also contains chlorobutanol (chloral derivative) 0.5%, methylaminoaceto pyrocatechol HCl, sodium bisulfite, sodium chloride, polyoxypropylene-polyoxyethylene-diol, and disodium edetate.] Package containing 7.5 cc. bottle with separate dropper-screw cap attachment.

ACTUAL SIZE

## NO MORE ACCIDENTAL ADHESIONS!

ONCE YOU GRASP THE LENS, AT NO TIME DOES THE IRIS OR ANY OTHER TISSUE ADHERE TO THE PROBE, EVEN WHEN THERE IS DIRECT CONTACT!. THIS EXCEPTIONAL ADVANTAGE IS DUE TO ITS SPECIALLY DESIGNED TIP.

OTHER IMPORTANT ADVANTAGES:

- Thin tip (2.75 mm.) with special shape for better visibility.
- Light weight (11 g.) Just like your ball pen.
- Heat-resistant, so it can be autoclaved repeatedly.
- Durable, it can be used a great number of times.
- Rechargeable, uses gas *"FREON" 12; commercially available.
- Low price.

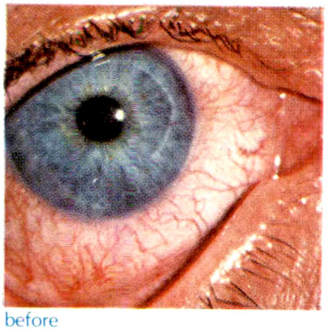
# A singular new antibiotic for the eye that works the way you think it should

## GARAMYCIN® brand of GENTAMICIN SULFATE OPHTHALMIC SOLUTION/OINTMENT

Each cc. or gram contains gentamicin sulfate equivalent to 3.0 mg. gentamicin.

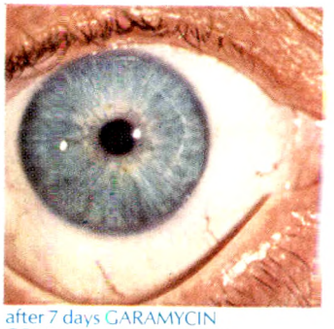
## You think it should have a wide antibacterial spectrum

GARAMYCIN's wide range of antibacterial action is equal to the spectrum commonly prescribed in the combinations of neomycin, polymyxin and bacitracin or gramicidin in the treatment of external eye infections due to susceptible organisms. It has activity against a wide variety of both gram-positive and gram-negative organisms, including the "difficult" ones—*Pseudomonas aeruginosa* strains and Proteus.



## You think it should be a single entity antibiotic

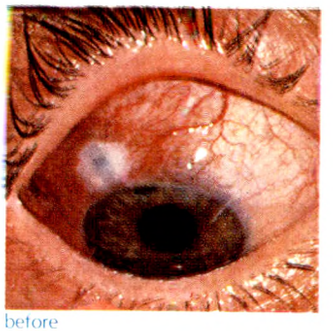
GARAMYCIN is a single entity antibiotic with a low incidence of sensitization or resistance*—can be used repeatedly with continued effectiveness, less concern about allergic potential (*Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.)



## You think it should be clinically effective

GARAMYCIN OPHTHALMIC has been described as appearing to be "...an antibiotic of choice for the initial treatment of external ocular infections."[1] It has "proved highly effective...for a wide variety of common bacterial eye infections..."[2] (due to susceptible organisms).
(1. Gordon, D.M.: Amer. J. Ophthal. 69:300 [Feb.] 1970. 2. Magnuson, R. H., and Suie, T.: JAMA *199*:427 [Feb. 6] 1967.)

In acute catarrhal conjunctivitis and episcleritis† due to *Staphylococcus aureus* coagulase negative



before

after 7 days GARAMYCIN OPHTHALMIC SOLUTION

In infected bleb (post-glaucoma surgery)† due to *Staphylococcus aureus* coagulase negative and *Streptococcus viridans*

before

after 9 days GARAMYCIN OPHTHALMIC SOLUTION

In acute conjunctivitis and dacryocystitis¶ due to pneumococcus

after 7 days GARAMYCIN OPHTHALMIC SOLUTION

after 11 days GARAMYCIN OPHTHALMIC SOLUTION

# New GARAMYCIN® ophthalmic

brand of GENTAMICIN SULFATE SOLUTION/OINTMENT

†Photographs courtesy of D. Gordon, M.D., N. Y. ¶Photographs courtesy of S. Fox, M.D., Baltimore, Md.

# You think it should have flexibility in dosage forms

GARAMYCIN OPHTHALMIC SOLUTION, sterile, isotonic, and buffered to pH of tears, does not blur vision, is well suited to daytime use—supplied in an unbreakable, easy-to-handle dispenser.
GARAMYCIN OPHTHALMIC OINTMENT provides gentle emollient action and keeps medication in contact with tissues for longer periods. It is particularly advantageous for nighttime use or in non-ambulatory patients—supplied in easy-to-use ophthalmic tube.

## Clinical Considerations

**Description:** GARAMYCIN is an antibiotic of the aminoglycoside group active against a wide variety of pathogenic gram-negative and gram-positive bacteria.

GARAMYCIN Ophthalmic Solution is a sterile aqueous solution buffered to approximately pH 6.7 for use in the eye. Each cc. contains gentamicin sulfate (equivalent to 3.0 mg. gentamicin), disodium phosphate, monosodium phosphate, sodium chloride, and benzalkonium chloride as a preservative.

GARAMYCIN Ophthalmic Ointment contains, in each gram of ointment, gentamicin sulfate (equivalent to 3.0 mg. gentamicin), and methylparaben and propylparaben as preservatives in a bland base of clear petrolatum.

Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.

**Indications:** GARAMYCIN Ophthalmic Solution and Ointment are indicated in the topical treatment of infections of the external eye and its adnexa caused by susceptible bacteria. Such infections embrace conjunctivitis, keratitis and keratoconjunctivitis, corneal ulcers, blepharitis and blepharoconjunctivitis, acute meibomianitis, and dacryocystitis.

**Contraindications:** GARAMYCIN Ophthalmic Solution and Ointment are contraindicated in patients with known hypersensitivity to any of the components of these preparations.

**Precautions:** Prolonged use of topical antibiotics may give rise to overgrowth of nonsusceptible organisms such as fungi. Should this occur, or if irritation or hypersensitivity to any component of the drug develops, discontinue use of the preparation and institute appropriate therapy.

**Dosage and Administration:** GARAMYCIN Ophthalmic Solution: One or two drops every four hours. In severe infections, dosage may be increased to as much as two drops once hourly.

GARAMYCIN Ophthalmic Ointment: Apply a small amount to the affected eye two to three times daily.

**How Supplied:** GARAMYCIN Ophthalmic Solution, 5 cc. plastic dropper bottle, sterile, box of 1. GARAMYCIN Ophthalmic Ointment, 1/8 ounce tube, box of 1.

Note: Store away from heat.

ECK EDWARD WECK & COMPANY, INC.

**Indications:** Relief and management of nonpurulent Blepharitis and Conjunctivitis.

**Dosage:** Initially, 1 or 2 drops placed in the conjunctival sac every hour until improvement occurs.

Thereafter, 1 or 2 drops 2 to 4 times daily.

**Composition:**

Prednisolone-21-phosphate sodium .....0.25%
(Equivalent to Prednisolone 0.2%)
Sulfacetamide sodium ....10.0%
Phenylephrine HCl .....0.125%
Methylparaben .....0.02%
Propylparaben .....0.005%

In a stabilized aqueous solution containing sodium thiosulfate and *SMP-68 (a combination of polyoxypropylene compound and polysorbate 80).

**Effectiveness:** The antibacterial spectrum of Vasocidin is particularly effective against the gram positive pyogenic cocci; E. coli, N. gonorrhoeae, Koch-Weeks bacillus and other bacteria susceptible to sulfacetamide. Because Vasocidin is a true solution, dosage is uniform and each drop is free of any irritating particles. The Vasocidin vehicle enhances the dispersion of active components. Sulfacetamide combats a wide range of pathogens; prednisolone reduces inflammatory reaction; phenylephrine relieves hyperemia. Local effects of active therapeutic agents appear to be prolonged by phenylephrine-induced vasoconstriction.

**Caution:** Federal law prohibits dispensing without prescription.

**Contraindications:** Steroids are contraindicated in dendritic ulcers (herpes simplex), vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, as well as in fungal and tubercular ocular disease. Contraindicated in the treatment of purulent conjunctivitis or blepharitis. Should not be used by persons with narrow-angle glaucoma or those sensitive to sulfonamides. If irritation persists or increases, discontinue use and consult physician.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.

Vasocidin is sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area with the dropper tip of bottle. Keep container tightly closed.

**Supplied:** Plastic dropper-tipped vials, 5 cc.

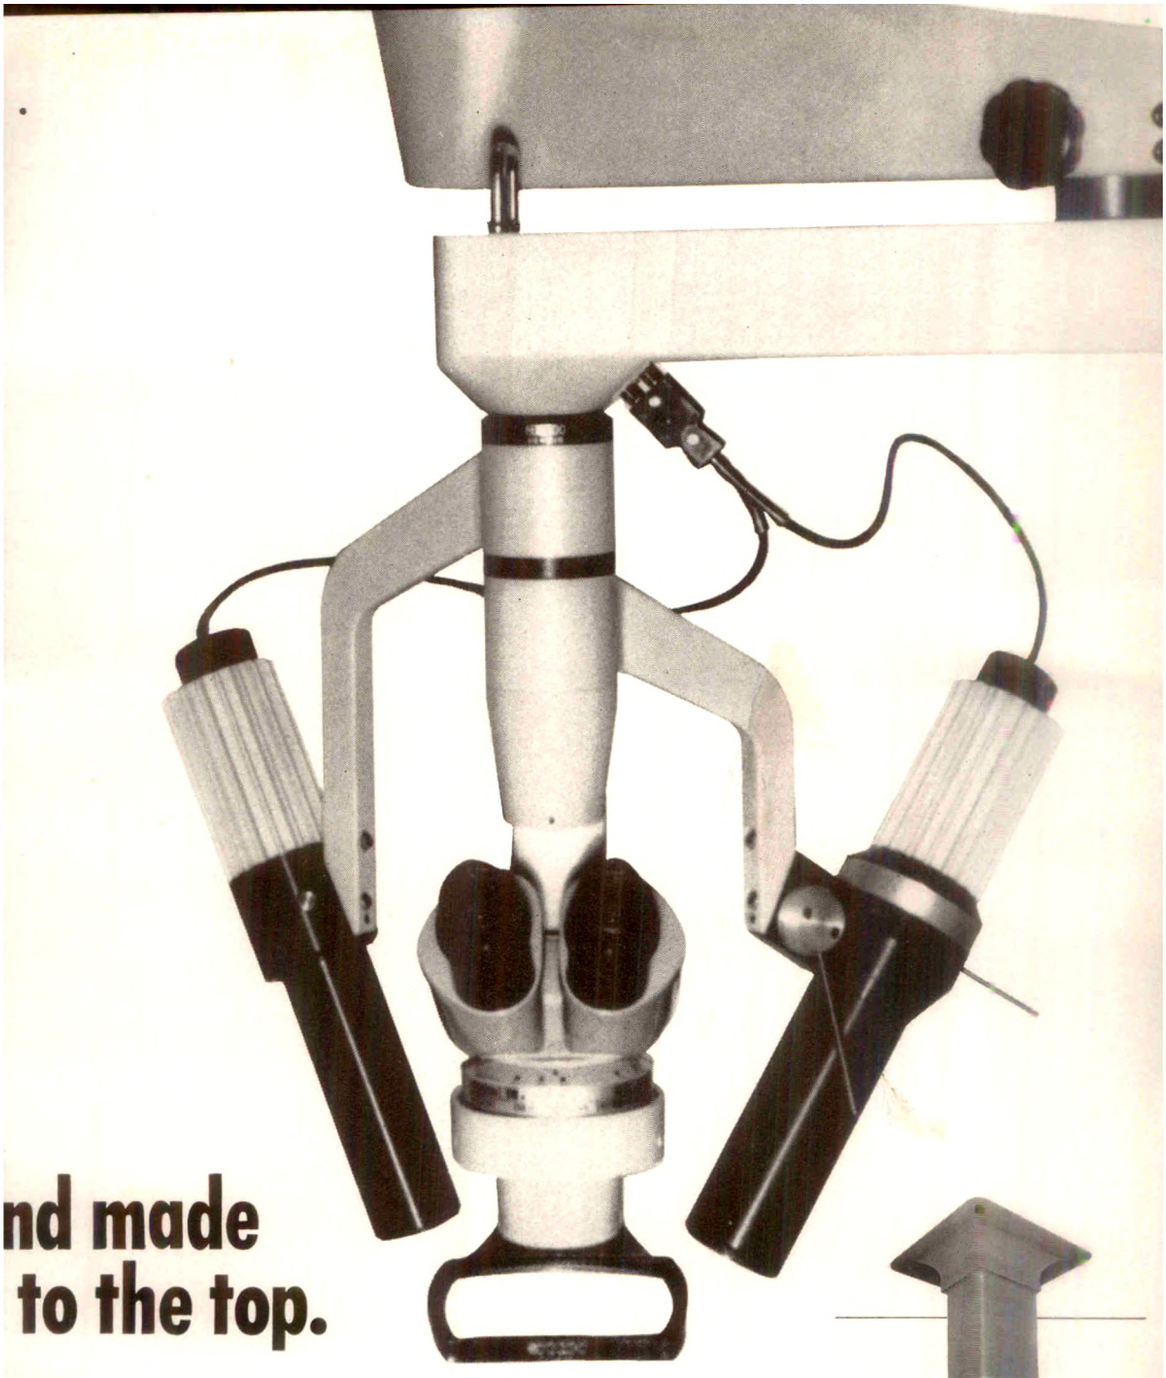
# CONTACT LENSES AND THE APHAKIC PATIENT

## Part 2: Keyhole and Upward-Displaced Pupils

In order to avoid visual disturbances such as flare, ghost images or double vision, it is necessary to fit the aphakic patient so *that the optical portion of the corneal contact lens covers the entire exposed pupil at all times*. With a keyhole or upward-displaced pupil, the lens must usually be positioned somewhat above corneal center to provide this pupillary coverage. Such positioning can often be attained by using a MINUS-CARRIER LENTICULAR LENS which, due to its flat anterior peripheral (carrier) curve, gives the lens periphery *the shape and the performance of a high-minus lens*.

Use of the flat carrier curve increases the upward vector component of the upper lid pull on the contact lens. Thus, with sufficient upper lid cover of the cornea (at least 1.5 mm needed) to grab the lens and pull it up, the lens will usually be held in a position about 1 mm above corneal center. This upward positioning can also be useful for patients with low or very flaccid lower lids, where it is desired to keep the lens from riding down and irritating the lower limbus.

In cases of keyhole pupils or upward-displaced pupils *with little or no coverage by the upper lids*, all aphakic lenses will ride low, and it is often impossible to have optical coverage of the entire pupil with a corneal lens. Sometimes these patients can be fitted with a SINGLE-CUT LENS,



large enough to completely cover the pupil and supported by the lower lid. Such a lens should be made *as small as possible*, because thickness and weight increase very rapidly with size; and it should be made *without any posterior secondary or peripheral curves*, so that the entire lens can be optically functional. For its satisfactory application, a high lower lid is needed, sufficiently tight to support the heavy weight of the lens. Since the lens diameter will be slightly more than the distance from the lower lid to the upper edge of the exposed pupil, it is evident that the higher the lower lid, the smaller (thus thinner and lighter) the lens and the better the chances for successful wear.

# CONTACT LENSES AND THE APHAKIC PATIENT

## Part 2: Keyhole and Upward-Displaced Pupils

In order to avoid visual disturbances such as flare, ghost images or double vision, it is necessary to fit the aphakic patient *so that the optical portion of the corneal contact lens covers the entire exposed pupil at all times.* With a keyhole or upward-displaced pupil, the lens must usually be positioned somewhat above corneal center to provide this pupillary coverage. Such positioning can often be attained by using a MINUS-CARRIER LENTICULAR LENS which, due to its flat anterior peripheral (carrier) curve, gives the lens periphery *the shape and the performance of a high-minus lens.*

Use of the flat carrier curve increases the upward vector component of the upper lid pull on the contact lens. Thus, with sufficient upper lid cover of the cornea (at least 1.5 mm needed) to grab the lens and pull it up, the lens will usually be held in a position about 1 mm above corneal center. This upward positioning can also be useful for patients with low or very flaccid lower lids, where it is desired to keep the lens from riding down and irritating the lower limbus.

In cases of keyhole pupils or upward-displaced pupils *with little or no coverage by the upper lids,* all aphakic lenses will ride low, and it is often impossible to have optical coverage of the entire pupil with a corneal lens. Sometimes these patients can be fitted with a SINGLE-CUT LENS,

large enough to completely cover the pupil and supported by the lower lid. Such a lens should be made *as small as possible,* because thickness and weight increase very rapidly with size; and it should be made *without any posterior secondary or peripheral curves,* so that the entire lens can be optically functional. For its satisfactory application, a high lower lid is needed, sufficiently tight to support the heavy weight of the lens. Since the lens diameter will be slightly more than the distance from the lower lid to the upper edge of the exposed pupil, it is evident that the higher the lower lid, the smaller (thus thinner and lighter) the lens and the better the chances for successful wear.

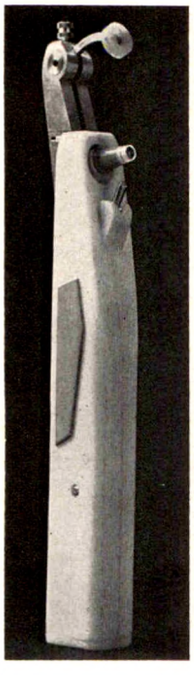
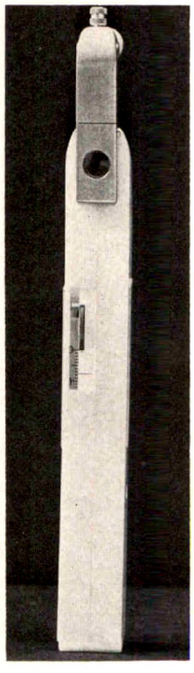
## Only Glazcote lets the plastic eyeglass wearer see what he's missing.

Just one dot of Glazcote® on each side of a plastic or hard resin lens fills hair line scratches and helps protect the lenses against future possible scratches. This unique product was developed for the Space Program, for use on spacecraft windows, and to clean, polish and protect astronauts' plastic face shields. And continuous use of optically clear Glazcote helps keep the lenses clean, static free, and polished as well as filling hair line scratches. ALLERGAN Irvine, Calif.; Montreal, Canada

# Recommend Glazcote...just a dot does it.

# NEW DEVELOPMENTS . . .





## ORA SERRATA ATTACHMENT TO THE GOLDMANN 3 MIRROR LENS

The periphery of the fundus near the ora serrata and the ciliary body cannot be examined under normal conditions with the 3-mirror lens alone. The ora serrata attachment along with the 3-mirror lens allows the observation of these most peripheral parts in its entire circumference.

The attachment is shaped like the 3-mirror lens. Half a steel-ball is fixed to the scleral part of the attachment which presses on the sclera above the ora serrata so that the fundus at its periphery near the ora serrata can be seen in the gonio mirror of the 3-mirror lens. The ora attachment can be used either with the 3-mirror lens in a locked or moveable position.

# Spectacle Indirect

Split personalities can have problems, ask Dr. Jekyl
However when two separate identities perfect
tuned to their individual roles join forces there ca
never be problems. You'll find no problems wit
this revolutionary new system.

The light, bright, stereo-vision Spectacle Indirect Ophthalmoscope (that's fitted so easily) converts in seconds to a spectacle magnifier, with a removable light source and flip-up loupes.

Split personality or marriage of the year? Either way you win with the Spectacle Indirect.

**KEELER**
456 Parkway, Broomall, PA 19008

**Composition:**

**Inflamase**

*Prednisolone Sodium Phosphate .....0.125%
(Equivalent to Prednisolone 0.1%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

**Inflamase Forte**

*Prednisolone Sodium Phosphate 1.0%
(Equivalent to Prednisolone 0.8%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

Prednisolone Sodium Phosphate is a water soluble inorganic ester of prednisolone. It is approximately 2,000 times as soluble in water at 25°C. as is hydrocortisone.

*Licensed under patent #3,134,718.

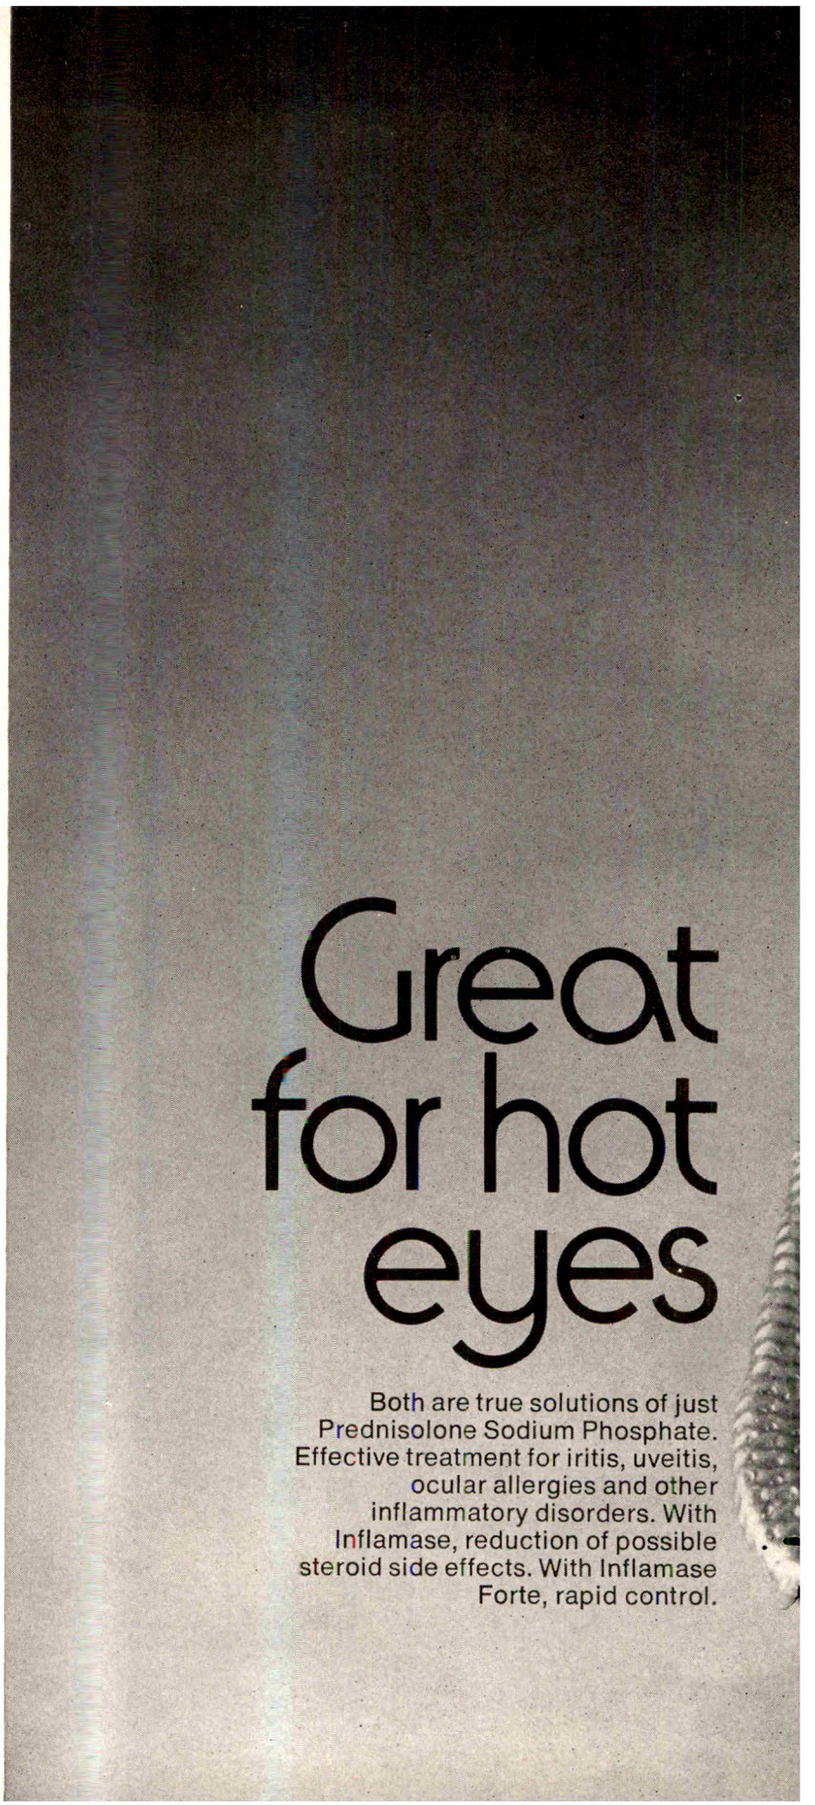
**Indications:** Inflamase and Inflamase Forte ophthalmic solutions may be used effectively in the following conditions of the anterior segment of the eye: superficial keratitis, including punctate epithelial lesions (Thygeson type), phlyctenular keratoconjunctivitis, and Sjogren's keratoconjunctivitis (with systemic steroids); deep keratitis, including interstitial or parenchymatous keratitis, acne rosacea, sclerosing keratitis; herpes zoster opthalmicus (do not use in herpes simplex); non-purulent conjunctivitis, including vernal, allergic, catarrhal; iridocyclitis; acute iritis; recurrent marginal ulceration, whether endogenous or due to atopic or contact allergies, or microbial allergy; corneal injuries, such as aseptic thermal, radiation, or chemical burns and corneal injuries following surgery or the penetration of foreign bodies; lid allergy; and non-purulent blepheritis, including catarrhal and allergic.

Inflamase and Inflamase Forte ophthalmic solutions have their principal effect on the anterior segment of the eye (cornea and the anterior uvea), with acute disorders responding more favorably than chronic disorders. Inflamase Forte 1% solution is recommended for moderate to severe inflammations particularly when rapid control is desired. In stubborn cases of anterior segment eye disease, systemic adrenocortical hormone therapy may be required. When the deeper ocular structures are involved, systemic therapy is necessary.

**Dosage:** Initially, 1 or 2 drops placed in conjunctival sac every hour during day and every 2 hours during night until improvement occurs. Thereafter, 1 or 2 drops 2 to 4 times daily.

**Contraindications:** Contraindicated in acute herpes simplex, ocular tuberculosis, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva; fungal diseases of the eye. Purulent conjunctivitis, purulent blepharitis, and infectious conditions are contraindications to the use of steroids.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.



**Warning:** If irritation persists or develops, patient should be advised to discontinue use and consult prescribing physician.

**How Supplied:** 5 cc plastic squeeze bottle with dropper tip. These products are sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area, or other areas with the dropper tip of the bottle. Keep bottle tightly closed when not in use.

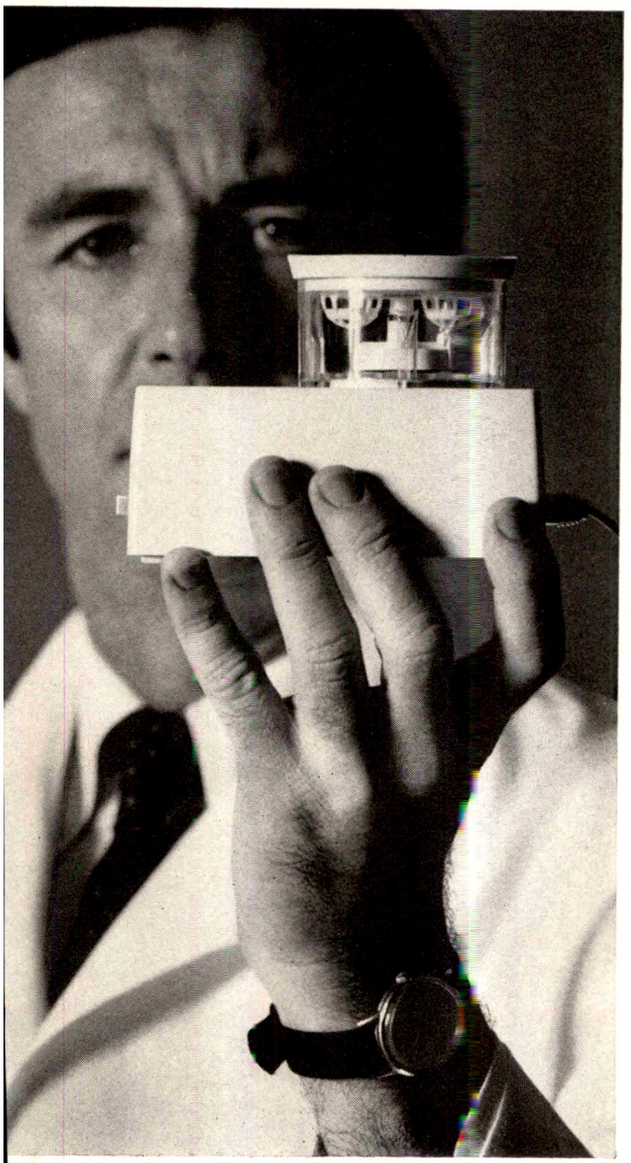
Store in cool place. Protect from light.

**Caution:** Federal law prohibits dispensing without prescription.

**Smith, Miller & Patch, Inc.**
401 Joyce Kilmer Avenue
New Brunswick, N.J. 08902

# Great for hot eyes

Both are true solutions of just Prednisolone Sodium Phosphate. Effective treatment for iritis, uveitis, ocular allergies and other inflammatory disorders. With Inflamase, reduction of possible steroid side effects. With Inflamase Forte, rapid control.



**Inflamase**
for most inflammations.

**Inflamase Forte**
for the tough ones.

# Introducing SWIRL CLEAN™

## electric contact lens cleaner by Contique™

# the professional way to clean contact lenses

Until now, the most common method o cleaning contact lenses has been to rub ther between the fingers. As you know, this syster has three serious drawbacks: 1) it doesn't clea properly; 2) it *can* scratch or warp lenses; 3) may not be sanitary.

### A new, more efficient technique

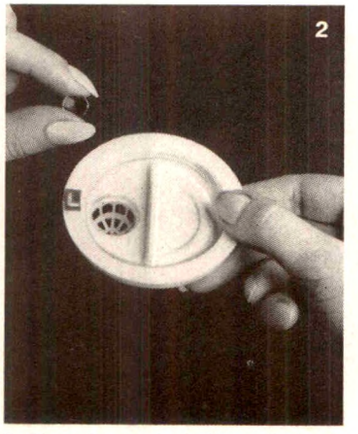
The new Swirl Clean electric contact len cleaner by Contique approaches the problem i a totally different manner: It combines th cleaning power of a high-speed agitator wit the detergent action of Contique Cleaning Solu tion. The result is thorough but gentle clear ing—with a minimum of handling and les chance of lens loss.

Swirl Clean doesn't stop there. It provide a convenient place to soak and store lenses be tween wearings.

### Perfect for office use

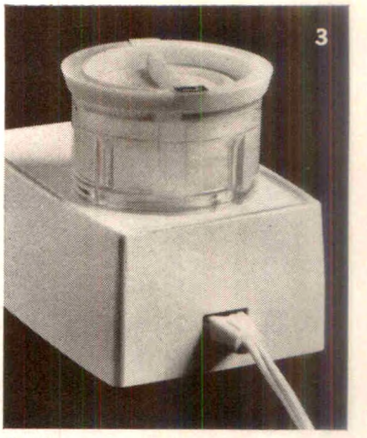
How many times have you wished for jus such an efficient way to clean your patients contacts—when you are delivering a new pai or after making an adjustment?

Swirl Clean fills this long-felt need per fectly. It's compact. Easy to use. And it *look* highly professional. Your patients can se you've gone to the expense of securing the mos advanced cleaning device available to mak sure their lenses are clean and comfortable.



And it takes only a few seconds to clea contacts with the Swirl Clean. Once you get int the habit, you'll wonder how you managed with out it.

### Your patients will want one, too

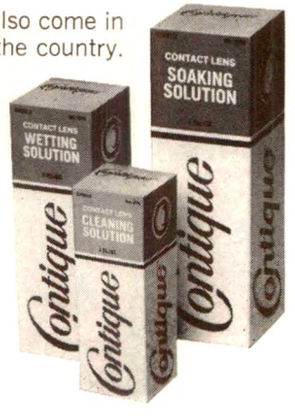


When they see how effortlessly you clea their contacts with the Swirl Clean, your ne contact lens wearers will want one of their ow to use at home. That's why it makes good busi ness sense to stock a few units to sell or recom mend to your patients. They'll never be mor psychologically receptive than at the momen

**1** *Fill cleaning chamber ¾ full with cold water. Add 6-8 drops of Contique Cleaning Solution and place on base.*

**2** *Place lenses in bottom of clearly marked LEFT and RIGHT baskets of lens holder. Close lid. Place lens holder on cleaning chamber.*

**3** *Flip "ON" switch and run Swirl Clean 30-60 seconds. You can see the lenses being swirled clean before your eyes.*



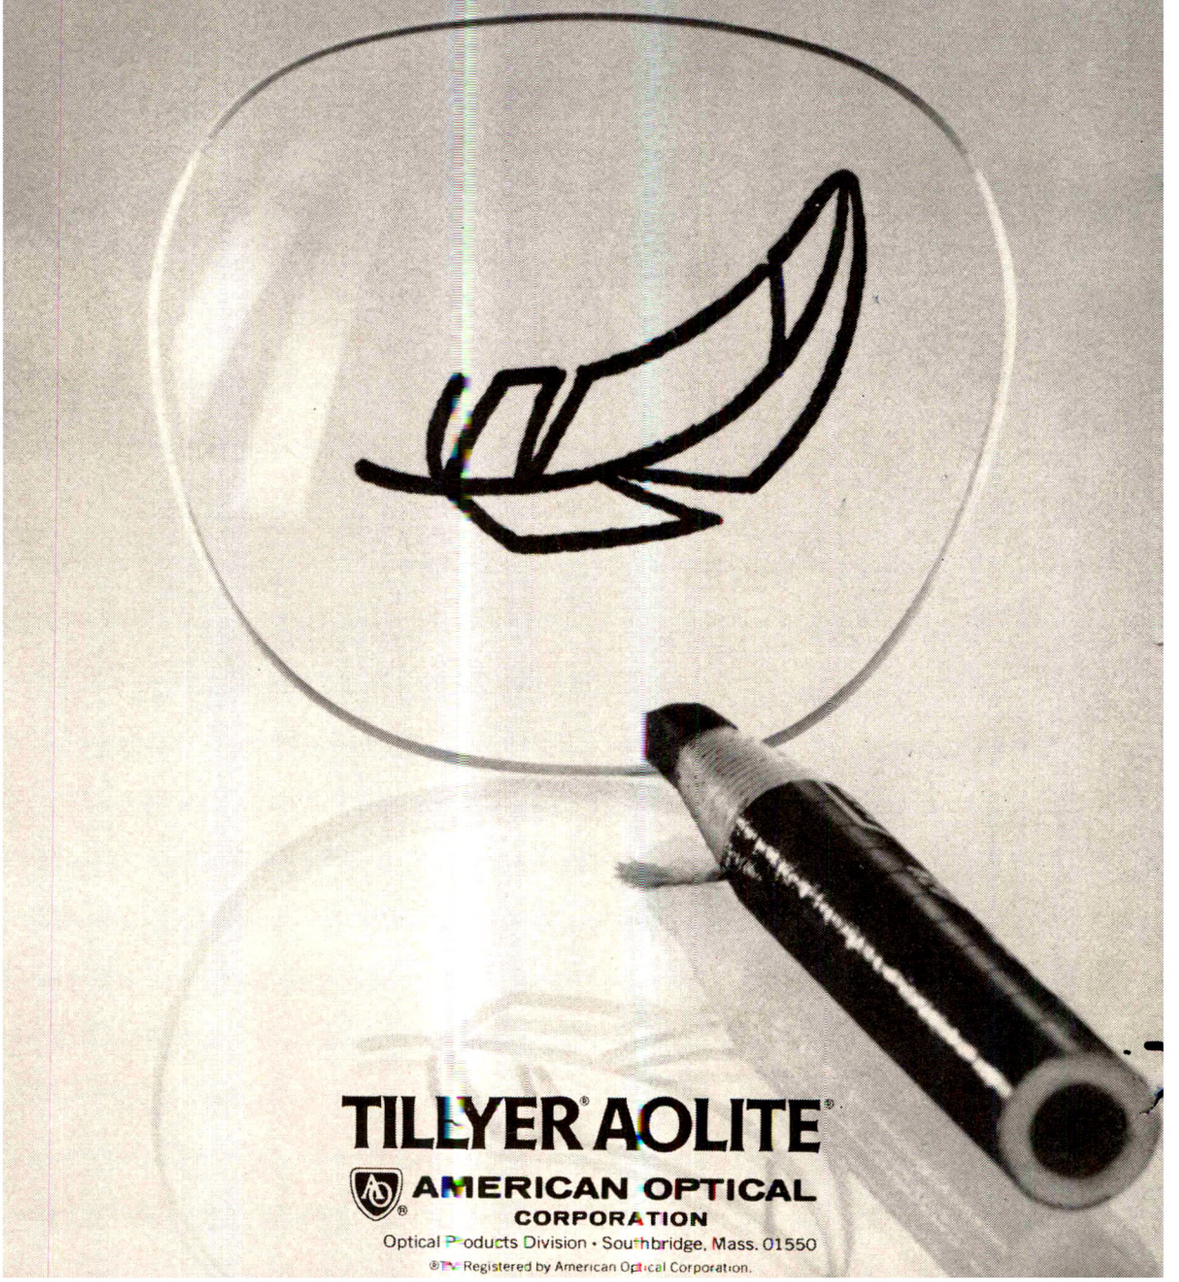
they get their new contacts. It's also a good way of starting them off on a proper lens-care regimen and helping them become satisfied wearers.

### Read what Swirl Clean users say

An O.D. in Knoxville, Tenn. writes: "The compactness of this unit makes its use a pleasure in my office." An M.D. in Bakersfield, Calif. calls Swirl Clean "a very valuable asset to our office." An optician in Long Beach, Calif.: "Excellent method of cleaning lenses after lab adjustment."

Enthusiastic comments have also come in from contact lens wearers all over the country. "My vision is so much better with clean contacts." (Boston, Pa.) "I enjoy its convenience and notice my lenses are more comfortable." (East Point, Ga.) "Cleans lenses 100% better than by hand." (Hyde Park, Mass.) "I wear lenses 16 hours a day and find their comfort greatly increased." (Indianapolis, Ind.)

These comments are on file at Alcon Laboratories and may be examined by anyone interested.



### Complete lens care by Contique

Used with the new Swirl Clean, *Contique Cleaning Solution* dissolves eye-irritating deposits such as mucus, oil and film. Yet it's so gentle you can recommend it with complete confidence. *Contique Soaking Solution* "conditions" lenses by keeping them chemically moist when stored in the special Swirl Clean soaking dish, increasing wettability and wearing comfort. *Contique Wetting Solution* creates a liquid cushion between lens and eyes, makes placement smooth and easy, and can also be used to re-wet lenses during the day.

This family of lens care products from Contique can help your patients become successful, satisfied contact lens wearers. Almost $6 worth of Contique solutions are packed with every Swirl Clean at no additional cost. For more information about the new Swirl Clean and other Contique products, call your optical wholesaler today.

*Send for brochure*

**ECK EDWARD WECK & COMPANY, INC.**

**Indications:** Relief and management of nonpurulent Blepharitis and Conjunctivitis.

**Dosage:** Initially, 1 or 2 drops placed in the conjunctival sac every hour until improvement occurs.

Thereafter, 1 or 2 drops 2 to 4 times daily.

**Composition:**

Prednisolone-21-phosphate sodium .....0.25%
(Equivalent to Prednisolone 0.2%)
Sulfacetamide sodium ....10.0%
Phenylephrine HCl .....0.125%
Methylparaben .....0.02%
Propylparaben .....0.005%

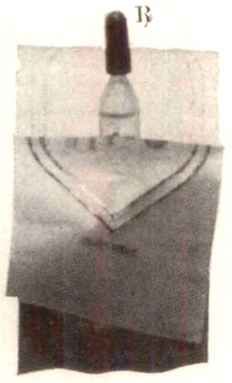
In a stabilized aqueous solution containing sodium thiosulfate and *SMP-68 (a combination of polyoxypropylene compound and polysorbate 80).

**Effectiveness:** The antibacterial spectrum of Vasocidin is particularly effective against the gram positive pyogenic cocci; E. coli, N. gonorrhoeae, Koch-Weeks bacillus and other bacteria susceptible to sulfacetamide. Because Vasocidin is a true solution, dosage is uniform and each drop is free of any irritating particles. The Vasocidin vehicle enhances the dispersion of active components. Sulfacetamide combats a wide range of pathogens; prednisolone reduces inflammatory reaction; phenylephrine relieves hyperemia. Local effects of active therapeutic agents appear to be prolonged by phenylephrine-induced vasoconstriction.

**Caution:** Federal law prohibits dispensing without prescription.

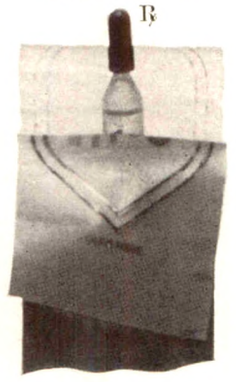
**Contraindications:** Steroids are contraindicated in dendritic ulcers (herpes simplex), vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, as well as in fungal and tubercular ocular disease. Contraindicated in the treatment of purulent conjunctivitis or blepharitis. Should not be used by persons with narrow-angle glaucoma or those sensitive to sulfonamides. If irritation persists or increases, discontinue use and consult physician.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.



Vasocidin is sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area with the dropper tip of bottle. Keep container tightly closed.

**Supplied:** Plastic dropper-tipped vials, 5 cc.



**Smith, Miller & Patch, Inc.**

Cooper COOPER LABORATORIES, INC. WAYNE, NEW JERSEY 07470

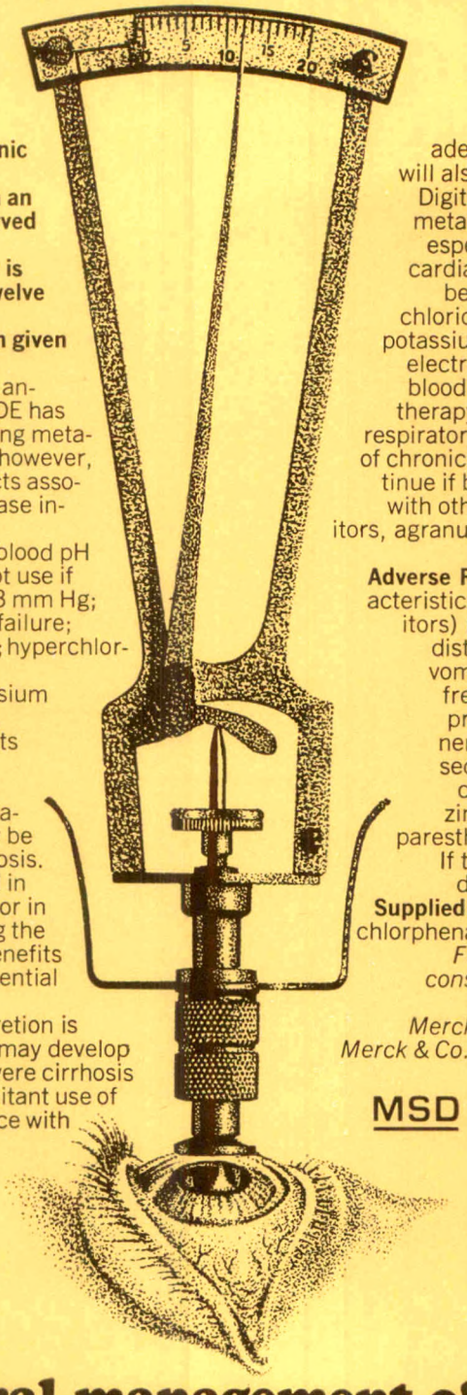
# It's been helping to save sight for a long time

And DIAMOX does not interfere with other forms of glaucoma therapy which influence the outflow mechanism. In fact, a complementary effect may be obtained when DIAMOX is used in conjunction with miotics.

Treatment with DIAMOX may retard progress of glaucoma by reducing secretion of aqueous humor and thus intraocular pressure. With DIAMOX SEQUELS, acetazolamide is slowly released, and concentrations peak at 8 to 12 hours. A single dose may provide a therapeutic effect for as long as 18 to 24 hours. It is thus possible to maintain the inhibitory effect on aqueous humor formation with a twice-daily regimen . . . an important consideration for the patient's rest and for minimization of side effects.

**DIAMOX®**
ACETAZOLAMIDE
**SEQUELS®** 500 mg
Sustained Release Capsules

**Contraindications**—Situations in which sodium and/or potassium serum levels are depressed, in kidney and liver disease or dysfunction, suprarenal gland failure and hyperchloremic acidosis. Long-term administration is contraindicated in chronic noncongestive angle closure glaucoma.



**Warning**—Although teratogenic and embryocidal effects demonstrated in mice at more than ten times the equivalent therapeutic doses have not been evidenced in humans, DIAMOX Acetazolamide should not be used in pregnancy, especially during the first trimester, unless the expected benefits outweigh these potential adverse effects.

**Precautions**—Increasing the dose may increase drowsiness and paresthesia and decrease diuresis. Reactions common to sulfonamides may occu fever, rash, crystalluria, renal calculus, bone marrow depression, thro bocytopenic purpura, hemolytic anemia, leukopenia, pancytopeni agranulocytosis. If such occur, discontinue drug and institute appropria therapy.

**Side Effects**—During short-term therapy: paresthesias, loss of appeti polyuria, drowsiness, confusion. In long-term therapy an acidotic sta may supervene. Transient myopia has been reported. Other occasional r actions: urticaria, melena, hematuria, glycosuria, hepatic insufficienc flaccid paralysis, convulsions. 354

Lederle LEDERLE LABORATORIES, A Division of American Cyanamid Company, Pearl River, New York 10965

# the measure of success...

- **orally effective, potent carbonic anhydrase inhibitor**
- **onset of action usually within an hour; maximal effect is observed in two to four hours**
- **lowered intraocular pressure is often maintained for six to twelve hours**
- **usually most successful when given in conjunction with miotics**

Compared to other carbonic anhydrase inhibitors, DARANIDE has a lesser propensity for causing metabolic acidosis. Please note, however, that this and other side effects associated with carbonic anhydrase inhibitors may occur.

**Contraindications:** To avoid blood pH decreases below 7.20, do not use if arterial $pCO_2$ greater than 63 mm Hg; hepatic insufficiency; renal failure; adrenocortical insufficiency; hyperchloremic acidosis; conditions in which sodium and/or potassium serum levels are depressed. Should not be used in patients with severe pulmonary obstruction who are unable to increase their alveolar ventilation since their acidosis may be increased to the point of narcosis.

**Warning:** Should not be used in women of child-bearing age or in pregnancy, especially during the first trimester, unless the benefits to be expected outweigh potential adverse effects.

**Precautions:** Potassium excretion is increased and hypokalemia may develop with brisk diuresis, when severe cirrhosis is present, or during concomitant use of steroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Hypokalemia may be treated by use of potassium chloride or giving foods with a high potassium content. A close check on electrolyte balance, blood pH, and blood gases should be kept during therapy. Use with caution in severe respiratory acidosis or in the presence of chronic pulmonary infection; discontinue if blood pH falls below 7.20. As with other carbonic anhydrase inhibitors, agranulocytosis, thrombocytopenia, or renal calculi are possible.

**Adverse Reactions:** Side effects (characteristic of carbonic anhydrase inhibitors) may include gastrointestinal disturbances (anorexia, nausea, vomiting), constipation, urinary frequency, mild skin eruptions, pruritus, headache, weakness, nervousness, globus hystericus, sedation, lassitude, depression, confusion, disorientation, dizziness, ataxia, tremor, tinnitus, paresthesias of hands, feet, tongue. If they occur, reduce dosage or discontinue drug temporarily.

**Supplied:** Tablets containing 50 mg dichlorphenamide each, in bottles of 100.

*For more detailed information, consult your MSD representative or see the Direction Circular.*

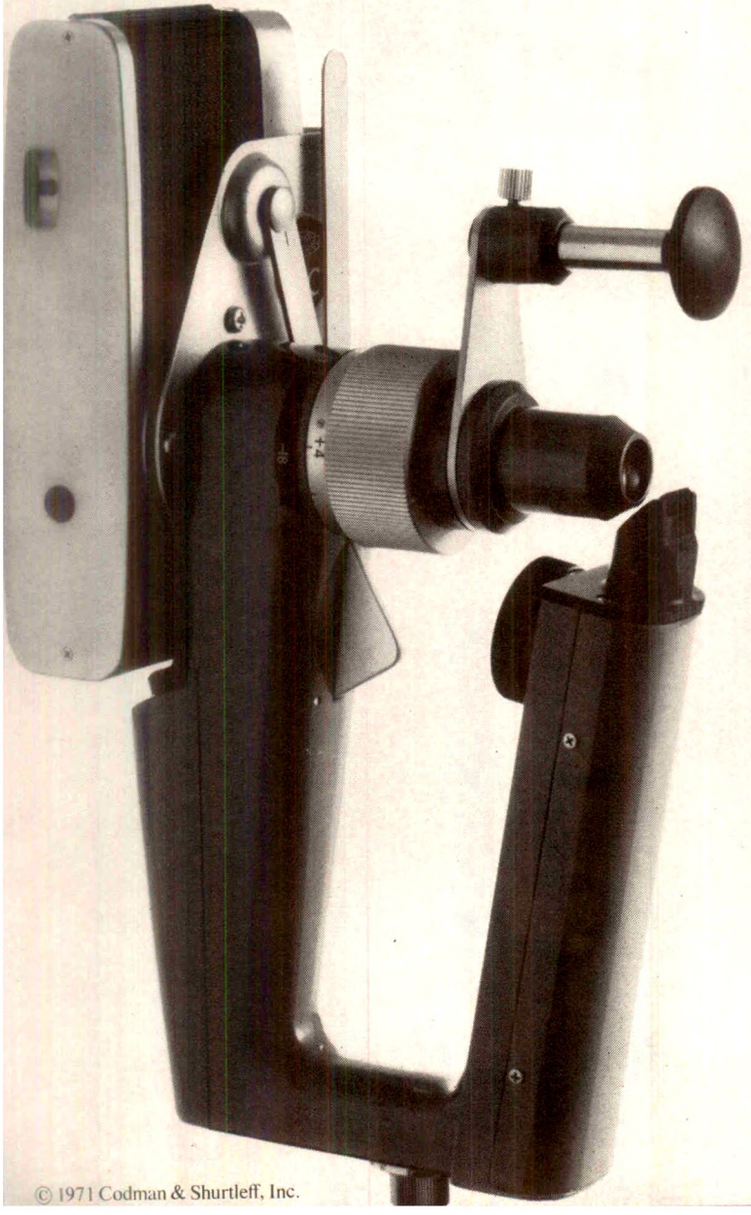
Modern materials and design techniques have made this camera more versatile and easier to use than older types, and lowered the cost as well.



The Olympus Fundus Camera from Mentor is light, compact, balanced – ideal for office diagnosis and records. No additional apparatus is required for very sharp, evenly illuminated photographs – regardless of patient or camera movement.

Trigger, lens selection, and fine focusing are controlled by one hand while you view the area of interest through a bright, clear viewing system. Diopter settings range from +16 to −22 (making external photographs possible) including ±4 of fine focus. Newly developed objective optics completely eliminate spurious light reflections and produce excellent color records – 40 on a standard 20-exposure roll.

There is nothing like the Olympus Fundus Camera from Mentor and there is nothing like its price: $985 complete. Write for full information. Mentor Division, Codman & Shurtleff, Inc., Randolph, Mass. 02368.

## in open-angle glaucoma

# HUMORSOL®

## (DEMECARIUM BROMIDE | MSD)

OPHTHALMIC SOLUTION, 0.125% and 0.25%

## the cholinesterase inhibitor that needs no pampering

IN OCUMETER® OPHTHALMIC DISPENSER

**FOR TOPICAL APPLICATION INTO THE CONJUNCTIVAL SAC ONLY**

**Contraindications:** Known hypersensitivity; active uveal inflammation; most cases of narrow-angle glaucoma.

**Warnings:** Should be administered with extreme caution to patients with myasthenia gravis who are on systemic anticholinesterase therapy; conversely, systemic anticholinesterase drugs for myasthenia gravis should be added cautiously. Succinylcholine should be administered with extreme caution before or during general anesthesia, because of possible respiratory and cardiovascular collapse.

*Use in Pregnancy:* Safe use in pregnancy has not been established, nor has the absence of adverse effects on the fetus or on respiration of the neonate. During pregnancy weigh potential benefits against possible hazards.

**Precautions:** Gonioscopy is recommended before therapy. Do not use, or use cautiously, when an intraocular inflammatory process is present.

Compression of the lacrimal sac during and following instillation for a minute or two minimizes drainage into the nasal chamber. Wash hands immediately after instillation. Discontinue use if salivation, urinary incontinence, diarrhea, profuse sweating, muscle weakness, respiratory difficulties, shock, or cardiac irregularities occur.

Persons exposed to organophosphate-type insecticides and pesticides (gardeners, organophosphate-manufacturing plant or warehouse workers, farmers, residents of communities which are undergoing insecticide spraying or dusting, etc.) should be warned of added systemic effects possible from absorption through the respiratory tract or skin. Wearing of respiratory masks, frequent washing, and clothing changes may be advisable.

Use with extreme caution, if at all, in patients with marked vagotonia, bronchial asthma, spastic gastrointestinal disturbances, peptic ulcer, pronounced bradycardia and hypotension, recent myocardial infarction, epilepsy, parkinsonism, and other disorders that may respond adversely to vagotonic effects. Use extreme caution before intraocular surgery because of the possibility of hyphema.

Despite observance of all precautions, repeated administration may cause depression of the concentration of cholinesterase in the serum and erythrocytes, with resultant systemic effects.

**Adverse Reactions:** Stinging, burning, lacrimation, lid muscle twitching, conjunctival and ciliary redness, brow ache, headache, and induced myopia with visual blurring; activation of latent iritis or uveitis; retinal detachment has been reported occasionally. Iris cysts may form, enlarge, and obscure vision, more frequently in children; cysts usually shrink when the miotic is discontinued but, rarely, may rupture or break free into the aqueous. Frequent examination is advisable.

Prolonged use may cause conjunctival thickening and obstruction of nasolacrimal canals. If systemic effects occur (e.g., salivation, urinary incontinence, nausea, abdominal cramps, vomiting, diarrhea, dyspnea, bradycardia, cardiac irregularities), parenteral administration of atropine is indicated: 0.4 to 0.6 mg or more for adults, proportionately less for children; artificial respiration may be required. Similar therapy is indicated for overdosage.

Lens opacities have been reported, and routine slit-lamp examinations should accompany prolonged use. Paradoxical increase in intraocular pressure may occur and be alleviated by a mydriatic.

**Dosage and Administration:** Initial titration and dosage adjustments must be individualized to obtain maximal therapeutic effect. Patient must be observed closely during initial period. If response is not adequate within first 24 hours, consider other measures. Keep frequency of use to a minimum in all patients, but especially in children.

Since technic is crucial to proper and safe administration, consult Direction Circular for full details.

**Supplied:** In 5-cc OCUMETER® Ophthalmic Dispenser containing 0.125 or 0.25 percent solution and sodium chloride; benzalkonium chloride 1:5000 added as preservative.

## *offers you visual fields*

. . . whenever you want
. . . as often as you want
without your being there

## *quickly . . . automatically!*

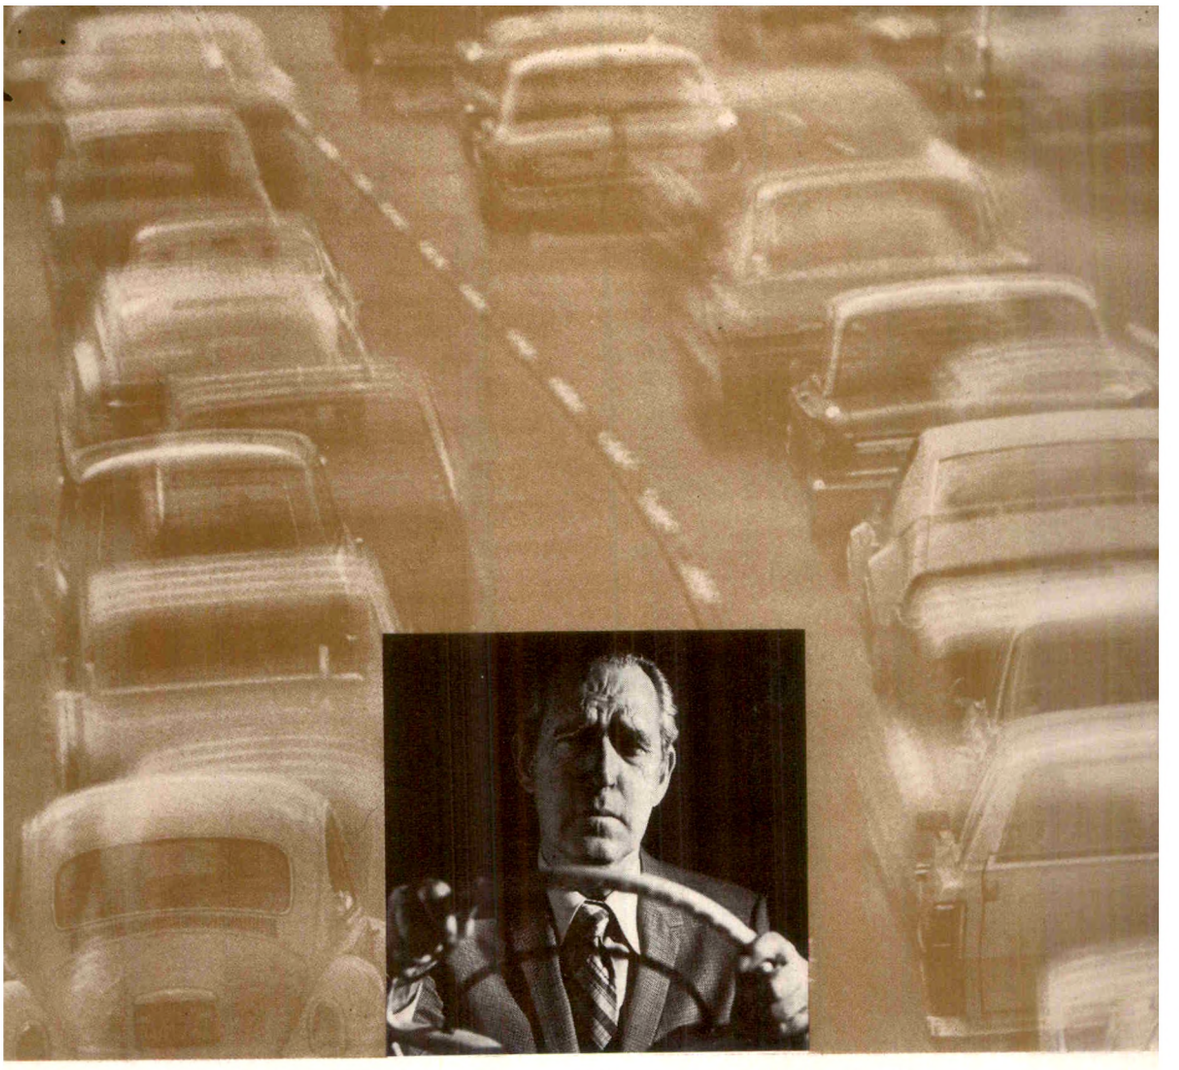
U.S. Patent Nos. 3,288,546
and 3,421,498

The Ocutron® Visual Field Tester, developed by a leading ophthalmologist, is a highly precise electronic instrument that automatically examines the visual field and records it permanently on the standard chart that you are accustomed to using and interpreting.

Without the presence of doctor or nurse, the patient tests himself by push-button response to stimuli of standard light targets as they appear within the white hemisphere. This response is electrically registered on the chart.

Difficult and time-consuming fields like the above glaucoma field are as easily and quickly tested as a simple normal field.

Background may be lighted or not, as desired, for light or dark adapted fields. Built-in check on patient fixation and patient reliability.



Particularly suitable for high volume performance. Simple enough for screening. Accurate enough for definitive, repeatable field study.

For further information write for new literature
or contact your ophthalmic distributor.

In an environment of repeated irritation...

## one drop of Albalon™ provides over 190 minutes of the most potent decongestant activity.

In a recent double blind study,* the superior decongestant activity of Albalon™ Liquifilm® was clearly demonstrated. Compared to three of the most familiar vasoconstrictors, just one drop of Albalon™ provided both immediate, effective eye-whitening, and 190 minutes of the most potent protection against repeated ocular insult.

Additionally, Albalon™ comes in the Liquifilm® vehicle to soothe, lubricate and comfort itchy, smarting, red eyes.

*from an independent study conducted on a controlled population; data on file, Allergan Research Department.

**Contains:** naphazoline HCl, 0.1%; Liquifilm® (polyvinyl alcohol), 1.4%; with benzalkonium chloride, disodium edetate, citric acid, sodium citrate, sodium chloride, sodium hydroxide and purified water. **Indications:** For use as a topical ocular vasoconstrictor. **Contraindications:** Hypersensitivity to the components of this preparation. **Precautions:** This preparation should be used only with caution in the presence of hypertension, cardiac irregularities, hyperglycemia (diabetes), hyperthyroidism. **Adverse Reactions:** Pupillary dilatation, increase in intraocular pressure, systemic effects due to absorption (i.e. hypertension, cardiac irregularities, hyperglycemia). **Warnings:** Should not be used in patients with narrow angle glaucoma. If irritation persists, or increases, discontinue use. **Dosage and Administration:** One to two drops instilled in each eye every three to four hours or less frequently, as required to relieve symptoms.

# Who needs contact lens insurance?

# You do.

# and ...
# your patients do!

It's amazing how some contact lens specialists think of contact lens insurance this way. Maybe it's not as amazing as it is appalling.

RLI's contact lens insurance program has a proven record for reducing a patient's natural apprehension about loss. And this can make your job easier.

RLI offers an optional 80% effective recall system for you. We also give the patient a bonafide policy.

We do a lot more for you—and your patient. Think about it.

RLI—the practical solution to the lost and damaged lens problem.

**REPLACEMENT LENS, INC.**
804 Lehmann Building • Peoria, Illinois 61602
Telephone 309/676-0581
*"The company that cares about continuing eye care"*

RLI

***We now insure ALL soft contact lenses!***

Specific for
Herpes Simplex Keratitis

**STOXIL®**
**brand of IDOXURIDINE**

the only brand of IDU
available in two forms:
Solution—Ointment

Both now available in Canada

# The choice is yours

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.

**Indications:** Only in the treatment of herpes simplex keratitis.

**Description: 'Stoxil' Ophthalmic Solution** contains idoxuridine (5-iodo-2'-deoxyuridine) **0.1% (1 mg./ml.)** in distilled water; sterile when packaged. Preserved with thimerosal, 1:50,000. **'Stoxil' Ophthalmic Ointment** contains idoxuridin **0.5% (5 mg./gram)** in a petrolatum base. (White petrolatum and liquid petrolatum are inactive ingredients.)

**Contraindications:** Contraindicated in patients with known or suspected hypersensitivity to any of its components.

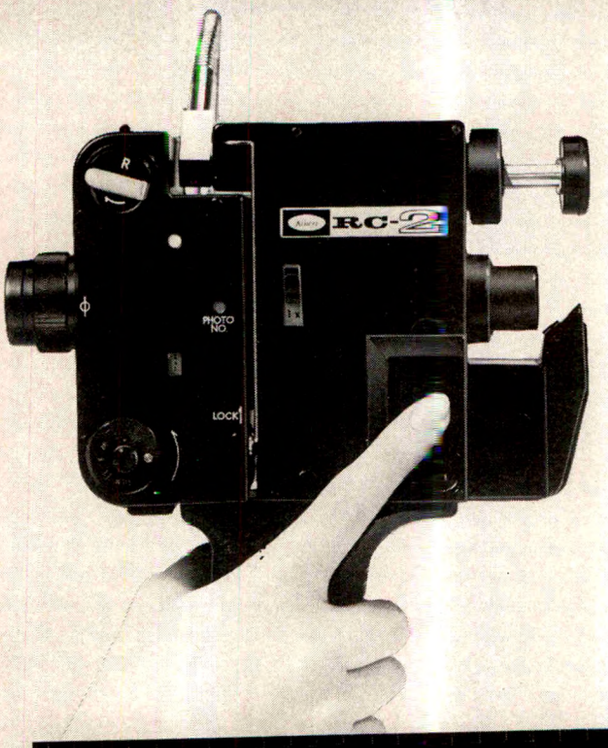
**Precautions:** Some strains of herpes simplex appear to be resistant. If there is no response in *epithelial infections* after 7 or 8 days of treatment, other forms of therapy should be considered.

The recommended frequency and duration of administration should not be exceeded.

'Stoxil' is not effective in corneal inflammations in which the virus is not present.

Corticosteroids are usually contraindicated in herpes simplex keratitis.

Boric acid should not be used during the course of therapy.

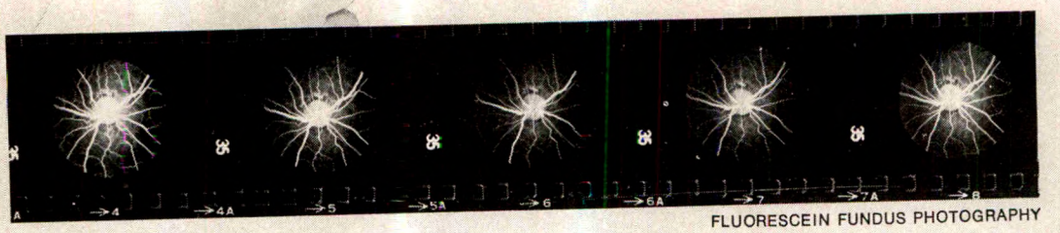


'Stoxil' Ophthalmic Solution should not be mixed with other medications.

**Adverse Reactions:** Occasionally, irritation, pain, pruritus, inflammation, edema of the eye or lids and, rarely, allergic reactions have been reported. Photophobia has occurred. Occasionally corneal clouding, stippling and small punctate defects in the corneal epithelium have been observed. The punctate lesions may be a manifestation of the infection.

**How Supplied:** 0.1% Ophthalmic Solution (1 mg./ml.), in 15 ml. bottles with dropper; 0.5% Ophthalmic Ointment (5 mg./gram) in 4 gram tubes.

**Stability:** The Solution should be stored in refrigerator until dispensed. The Ointment does not require refrigeration.



SK&F Smith Kline & French Laboratories

# Kowa RC-2

## fundus camera

*The simple approach to fundus and fluorescein photography.*

FLUORESCEIN FUNDUS PHOTOGRAPHY

To be fully meaningful to the medical profession, all instrumentation must function as an extension of the user's eyes, hands, and mind. The Kowa RC-2 fundus camera fully embodies this principle.

- *Fundus and External Photography* The basic RC-2 incorporates every conceivable advance in optics, mechanics, and electronics. Standard are built-in flash, 2X magnifying lens automatic frame numbering for patient coding, and more. It will produce impeccable 35mm results even for inexperienced users.

- *Fluorescein Photography* By simply adding an auto-wind back, filters, and a quick-cycling power unit, the RC-2 becomes a flawless fluorescein photographic instrument.

- *Polaroid® Photography* An attachment gives you 60-second fundus photographs.

To see why the *total systems approach* has made Kowa's RC-2 the standard by which all others are measured, contact the representative in your area.

# Jet or Drop

***DACRIOSE gives you complete control of ocular irrigation. You can provide a gentle but thoroughly cleansing "jet-like" action . . . or you can use it drop-by-drop.***

This modern irrigating solution, in the unique *Jet-Stream* dispenser, is ready-to-use and self-sterilizing.

Use DACRIOSE

☐ *In the office:* after tonometry and gonioscopy — to wash away fluorescein — to wash out secretions and discharges.

☐ *In the emergency room:* for quick, safe removal of foreign bodies.

☐ *In the operating room:* for sterile and convenient irrigation of the eye pre- and post-operatively.

☐ *At the bedside:* to clean and irrigate eyes — to save staff time.

**Formula:** A sterile, stable, buffered isotonic solution of boric acid, sodium carbonate, potassium chloride. Preserved with benzalkonium chloride, 0.01%; with 0.01% disodium ethylenediamine tetraacetate.

**Warning:** Do not dilute or reuse the solution. Do not touch dropper tip to eye or any surface as this may contaminate solution.

**Supply:** 0.95 fl. oz. and 4 fl. oz. plastic Irrigator bottles.

## DACRIOSE®

E. WILLIAM TILLYER

# LENSOMETER® lens measuring instrument

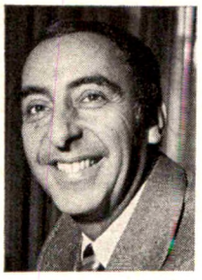
The Lensometer is a meter or instrument designed to measure the power of a lens when light enters the lens in parallel rays. It gives the power in dioptric values. The basic optical design of Lensometer instruments is almost fifty years old. But the function and limitations are still often misunderstood.

The Lensometer instrument is very accurate in checking the power of a single-vision lens or the distance portion of a multi-focal lens. However, when checking the power of a bifocal addition, it is important to understand the limitations of the Lensometer instrument.

When you refract, you first determine the patient's requirements for comfortable distance vision. You then add to his correction the amount of plus power required for comfortable near vision. This requirement is for vision at 13″ to 16″—*and the rays of light as they come from this near image to the eye are divergent.*

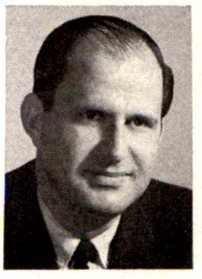
Your prescription, as it is written, indicates that you have given your patient a certain amount of power for distance. And then added a plus lens for near vision. When the prescription has been made up, it should be checked on the Lensometer instrument to make sure the Rx is what you ordered for your patient.

Therefore, you check the Rx with the convex side of the lens toward you. The Lensometer instrument will give a true and accurate reading for the distance portion. But if you check the power through the segment—without reversing the lens in the instrument—the difference between the distance power and the power through the segment will not always equal the power you prescribed as an addition.



This is because the segment of the lens is being measured for use at infinity. Whereas you prescribed the addition for use at near, with rays divergent rather than parallel.

To make sure you get what you prescribe, you must check the addition by reversing the prescription in the Lensometer instrument and checking the power of the lens through the segment as compared with the power of the lens at an equal distance above the optical center. This will enable you to determine if the plus lens you prescribed for an addition is duplicated in the Rx.



When improperly checked, the power of the addition can vary anywhere from .09D to .37D from what your Rx called for (depending upon the power and thickness of the distance lens).

It's inconvenient to reverse the lens to determine the power of the addition. But it's the only way to determine the true value of the Rx. And it's the *only* way to make sure that your patient gets the quality lens that you prescribed.

# CONTACT LENS PRACTITIONERS

The next few years promise tremendous changes in the contact lens field. New types of lenses, materials, equipment and fitting techniques will compete for the practitioner's time and attention.

We believe the fitter will look to his laboratory for advice and instruction, as well as for the latest and best lenses. Thus, the need for dependable laboratories with research facilities, knowledgeable personnel and adequate resources, will be evident as never before.

Recognizing this need, we have formed UNION OPTICS CORPORATION, comprising a select group of established laboratories under the leadership of respected contact lens authorities. This organization is now the second largest contact lens manufacturing entity in the U.S.A. We expect it to play a major part in research, development and improvement of contact lenses in the future.

If you are not yet acquainted with our laboratories, we invite you to get in touch with the one nearest you.

Significant new findings
Drug penetration
into the human eye

# for the first time independent research relates ocular drug penetration in humans to your choice of ophthalmic vehicles

## Proof of penetration—new fluorophotometry concentration/duration study[1]

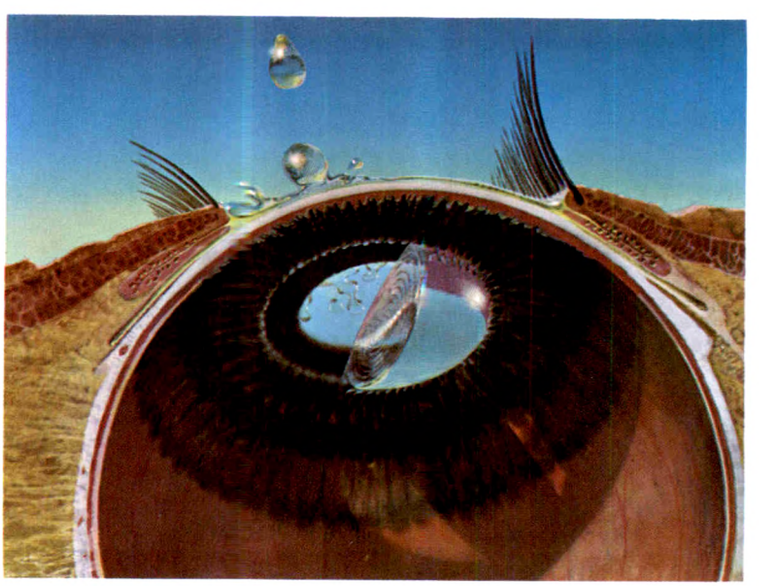
Using a slit lamp fluorophotometer, "the effects of ophthalmic vehicles on the intraocular penetration of topical fluorescein in man" were determined. "Quantitative data on ocular penetration of this drug, in man, in vivo are presented."

### The study

Fluorescein combined with hydroxypropyl methylcellulose 0.5%, polyvinyl alcohol 1.4% and aqueous; each vehicle instilled in the eyes of 20 normal subjects; each subject served as his own control; hourly measurements of attained drug concentration were made quantitatively using a slit lamp fluorophotometer.

### The findings

CORNEA



Over a three hour period, hydroxypropyl methylcellulose produced corneal drug levels 85% higher than polyvinyl alcohol and 43% higher than the aqueous vehicles.‡

AQUEOUS HUMOR

Over a three hour period, hydroxypropyl methylcellulose produced aqueous humor drug levels 93% higher than polyvinyl alcohol and 42% higher than the aqueous vehicle.‡‡

### The authentication

The authors state that their findings may, or may not, be true for drugs other than fluorescein. However, the findings reported above were achieved "consistently and reproducibly"; data were analyzed and tested for significance on a computer.

# ...all pilocarpines are *not* the same
# **Isopto® Carpine**
# provides measurably greater response

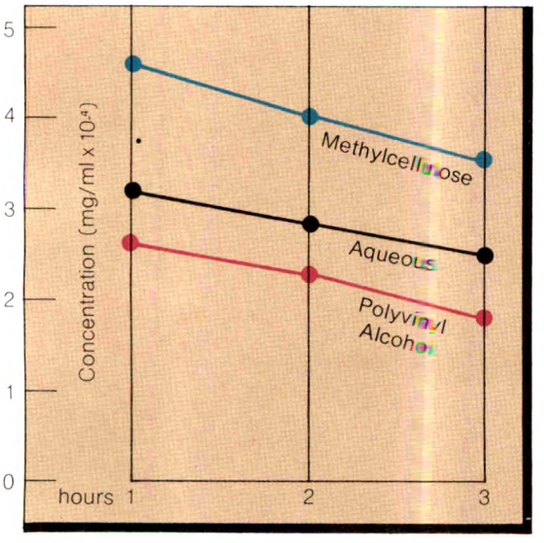
significantly greater lowering of IOP[2]

demonstrably greater miosis[2]

## the ideal ophthalmic vehicle is the difference

because the ISOPTO® vehicle

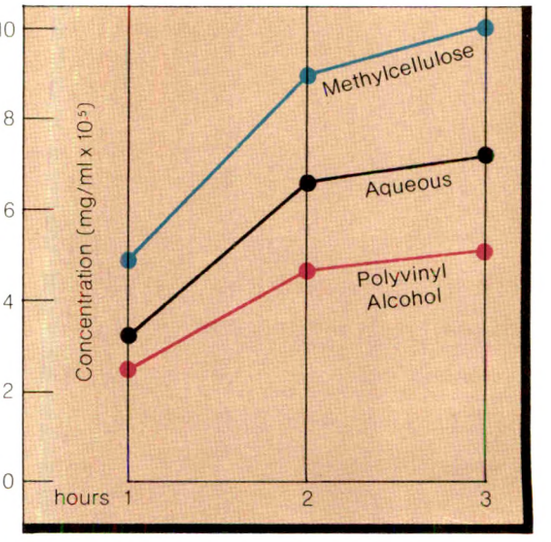
resists tear dilution and drug washout[3]



sustains tissue contact[1,4]

increases intraocular penetration[1]

Isopto® vehicle (hydroxypropyl methylcellulose 0.5%)
produced significantly higher drug penetration and concentration
compared with 1.4% polyvinyl alcohol or aqueous vehicles.

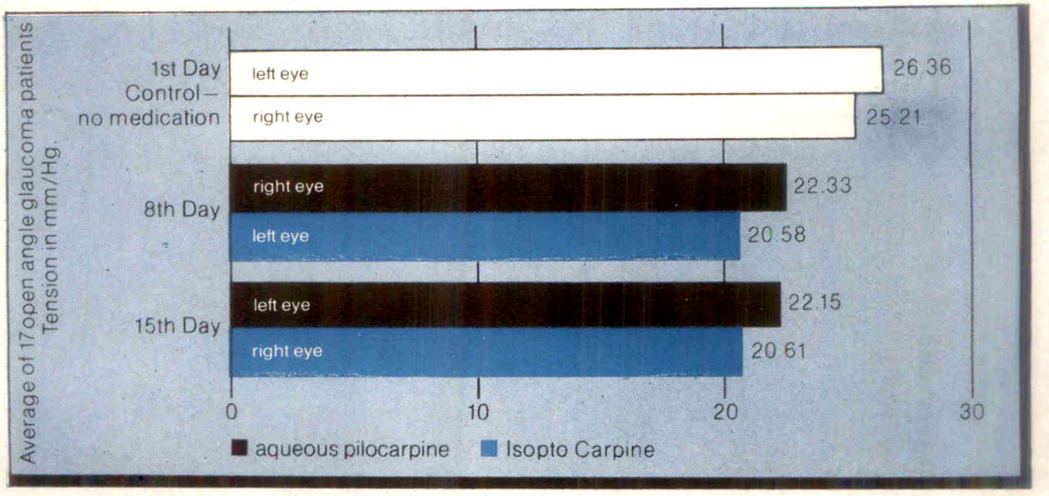


‡Concentration in human cornea

Corneal fluorescein concentration after topical
2% fluorescein in various vehicles

‡‡Concentration in human aqueous humor

Aqueous humor fluorescein concentration after
topical 2% fluorescein in various vehicles.



Adapted from Waltman, S.R. and Patrowicz, T.C. Effects of hydroxypropyl methylcellulose and polyvinyl alcohol on intraocular penetration of topical fluorescein in man. Invest. Ophthal. 9:966, 1970.

...therefore, when penetration makes the clinical difference

# Proven Performance

Study of open angle glaucoma patients shows the clinical difference in vehicles

Adapted from Haas, J.S., and Merrill, D.L.:
The effect of methylcellulose on responses to solutions of pilocarpine, Amer. J. Ophthal. 54:21, 1962.

Results: Significantly greater lowering of IOP with hydroxypropyl methylcellulose solution of pilocarpine (Isopto®Carpine) as compared to aqueous pilocarpine.

# Your assistant's assistant.

The Nikon Projection Vertexometer lets your assistant completely take over the task of measuring lenses with no lengthy training period or sacrifice of accuracy.

Your assistant can read spherical power, cylindrical power, prism power, and axis from a 5″ diameter screen without any chance of error since individual diopter correction is simply not necessary.

And at any time, you can check the readings yourself by a mere glance at the target pattern on the screen which appears clear and bright in a normally lighted room.

For the busy ophthalmologist, the Nikon Projection Vertexometer makes lens measuring a time-saving, almost automatic, fail-safe routine that your assistant can handle easily and surely.

And what's more, Nikon stands behind each Projection Vertexometer with a 10 year guarantee. For a limited time only, you can try the Nikon Projection Vertexometer in your office for 10 days without any charge. To take advantage of this free offer, call or write:

**AMERICAN OPTICAL CORPORATION**
BUFFALO, NEW YORK 14215

Rapid de-frost is important. The surgeon needs that element of control in retinal detachment procedures and in cataract operations. Its importance increases with every additional "plus feature" that the Amoils system employs with it. The Amoils System is a complete system with due emphasis on safety, efficiency, economy, simplicity and performance. All the pencils are light and manoeuvrable but lose no strength or robustness because of it. They are all flash autoclavable. Accidental adhesions are eliminated because the pencils are applied warm to tissue before freezing starts. The Amoils Ophthalmic Cryo Unit is important because of its superiority, and it's superior because of the unique combination of individual features, like rapid de-frost.

*Active:* dexamethasone 0.1%, neomycin sulfate equivalent to 3.5 mg/cc neomycin, polymyxin B sulfate 6000 units/cc.

available as sterile ophthalmic drops and sterile ointment...

Alcon *dedicated to advances in ophthalmic therapy*

DESCRIPTION: *DROPS*—Sterile suspension containing: *Active:* Dexamethasone 0.1%, Neomycin (present as sulfate) 3.5mg/cc, Polymyxin B Sulfate 6000 units/cc; Vehicle: Hydroxypropyl Methylcellulose 0.5%; *Inactive:* Sodium Chloride, Polysorbate 20, Hydrochloric Acid and/or Sodium Hydroxide (to adjust pH), Purified Water; Preservative: Benzalkonium Chloride 0.004%. *OINTMENT—Active:* Dexamethasone 0.1%, Neomycin Sulfate equivalent to 3.5mg/gm Neomycin; Polymyxin B Sulfate 6000 units/gm; *Inactive:* White Petrolatum, Anhydrous Liquid Lanolin; Preservatives: Methylparaben 0.05%, Propylparaben 0.01%. CONTRAINDICATIONS: This drug is contraindicated in tuberculous, fungal, and most viral lesions of the eye (herpes simplex/dendritic keratitis); vaccinia, varicella; acute purulent conjunctivitis and acute purulent blepharitis, and in those persons who have shown hypersensitivity to any of its components. PRECAUTIONS: Extended use may cause increased intraocular pressure which should be checked frequently and may result in overgrowth of nonsusceptible organisms. Perforation can occur in diseases causing thinning of the cornea. Discontinue use if sensitivity occurs. Not recommended for long-term use in pregnant patients.

AMERICAN JOURNAL OF OPHTHALMOLOGY

VOLUME 72 OCTOBER, 1971 NUMBER 4

# A MODIFIED TECHNIQUE OF EXTERNAL DACRYOCYSTORHINOSTOMY

FIRST AMERICAN JOURNAL OF OPHTHALMOLOGY LECTURE

PAN AMERICAN ASSOCIATION OF OPHTHALMOLOGY

GUILLERMO PICÓ, M.D.

*San Juan, Puerto Rico*

In 1966, Dr. William A. Mann performed a valuable service to us all by preparing a detailed—and most interesting—history of The American Journal of Ophthalmology[1] from its origin in 1884 to the present. This is, beyond question, one of the most distinguished medical journals of the world, and one of its most important accomplishments is the contribution it has made to the development of close scientific and personal relations among ophthalmologists of the Americas, particularly through the Pan American Association of Ophthalmology. As I speak these words, many names come to my mind, as I am sure they come to yours. Among them are:

Dr. Manuel Uribe Troncoso, who served on the editorial board of the Journal for 40 years, from 1918 to 1958.

Dr. Harry Gradle, who served on the editorial board from 1929 to 1949, and who was responsible for the foundation of the Pan American Association of Ophthalmology in 1934.

Dr. Derrick T. Vail, who was editor of the Journal from 1940 to 1965.

Dr. Frank W. Newell, who has been editor of the Journal since 1965, and who has continued its traditional support of the Pan American Association of Ophthalmology, to the great betterment of this specialty throughout the Americas.

Dr. Newell and his editorial board conceived the idea of an American Journal of Ophthalmology Lecture, the first of which I have the honor to deliver today and which will be delivered every second year hereafter. These lectures will, of course, be published in the Journal.

I cannot find what Kipling once called "the magic of the necessary word" to express my gratitude to the committee from the Pan American Association and the editorial board of the American Journal of Ophthalmology for selecting me to deliver the first of these lectures. Believe me, I feel the responsibility as well as the honor of the selection, for, as I conceive it, they are symbols of the scientific union among the United States of America, the Americas to the south, and Canada. I might add that I am particularly gratified that the educational endeavors in which I am so vitally interested played some part in the honor that has come to me.

## GENERAL CONSIDERATIONS OF SURGERY IN DACRYOCYSTITIS

I have elected to speak to you today on a procedure for the relief of dacryocystitis for several reasons:

1. I am frequently called upon to produce this relief. I have no statistical proof, but it is my impression that this condition is more

From the Department of Ophthalmology, University of Puerto Rico School of Medicine, San Juan. Presented at the Seventh Interim Congress of the Pan American Association of Ophthalmology February 1, 1971, in Bogotá, Colombia.

Reprint requests to: Guillermo Picó, M.D., Department of Ophthalmology, University of Puerto Rico School of Medicine, San Juan, Puerto Rico 00905.

common in the tropics than in more temperate regions.

2. Dacryocystitis is always a source of annoyance and discomfort to the patient, and not infrequently the epiphora is disabling.

3. The necessity of surgery for this condition is not always appreciated. Once it has become established in adults, medical management, including potent antibiotic therapy, is futile; the epiphora, which is the patient's chief concern, will continue. In children, dacryocystitis is usually the result of congenital stenosis of the nasolacrimal duct. Probing, though it should be tested, is generally ineffective after the age of three years and the operation should be performed at that age or shortly thereafter.

4. Finally, for some reason which has always eluded me, even competent ophthalmic surgeons are often not equipped, either by training or experience, to perform the surgery required in dacryocystitis. For many years, both as a practicing ophthalmologist and as a teacher, I have been disturbed by the fact that so many otherwise highly competent ophthalmic surgeons, who are well skilled in other procedures, are so inept—I use the word deliberately—when they are faced with surgical problems of the lacrimal drainage system. Perhaps the principal explanation for this situation is that many of the procedures advocated for them are so difficult technically and so prone to complications that the average surgeon becomes frustrated and drops them from his armamentarium.

I must confess that I myself would never have become interested in dacryocystorhinostomy if:

1. I had to deal with the excessive bleeding from the nasal mucosa and the angular blood vessels that occurs when precautions are not taken to prevent it.

2. I had to perform the operation in the restricted space available to working without the separation of the medial canthal tendon from its insertion at the anterior lacrimal crest.

3. The difficult suturing of two flaps of nasal mucosa to two flaps of lacrimal sac were necessary in the technique I employ, as it is in the Dupuy-Dutemps operation.

## Historical note

I have made no comprehensive review of the literature for this presentation, but I think my remarks will be clearer if I begin with a brief historical note on dacryocystorhinostomy. Its origin, according to Chandler,[2] dates from the time of Celsus, in the first century of the Christian era. Galen, in the second century, also employed surgery to create a new passageway from the lacrimal sac into the nose. Other details of the first use of this operation can be found in Chandler's article, as well as in other excellent articles by Arruga[3] and by Welt.[4]

Modern surgery of the lacrimal sac began in Italy, in 1904, with Toti's[5] description of an operation which involved (1) creation of an opening into the nasal wall with hammer and chisel, and (2) removal of the nasal mucosa in this opening and the medial half of the lacrimal sac. Sutures were used only in the skin. Toti was successful in about half of his cases. Blascovics,[6] in 1912, used the Toti technique but removed the entire lacrimal sac except for a small portion surrounding the opening of the canaliculi.

Thereafter, the basic technique of dacryocystorhinostomy was successively modified as follows:

In 1914, Kuhn[7] cut the nasal mucosa in horseshoe fashion, leaving it attached anteriorly and suturing it to the periosteum anterior to the bony opening.

In 1921, Mosher[8,9] combined the Toti technique with intranasal removal of the tip of the middle turbinate and suture of the anterior border of the opening in the lacrimal sac to the tissues anterior to the bony opening. He anticipated success in 90% of all cases. In 1947, Hogan[10] reported such results in 49 operations performed by a modification of the Mosher-Toti technique.

In 1920, and again in 1922, Dupuy-Du-

temps and Bourguet,[11,12] in France, and in 1921, Ohms,[13] working independently in Germany, modified the Toti technique by dissecting the anterior and posterior flaps of the nasal and lacrimal mucosa and then suturing the flaps together. The French surgeons had successful results in 94.8% of more than 1000 operations. Since then a number of other observers[2,4,14-18] have reported large series of operations performed by this technique with success rates ranging from 85 to 100%.

In 1925, Basterra[19] modified the Dupuy-Dutemps technique by dissecting an anterior flap of nasal mucosa and suturing it to the anterior border of the opening in the lacrimal sac.

In 1944, Soria[20] recommended suturing a single flap of nasal mucosa to the posterior flap of the lacrimal sac. He also recommended suturing the anterior flap of the sac to the anterior border of the bony opening. Gauze drainage from the sac down to the nasal fossa was provided for 72 hours.

In 1911, Forsmark[21] recommended transplantation of the lacrimal sac. The same recommendation was made by Stock[22] in 1934 and by Gifford[23] in 1944. In this technique the sac is severed from the nasolacrimal duct at its junction with it, after which its lower end is pulled into the bony nasal opening by sutures brought out through the nostril.

In 1946, Arruga[3] brought together his experiences with dacryocystorhinostomy, which covered many years and which had previously been reported in a number of publications. His operations were performed by the Dupuy-Dutemps technique and were facilitated by several new instruments of his own design. He also described a technique for dacryocystorhinostomy applicable to patients who had previously undergone dacryocystectomy.

In 1954, Iliff[24] suggested that the Stryker saw be used to open the lateral bony nasal wall. This was a very helpful suggestion. The use of this instrument simplifies the technique, shortens the operating time, and diminishes the former risk of damage to the soft tissues. The rapid oscillating action of the saw is far less traumatic than the action of dental or other burs, bone chisels, and rongeurs.

In what has been said so far in this brief historial note one must be impressed by the many efforts made to modify the Dupuy-Dutemps technique. The reason, it seems, is that this is a difficult operation, particularly in respect to the accurate approximation of the corresponding flaps of nasal mucosa and lacrimal sac by direct sutures. Another reason for failure in a certain number of cases is postoperative closure of the newly created lacrimal tract, either by formation of granulation tissue at the new bony opening or by adhesion of the anterior flaps to the posterior flaps. Arriaga[25] puts particular stress on this latter possibility. To simplify the operation, several observers recommend that no sutures be used to unite the flaps but instead, plugging agents should be left between them.[24,26] Other surgeons use the basic Dupuy-Dutemps technique or some modification thereof and suture the flaps, but also leave some sort of plugging agents between them (rubber catheters, steel wire, silicone sponges, polyethylene tubes, umbilical tape, and wicks of suture material and gauze).[17,25,27-32]

To bring this resume to a close, in 1958, and again in 1963,[33,34] I myself presented a technique of external dacryocystorhinostomy, based in part upon the operation described by Ramón Castroviejo in 1942,[35] and itself a modification of the Dupuy-Dutemps technique. The flaps are sutured as recommended by Soria.[20] The bony opening is created by the Iliff trephine on the Stryker saw.[24] A 2-0 or 4-0 silk suture is left in the new lacrimal drainage pathway for several days, as recommended by Castroviejo.[35] I have used this technique over the past several years and have found it simple, safe, efficient, and uncomplicated. Absence of bleeding, when it is properly performed, is one of its most desirable features.

## Indications and preoperative measures

Useful as dacryocystorhinostomy is, dacryocystectomy is still indicated in three diseases of the lacrimal sac—namely, malignant lesions, tuberculosis, and syphilis. This operation was formerly the favored procedure for all conditions of the lacrimal sac, but now it has been almost entirely replaced by external dacryocystorhinostomy. Dacryocystorhinostomy takes a little longer to perform, it is true, which is undesirable in older patients, and it is somewhat more traumatic than simple excision of the sac, but these disadvantages are more than compensated for by the better end results.

If a chronic dacryocystitis must be corrected before intraocular surgery, dacryocystorhinostomy is the preferred operation. Even if the epiphora that tends to persist after the excision operation is not severe, stagnation of tears in the conjunctival sac can create a dangerous, persistent infection that may complicate any subsequent intraocular procedure.

Dacryocystorhinostomy is also indicated for the relief of disabling epiphora due to physiologic insufficiency of the lacrimal pump or to atonic distension of the lacrimal sac.

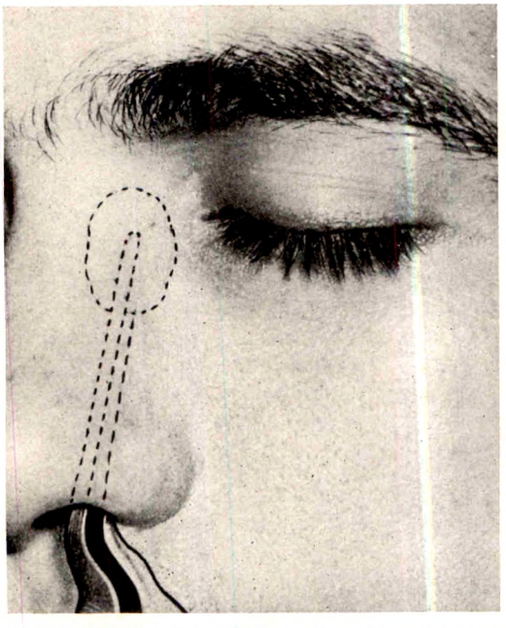

Fig. 1 (Picó). Introduction of moistened cotton tampon into nose.

The surgeon who undertakes any operation on the lacrmial sac must possess a precise knowledge of the anatomy of the lacrimal excretory pathways and of their relations to other structures and landmarks. Bleeding will be excessive and dangerous, for instance, unless the surgeon bears in mind the position of the angular blood vessels, which are situated slightly anterior to the anterior lacrimal crest.

Preoperative dacryocystography may give valuable information. Two other preoperative precautions are important: Patency of the lower punctum, the common punctum, and the canaliculus must be assured, and good illumination must be provided, preferably with a Lempert head lamp.

## Technique of external dacryocystorhinostomy

*Anesthesia*—The best results in external dacryocystorhinostomy are obtained with general anesthesia supplemented by local anesthesia applied to the nasal mucosa and the superficial tissues over the lacrimal sac as follows:

A cotton tampon, well saturated with equal quantities of cocaine solution (4%) and epinephrine (1:1000) is introduced into the nose and brought into contact with the area of nasal mucosa which corresponds to the lacrimal fossa (Fig. 1). A length of thread attached to this tampon facilitates its later removal at the appropriate stage of the procedure. The shrinkage and ischemia which follow this application inhibit bleeding when the mucosa is incised.

The superficial tissues over the lacrimal sac are injected with 3 ml of procaine HCl solution, to which two drops of epinephrine (1:1000) have been added.

*Incision*—A vertical incision, 3.5 cm long, is made 3 mm medial to the inner canthus, through the skin and subcutaneous tissues up

to the medial canthal tendon (Fig. 2). A Stevenson lacrimal sac speculum is introduced into the incision.

An incision in this location carries with it no risk of damage to the angular blood vessels situated slightly anterior to the anterior lacrimal crest. As just pointed out, the surgeon who does not keep in mind the position of these vessels is likely to find himself confronted with excessive and dangerous bleeding.

*Steps of the procedure*—External dacryocystorhinostomy is performed in the following steps:

1. The medial canthal tendon is cut with scissors close to its insertion at the anterior lacrimal crest (Fig. 3), after which the overlying periosteum is incised with a knife and is separated anteriorly with a periosteal elevator, a step which leaves the bone bare. This technique, it must be admitted, is controversial.

Most descriptions of dacryocystorhinostomy in the American literature, contrary to those in the European literature, insist that the medial canthal tendon be left attached at its insertion and that the operation be carried out below the lower edge of this tendon. My experience has been that such a technique makes the operation more difficult because of the restricted area in which the work must be done, and that it is important, in the interest of visibility, to separate the medial canthal tendon from its insertion.

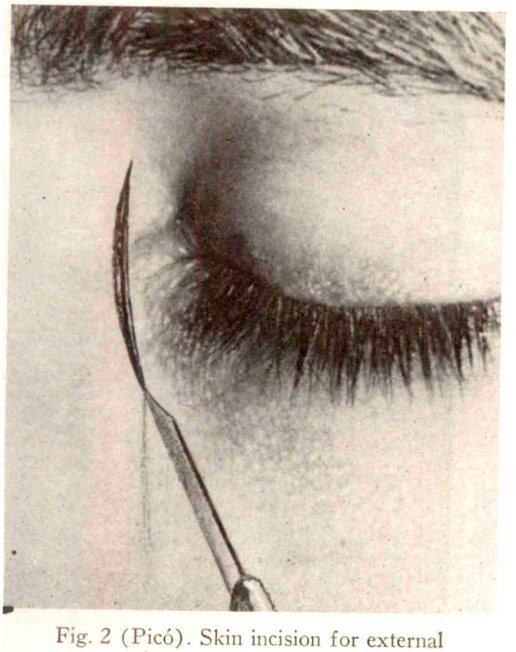

Fig. 2 (Picó). Skin incision for external dacryocystorhinostomy.

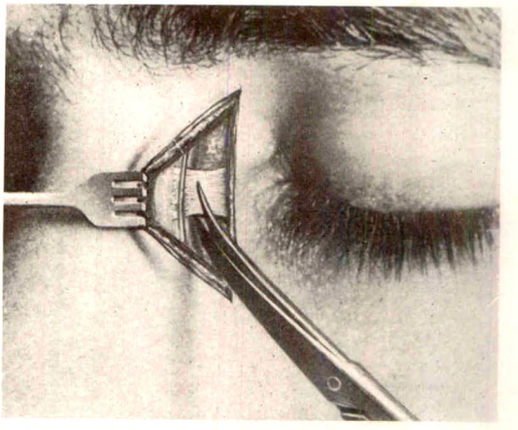

Fig. 3 (Picó). Division of medial canthal tendon. Note that the angular blood vessels are located just anterior to the insertion of this tendon.

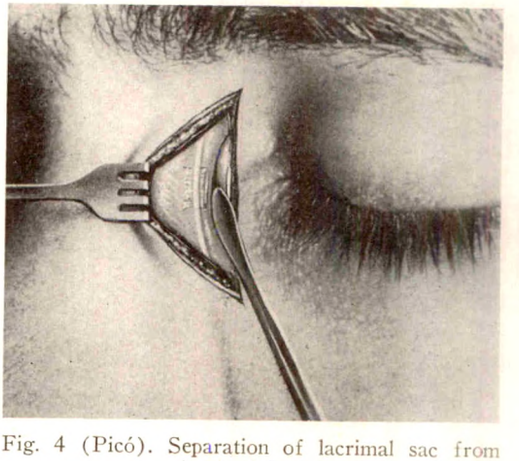

Fig. 4 (Picó). Separation of lacrimal sac from lacrimal fossa.

2. The lacrimal sac, which is located in the lacrimal fossa immediately posterior to the canthal tendon, is dissected free laterally from the fossa (Fig. 4). The periosteum is also separated from the fossa.

3. The Stevenson lacrimal sac speculum is

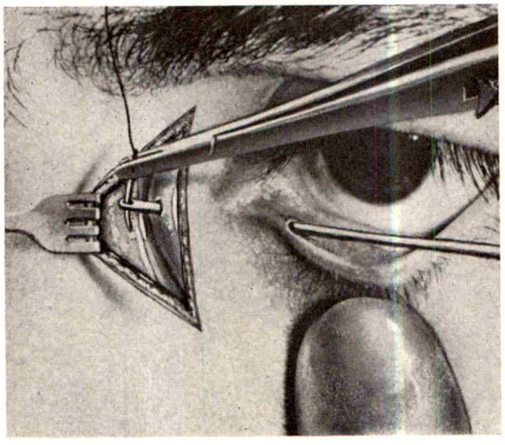

Fig. 5 (Picó). Passage of silk suture through Castroviejo probe after passage of probe through canaliculus and lacrimal sac.

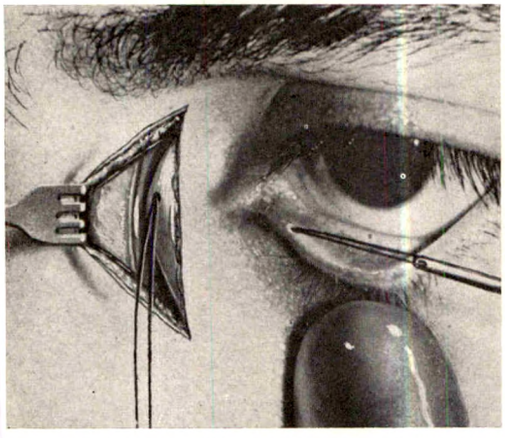

Fig. 6 (Picó). Withdrawal of probe with suture.

now removed from the incision. A special Castroviejo probe, with an opening in the tip, is passed through the lower canaliculus and into the lacrimal sac and then is pushed further through the medial wall of the sac.

4. A needle threaded with 2-0 or 4-0 silk suture is passed through the opening in the Castroviejo probe (Fig. 5). One end of this suture is brought out through the canaliculus and punctum lacrimale by withdrawing the probe (Fig. 6).

5. An opening is made in the nasal bony wall with the 10 mm Iliff trephine on the Stryker saw (Fig. 7). The trephine is so placed on the anterior lacrimal crest that a third of the opening is anterior to the crest and two-thirds is posterior to it. The center of the opening is at the level of the common punctum. Removal of the bone exposes the nasal mucosa (Fig. 8). If the ethmoidal cells are entered in this step of the procedure, as occasionally happens, they should be removed with forceps until nasal mucosa is exposed.

6. A flap of nasal mucosa is dissected along the border of the bony opening but is left attached posteriorly (Fig. 9). In an occasional case the tip of the middle turbinate is found to be encroaching on the bony opening and must be excised with the rongeur or forceps.

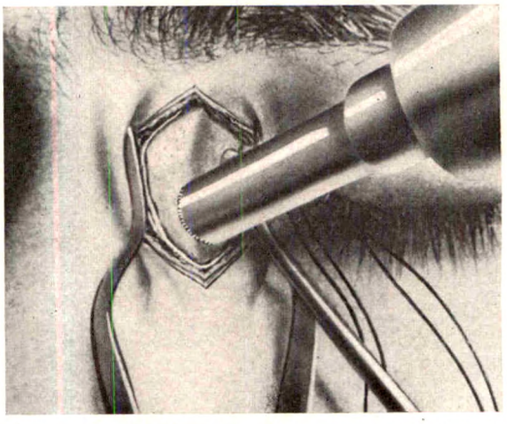

Fig. 7 (Picó). Creation of bony opening with 10 mm. Iliff trephine of Stryker saw.

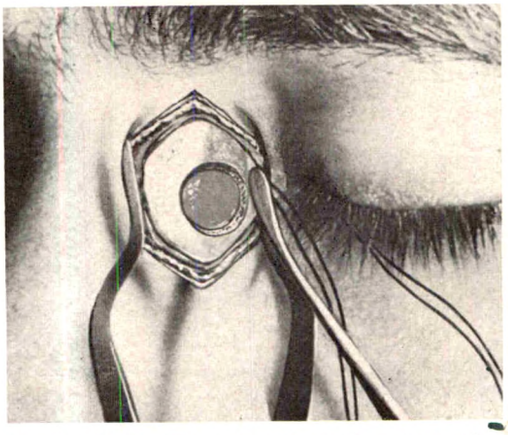

Fig. 8 (Picó). Exposure of nasal mucosa after removal of piece of bone.

7. The cotton tampon in the nasal cavity is removed.

8. A vertical incision is made in the nasal aspect of the lacrimal sac by introducing Westcott scissors through the opening previously made in the medial wall of the sac; anterior and posterior flaps of sac are thus created (Fig. 10). I join a number of other surgeons (Hallum,[17] McPherson,[18] Callahan,[30] and Werb[36]) in warning the surgeon to be certain at this point that the wall of the lacrimal sac has been completely opened and the lumen has been reached and exposed.

9. The posterior flap formed from the lacrimal sac is sutured to the flap formed from the nasal mucosa. A spatula type of needle is used to introduce three sutures of 4-0 chromic catgut (Fig. 11). In the technique I am describing this step is carried out without the difficulty experienced in the Dupuy-Dutemps technique because the single flap which I employ is larger than the posterior flap used in the Dupuy-Dutemps technique.

10. The other end of the silk suture in the

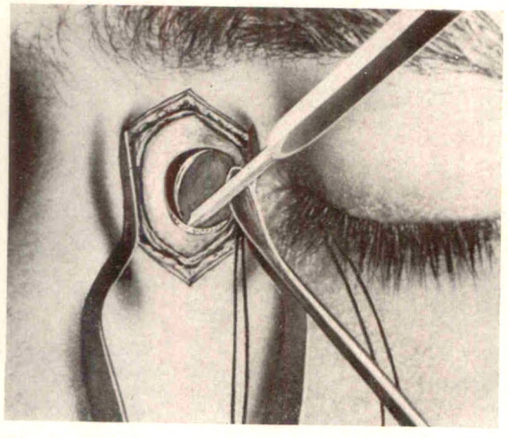

Fig. 9 (Picó). Dissection of flap of nasal mucosa.

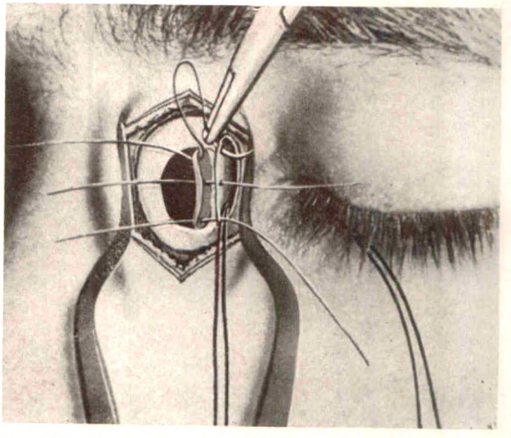

Fig. 11 (Picó). Suture of flap of nasal mucosa to posterior flap of lacrimal sac.

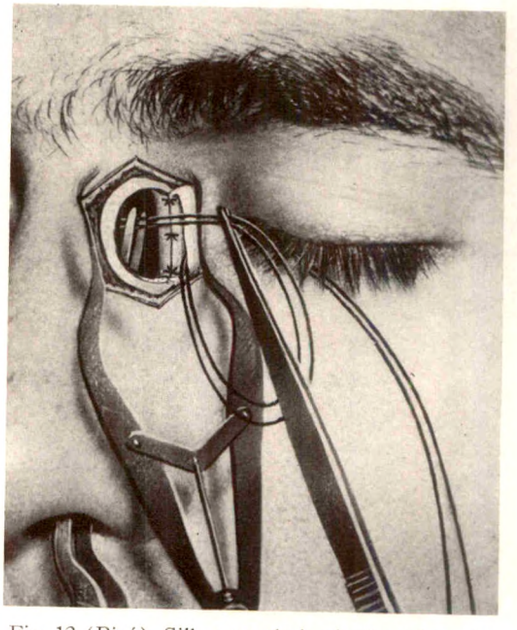

Fig. 12 (Picó). Silk suture in lacrimal sac brought down outside of nose.

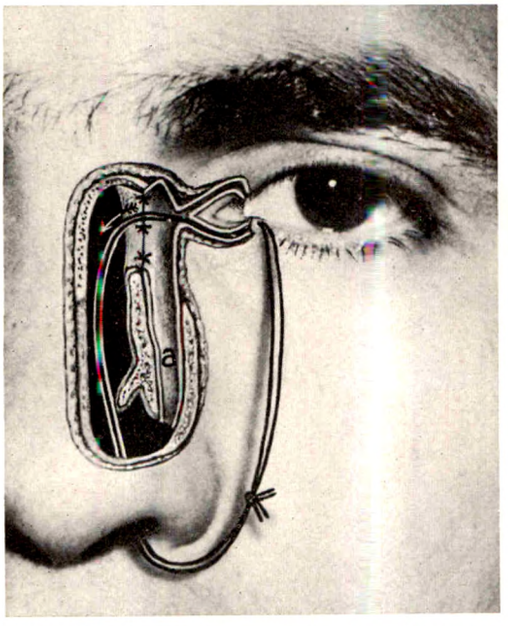

Fig. 13 (Picó). Diagram showing silk suture passed through new pathway and down nasal cavity to exterior.

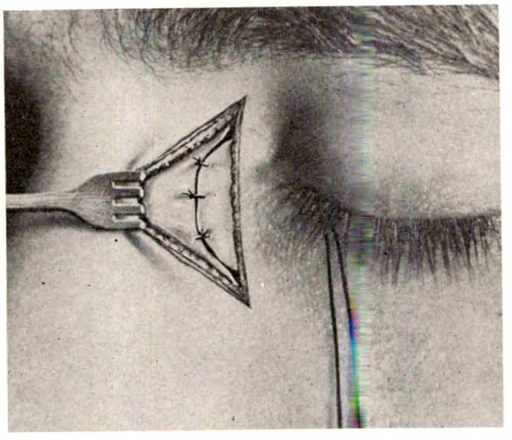

Fig. 14 (Picó). Suture of anterior flap of lacrimal sac to periosteum anterior to bony opening.

lacrimal sac is brought down outside the nose (Fig. 12) and is tied to the end already brought out through the punctum (Step 4, Fig. 13).

*Closure of wound*—The anterior flap of the incised lacrimal sac is sutured to the periosteum that was retracted anterior to the bony opening with three sutures of 4-0 chromic catgut. The medial canthal tendon is reattached without direct sutures; there is no need for them because the tendon will be displaced nasally when the anterior flap of the lacrimal sac is sutured to the periosteum anterior to the bony opening (Fig. 14). Additional sutures are used to approximate the subcutaneous tissues.

The skin is closed with a continuous 6-0 silk suture (Fig. 15). Finally, a light dressing is applied.

*Dacryocystorhinostomy after dacryocystectomy*—If the patient has already undergone dacryocystectomy, it may still be possible to perform dacryocystorhinostomy, though only if the lower canaliculus is patent. Two flaps of the fibrous tissue that has replaced the lacrimal sac are used instead of the two flaps of lacrimal sac used in the basic operation. One of the flaps of fibrous tissue is anterior to the common punctum and the other is posterior to it. The anterior flap is attached to the periosteum that was retracted anterior to the bony opening and the posterior flap is attached to the single flap of nasal mucosa. Otherwise, the usual technique is followed.

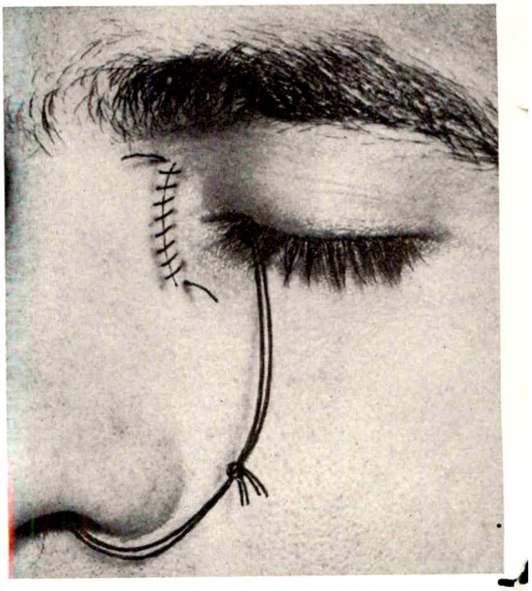

Fig. 15 (Picó). Closure of skin by continuous silk suture.

*Postoperative management*—Dressings are changed every second day. Each time the eye is dressed the silk suture in the newly created nasolacrimal passage is moved toward the nose in order to dislodge any granulation tissue or blood clot that might be present in the bony opening.

Both the silk suture in the nose and the skin suture are removed on the seventh postoperative day. The new lacrimal passage is irrigated at the end of the second postoperative week and at weekly intervals thereafter for the next four weeks.

## Analysis of cases

### Material and methods

The material on which this presentation is based consists of 121 consecutive external dacryocystorhinostomies performed between 1963 and 1969 for chronic dacryocystitis with epiphora and obstruction of the nasolacrimal duct. Sixteen of the patients had histories of acute attacks.

Ninety-one of these operations, 10 of which were bilateral, were performed at the Puerto Rico Medical Center by members of the house staff. Each operation was supervised by a member of the attending staff, who acted at it as first assistant. The other 30 operations, five of which were bilateral, were performed in my private practice.

All these patients were followed for at least six months and most of them were observed for over a year. The operation was considered successful if epiphora was eliminated and normal irrigation through the new drainage channel was possible.

Over the 1963–69 period, in addition to the 121 operations (15 bilateral) performed by the technique just described, 10 other operations were performed for this condition by other techniques. The data in these cases are included in the age and sex incidence to be discussed shortly.

### Results

By the criteria just laid down there were only four failures in these 121 operations, three in the public hospital cases and the other in my private practice. One of these patients had had a previous dacryocystectomy elsewhere. In every instance the cause of the failure was found at secondary surgery to be an obstruction of the new drainage channel by an occluding membrane, which histologic examination showed to be composed of organized granulation tissue.

Secondary surgery, which was successful in all four cases, consisted of removing the obstructing membrane by opening the anterior wall of the new pathway and exposing the bony opening.

### Complications

*Anatomic complications and their management*—Anatomic complications encountered at operation consisted of:

1. Total absence of the lacrimal sac because of previous dacryocystectomy (three cases) and small sacs (four cases). In either of these circumstances, adequate anastomosis of a single flap of nasal mucosa to a small posterior flap of lacrimal sac is usually possible, or the anastomosis can be accomplished by use of the small remnant of lacrimal sac mucosa left around the common punctum after a previous dacryocystectomy.

2. Thinning and atrophy of the nasal mucosa (one case). In such cases it is usually possible to dissect a single flap and suture it to the posterior flap of the lacrimal sac.

3. Distortion of the bony anatomy caused by the presence of ethmoidal cells in the area of trephination (three cases). In such cases the thin bony walls and the mucosal lining of the cells must be removed with strong forceps until true nasal mucosa is reached.

4. Encroachment of the top of the middle turbinate on the bony opening (one case). Excision of the tip solves this problem.

5. Obstruction at the common punctum (one case). When a stricture is present in this location as part of the chronic dacryocystitis (it may not appear until weeks or even months later), the operation should be concluded by leaving a Veirs rod in the lu-

men of the canaliculus, the common punctum and the newly created lacrimal drainage passageway for six weeks.

6. Fistulas of the lacrimal sac to the skin (two cases). Such fistulas are managed by dissecting them out at operation as part of the skin incision.

7. Tenacious adhesions of the anterior wall of the lacrimal sac to the posterior aspect of the medial canthal tendon (one case). Separation of the adherent structures requires only careful dissection.

None of the 16 complications just described presented any serious difficulties at operation.

*Technical complications*—Complications encountered at operation were few and readily handled. Bleeding occured in five cases. In two instances it originated from the angular vessels and in the other three from the nasal mucosa. In one case the nasal mucosa was accidentally severed while the trephine bony opening was being made.

*Postoperative complications*—Postoperative complications were few. They consisted of serious nasal bleeding (one case), abscess of the skin incision (one case), an unsightly scar (one case), a partial stricture at the common punctum (one case), and obstruction at the bony opening (four cases). An unsightly skin scar can be prevented by use of a rectolinear incision and careful, precise suture of the skin and soft tissues. Strictures can usually be prevented by keeping the silk suture in the nose for at least a week after operation. Dilatation is helpful in late cases. The single instance of stricture in my series was found several weeks after operation and did not occlude drainage. Obstruction of the bony opening was the cause of the four failures.

## Comment

One of the most interesting features of the analysis of the combined series of operations (131 operations on 116 patients) is the sex and age distribution. There were 28 males and 88 females, and the age range was from three to 85 years. Before 20 years of age there was a predominance of males (7). This group included a number of patients with congenital dacryocystitis. After the menopausal years females predominated. Of the 88 female patients, 61 were between 40 and 70 years of age.

The age distribution in these 116 cases corresponds to that reported by McPherson and Egleston[18] and the sex distribution to that reported by Traquair.[37] According to Meller,[38] the lumen of the nasolacrimal duct is narrower in women than in men. If his data are correct, they might also explain the higher frequency of bilateral disease in women. At any rate, the sex differential exhibited in this and other series as related to age suggests a possible endocrine factor in the etiology of dacryocystitis.

The results of these 121 operations, in which there were only four failures, can fairly be considered good. A point in favor of the technique described in this communication is the sameness of the results achieved in the public hospital cases, in which the surgery was done by inexperienced residents, and in my private cases, in which it was done by a surgeon of long experience. Reflection has convinced me that the similarity of results in the two series can be explained by the careful attention paid in both circumstances to the following considerations:

1. The location of the skin incision 3 mm from the inner canthus. This permits precise identification of the angular blood vessels and their careful retraction under direct vision. The incidence of bleeding is thus greatly reduced. It is also reduced by the introduction into the nose, at the beginning of the operation, of a cotton tampon well saturated with cocaine solution and epinephrine.

2. The good exposure achieved by separation of the medial canthal tendon at its insertion.

3. Creation of an adequate bony opening (10 mm) with the Iliff trephine on a Stryker saw.

4. The use of a single flap of nasal mu-

cosa to be sutured to the posterior flap of the incised lacrimal sac, instead of double flaps as in the Dupuy-Dutemps technique.

5. Suture of the flaps, a step essential to good healing. Arruga[3] also emphasizes the importance of this step. He had better results in the operations in which flaps of nasal mucosa and the lacrimal sac were firmly anastomosed by suture. Another point to be emphasized in this connection is that proper fixation of the flaps by suture will prevent occlusion of the new channel by their derangement and collapse.

6. The use of a silk suture in the nose to maintain patency of the new nasolacrimal pathway. Manipulation of this suture every second day dislodges whatever blood clots may be present at the opening and also prevents whatever occlusion of the common punctum might occur as the result of surgical trauma.

7. The constant recollection that the key to the management of complications before and after operation is their prevention.

The four failures in this series were all due to the same cause, obstruction at the bony opening, which itself was due to organized granulation tissue, not to a bony growth. I have come to the conclusion that this complication is inevitable in an occasional case, no matter how precise the technique has been. I am strongly opposed to the use of any foreign materials between the walls of the new anastomosis as a preventive measure. They simply disrupt the suture lines in the flaps, and they may even stimulate the formation of obstructing granulation tissue by causing irritation in the bony opening.

## Summary

A modified technique of dacryocystorhinostomy has been developed for the treatment of chronic dacryocystitis. Important considerations are as follows: Skin incision should be located 3 mm from the inner canthus. The medial canthal tendon must be separated from its insertion. A large single posterior flap of nasal mucosa must be created, and this must be sutured to the posterior flap of the lacrimal sac. The anterior flap of the lacrimal sac must be sutured to the periosteum anterior to the bony opening. Reattachment of the medial canthal tendon must be without direct sutures. Special precautions must be taken to maintain the patency of the newly created nasolacrimal channel. The safety and efficiency of this operation, when it is performed by competent ophthalmic surgeons with a sound knowledge of regional anatomy, are shown by the results in two series of operations totaling 121 cases in which there were only four failures and only one serious complication.

## Acknowledgments

I thank Mr. Héctor Gotay and Mr. José A. Méndez, senior medical students, for their help in the collection of the statistical data.

# SURGICAL TREATMENT OF TRAUMATIC BLEPHAROPTOSIS

RAYNOLD N. BERKE, M.D.
*Palo Alto, California*

The surgical treatment of acquired blepharoptosis is more complex and the results less predictable than that of congenital blepharoptosis. This is especially true of the traumatic cases; they are relatively rare and no two cases are identical.

## INCIDENCE OF TRAUMATIC BLEPHAROPTOSIS

Less than 2% of all major ophthalmic operations are for blepharoptosis.[1] Reports[2-5] show that tramua was the indication in only 9% of 1109 operations for blepharoptosis (Table 1), and since the incidence of traumatic blepharoptosis is so very low, it is unlikely that any one surgeon can collect enough such cases during an entire lifetime to formulate reliable guidelines for surgical treatment. Nevertheless, I shall propose a simple formula for avoiding gross amounts of overcorrection or undercorrection after an external levator resection operation. I shall also show the results of this and other blepharoptosis operations for this condition when trauma is causative.

A simple classification of the various causes of acquired blepharoptosis is given in Table 2, based on the reports of the investigators cited in Table 1. In 101 consecutive cases of acquired blepharoptosis, trauma (Table 3) was the most common single cause.

## MATERIAL AND METHODS

Surgery was performed on 40 patients with unilateral traumatic blepharoptosis. An internal approach was used in 11 cases and an external approach in 26 in order to retrieve a severed levator muscle or to resect an intact one. A Berke-Motais[6] or a Crawford[7] operation was performed on three eyelids with no levator function, with disappointing results.

Reprint requests to Raynold N. Berke, M.D., 2275 Sharon Road, Menlo Park, California 94025.

When trauma is causative, other problems often complicate the correction of the blepharoptosis. In the present series, these problems consisted mainly of a gross hypotropia (15 cases), adhesions between the levator muscle and the globe (three cases), or between the upper eyelid and the superior orbital margin (three cases), and there may be other assorted problems resulting from previous unsuccessful attempts to repair the blepharoptosis. Some of these complications could be corrected along with the blepharoptosis, but others were insurmountable.

## BLEPHAROPTOSIS CAUSED BY SURGICAL TRAUMA

In 72% of the patients, blepharoptosis developed after an operation on the orbit, the upper eyelid, the globe, or one of the extraocular muscles.

*After orbitotomy*—A transcranial or a lateral orbitotomy caused blepharoptosis in eight patients, most of whom had a good result from a levator resection operation when the levator function was 6 mm or more (Fig. 1). But when the levator muscle was paralyzed, this operation failed. Consequently, such eyelids had to be suspended from the frontalis muscle with a less satisfactory result (Fig. 2).

*After enucleation*—Eight patients had 2-8 mm of unilateral blepharoptosis and an intact levator muscle after an apparently uncomplicated enucleation. Seven of these had 5-12 mm of true levator function,* and these were adequately corrected by either an internal[8] or by an external[9] levator resection (Fig. 3). In order to prevent final over- or

* *True* levator function occurred when the upper eyelid was elevated only by the levator muscle. The levator function was *false* when adhesions between the levator and the globe caused the eyelid to be elevated by the superior rectus muscle rather than by the levator.

TABLE 1

INCIDENCE OF SURGICALLY TREATED BLEPHAROPTOSIS

| Author | No. Cases | Congenital | Acquired | |
|---|---|---|---|---|
| | | | Traumatic | Nontraumatic |
| Johnson[2] | 108 | 85 (79%) | 9 (8%) | 14 (13%) |
| Hamilton[3] | 41 | 26 (63%) | 6 (15%) | 9 (22%) |
| Beard[4] | 140 | 89 (64%) | 16 (11%) | 35 (25%) |
| Smith[5] | 148 | 99 (67%) | 28 (19%) | 21 (14%) |
| Present series | 672 | 571 (85%) | 40 (6%) | 61 (9%) |
| Total | 1,109 | 870 (78%) | 99 (9%) | 140 (13%) |

undercorrection, each of these seven eyelids was positioned on its prosthesis at operation so as to compensate for a greater postoperative "lift" of the eyelid when the levator function was 8 mm or more than when it was only 5 mm. If a small amount of postoperative over- or undercorrection occurred, these defects could be reduced by ordering a new prosthesis of the proper thickness or by having the cornea of the prosthesis moved upward or downward to compensate for the over or undercorrection. Thus, a pleasing result (Fig. 4) could be achieved without additional surgery.

The eighth patient had 8 mm of blepharoptosis with no levator function after a long section of the optic nerve had been excised during an enucleation for retinoblastoma. Because the levator muscle was paralyzed, a subsequent levator resection failed to reduce the blepharoptosis. In this case, a Crawford[7] operation may have yielded a more acceptable outcome.

*After operation on conjunctiva*—Seven patients developed 2-12 mm of blepharoptosis after a subconjunctival tumor or cyst had been excised from the globe or from the upper eyelid. In each case the levator tissues above the tarsus had been injured; consequently, the levator function measured only 3-6 mm in three cases and 7-12 mm in the other four.

In five of these seven cases, the retracted end of the severed levator muscle was found through a skin approach and then reattached to the tarsus. When last examined an average of 30 months postoperation, four cases were fully or almost fully corrected (Fig. 5). A conjunctival approach was employed

TABLE 2

CLASSIFICATION OF 101 CASES OF ACQUIRED BLEPHAROPTOSIS

| Classification | Total Incidence |
|---|---|
| Trauma | 40% |
| Idiopathic | 23% |
| Blepharochalasis | 9% |
| Progressive external ophthalmoplegia | 9% |
| Tumors of upper eyelid | 8% |
| Horner's syndrome | 5% |
| Systemic disease | 5% |
| Microphthalmos | 2% |

TABLE 3

CLASSIFICATION OF CAUSES OF 40 CASES OF TRAUMATIC BLEPHAROPTOSIS

| Cause | No. Cases |
|---|---|
| Surgical trauma | |
| Orbital Operations | 8 |
| Enucleations | 8 |
| Conjunctival and eyelid operations | 7 |
| Operations on superior oblique muscle | 4 |
| Operations on lateral rectus muscle | 2 |
| Total | 29 (72% |
| Nonsurgical trauma | |
| Toy, stick, sled, football, golf club | 5 |
| Beer bottle, auto accident, fall | 5 |
| Bullet through orbit | 1 |

in two of the seven cases, but the retracted levator tissues could not be found by this technique; consequently, both were found to be much undercorrected months later.

When the external approach was employed to retrieve a severed levator muscle, an intact medial or lateral horn usually lead the surgeon to the retracted end of the muscle. But when both horns had been severed and the levator had receded out of sight into the epibulbar tissues, the lost levator could be found and identified only by grasping and pulling these tissues forward on a blepharoptosis clamp while the surgeon palpated the trochlea for Whitnall's check ligament. If the levator had been caught in the clamp, the surgeon would feel a cord-like band (Whitnall's ligament) extending from the trochlea towards the clamp. By this means the surgeon could find a lost levator and free it from the surrounding tissues without jeopardizing the underlying superior rectus or the superior oblique tendon.

When repairing this kind of blepharoptosis, the surgeon must realize that the postoperative lift of the eyelid will be greater when the levator action is good than when it is poor. In other words, he must position the blepharoptotic eyelid on its cornea at operation so as to fully compensate for this postoperative lift.

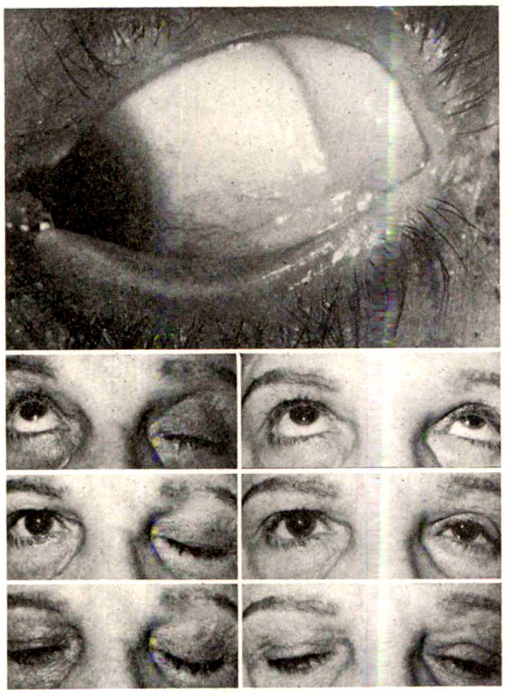

Fig. 5 (Berke). Traumatic blepharoptosis caused by excision of dermolipoma. Top: Position of tumor before excision. Left: Blepharoptosis after excision of tumor. Right: Two months after external levator resection.

*After extraocular muscle operations*—Two patients developed 3-5 mm of blepharoptosis after a strabismus operation had severed the latter horn of the levator aponeurosis. Both blepharoptotic eyelids were corrected by advancing the severed aponeurosis to the upper tarsus by an external (Fig. 6) or by an internal approach (Fig 7).

Four other patients developed an uncompromising type of blepharoptosis after an operation on the superior oblique tendon. In each case, the superior rectus had been severed from the globe in a prolonged and extensive search for the superior oblique tendon. So much excessive manipulation of the epibulbar tissues caused dense postoperative adhesions between the globe and the trochlea, and also between the levator muscle and the superior rectus. Consequently, each patient developed a spurious type of levator function, in which the blepharoptotic eyelid was elevated from downgaze to upgaze more by the superior rectus muscle than by the levator muscle. In such cases, a levator resection operation was most difficult and unpredictable, not only because the adhesions bound the levator to the superior rectus muscle, but also because the adhesions reformed —even when such inert materials as Gelfoam, Gelfilm, silicone rubber, or Supramide Extra had been placed under the levator to prevent their reformation.

Figure 8 illustrates one of the better cosmetic results obtained in one such case after two external levator resections. The blepharoptosis was well corrected, but the patient had to keep her eyelids taped together during

sleep for months to prevent postoperative exposure keratitis.

Another patient had blepharoptosis and levator-to-globe adhesions after an operation on the superior oblique tendon. She had a fascia lata frontalis operation with an outcome (Fig. 9) even worse than that shown in Figure 8

### Blepharoptosis caused by nonsurgical trauma

Nonsurgical trauma caused blepharoptosis in 11 patients. Ten experienced upper eyelid trauma, and in one, the blepharoptosis resulted from a self-inflicted bullet wound to the orbit. When these patients were examined months or even years after the initial trauma, the degree of blepharoptosis varied from 2 to 7 mm and the levator function from 3-10 mm.

In nine of the 11 patients the levator tissues had been severed above the tarsus. Some of these had obvious scars *only* on the underside of the lid—an observation completely missed by the examiner at the time of the initial repair. Another patient, whose blepharoptosis occurred after a blunt football injury, had no visible scars whatever on either surface. These observations indicate that we must examine both sides of the upper eyelid when repairing face lacerations.

An external approach was employed in eight of these 11 patients to find the retracted end of the severed levator tissues. After exposing the epibulbar tissues and rotating the globe downward, a thin layer of scar tissue or an intact medial or lateral horn usually guided the surgeon to the retracted end of the severed levator. But when the levator had retracted into the thick epibulbar tissues, it had to be retrieved by pulling the epibulbar tissues forward on a blepharoptosis

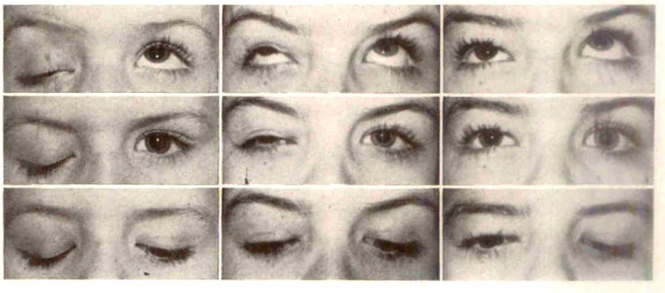

Fig. 9 (Berke). Traumatic blepharoptosis caused by resection of right superior oblique tendon. Left: Before Berke-Motais operation. Center: Before Crawford operation. Right: One year later.

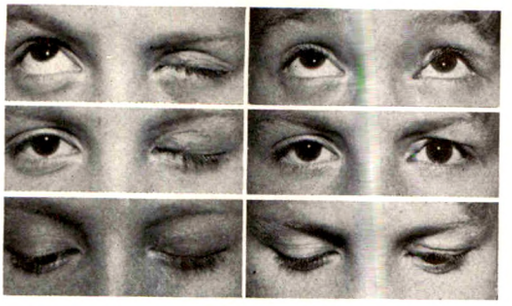

Fig. 10 (Berke). Traumatic blepharoptosis due to eyelid laceration by sled runner. Left: Two months after accident. Right: Six months after external levator resection. Note overcorrection.

clamp as previously described. By this maneuver, the surgeon could find the lost levator and reattach it to the tarsus.

Since the surgeon could rarely identify the exact end of the levator muscle, especially when it was imbedded in the epibulbar tissues, he had to decide whether to shorten the levator and risk final overcorrection (Fig. 10), or to merely advance it to the tarsus and chance getting final undercorrection (Fig. 11). Consequently, two of these nine patients required a subsequent levator resection (including patient shown in Fig. 11), while others needed a levator recession operation before a satisfactory outcome could be achieved. Until reliable guidelines become available, it seems wise to err on the side of overcorrection rather than undercorrection. The most important thing is to find the levator, and then aim for overcorrection, since receding the levator is less difficult than resecting the muscle for undercorrection.

The 11th case was a 53-year-old man who had 6 mm of blepharoptosis after a bullet injury to the right orbit. Examination years later disclosed 7 mm of levator function, a blind right eye, 30 prism diopters of right hypotropia, an atypical von Graefe sign, and corneal anesthesia.

Even after he had been alerted to the danger of postoperative keratitis, this patient was eager to have the blepharoptosis repaired because it was a source of embarrassment to him at his job.

At operation the right inferior rectus was receded for the hypotropia, and the levator was resected for the blepharoptosis. Two weeks later both appeared well corrected, and the cornea was clear. But in the ensuing weeks an intractable neuroparalytic keratitis developed, despite local treatment and intermarginal adhesions. At the patient's suggestion the eye was enucleated three months after the blepharoptosis operation. With a prosthesis in place, the blepharoptosis was fairly well corrected, but the final outcome was unsatisfactory (Fig. 12).

In retrospect, I believe this patient would have had a better result if a thick Gunderson flap had been turned down over the cornea[10] and a thin custom-made cosmetic shell fitted over the flap.

The final results of these 40 operations were appraised from one month (three cases) to 78 months (one case) after operation, the average being 19 months.

## Discussion

An internal approach to the levator yielded a good result only when the levator

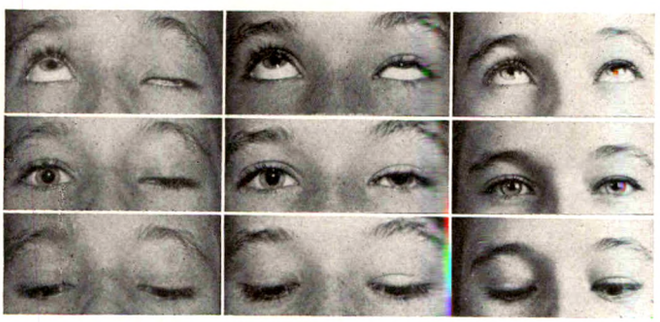

Fig. 11 (Berke). Traumatic blepharoptosis due to subconjunctival laceration of upper eyelid by golfer's putter. Left: After accident. Center: Undercorrection 10 months after external levator resection. Right: Six months after second external resection.

Fig. 12 (Berke). Traumatic blepharoptosis caused by bullet injury to right retrobulbar tissues. Left: Before external levator resection. Center: Corneal ulceration three months later. Right: Six months after enucleation.

function was more than 5 mm from downgaze to upgaze and the levator muscle was intact. An external approach usually gave better results when the levator function was less than 5 mm, or when the levator tissues had been severed above the tarsus. It was the operation of choice when the levator function measured 3 mm or more from downgaze to upgaze. This was so mainly because the external approach gave better exposure of the epibulbar tissues.

Since reliable guidelines for the correction of such cases were unavailable, 20 of the 26 external operations were analyzed to evolve a provisional formula for avoiding gross amounts of postoperative overcorrection and undercorrection by this procedure. Only two of these 20 blepharoptotic eyelids "fell" postoperatively. (An eyelid was said to have fallen when it covered more cornea postoperatively than it did at the end of operation. A postoperative "lift" occurred when the eyelid covered less cornea postoperatively than at the end of operation. Since the other 18 eyelids registered a greater postoperative "lift" when the levator function was good than when it was poor, the proposed guidelines were based on these observations.

These guidelines showed that the surgeon must position the blepharoptotic eyelid at operation so as to compensate for a greater postoperative lift when the preoperative levator function is 8 mm or more than when it is 5 mm or less. For example, if the normal eyelid covered its cornea 2 mm in the primary position (called the target area), and if the levator function indicated a postoperative lift of 4 mm, then the blepharoptotic eyelid should be raised at operation to cover its cornea 5 mm (3 mm below the target area) in order to offset a postoperative lift of 4 mm which would result in 1 mm of overcorrection.

Unfortunately, the 20 cases analyzed failed to provide enough data on which to calculate the amount of lift for each degree

TABLE 4

GUIDELINES FOR CORRECTION OF TRAUMATIC BLEPHAROPTOSIS BY EXTERNAL APPROACH

| Levator Function | Target Area* | Eyelid Position† at Operation | Postoperative Lift of Eyelid | Amount of Overcorrection |
|---|---|---|---|---|
| 3–4 mm | −2 mm | −2 mm | 1 mm | 1 mm |
| 5–6 mm | −2 mm | −3 mm | 2 mm | 1 mm |
| 7–8 mm | −2 mm | −4 mm | 3 mm | 1 mm |
| 9–10 mm | −2 mm | −5 mm | 4 mm | 1 mm |
| 11–12 mm | −2 mm | −6 mm | 5 mm | 1 mm |

* Target area is the position of normal eyelid below the upper limbus in primary position.

† Position of blepharoptotic eyelid below the upper limbus at the end of operation with cornea in primary position.

of levator function. Therefore, the guidelines in Table 4 are based upon extrapolations and can serve only as gross approximations for preventing large amounts of over- or undercorrection when an external approach is used. Table 4 may save the surgeon much guesswork when using an external approach for this type of blepharoptosis. These data are useful only when the levator and the orbicularis muscles are relaxed under deep surgical anesthesia. Moreover, they are designed to give over- rather than undercorrection for the reasons already mentioned.

## Summary

The surgical results in 40 patients with traumatic blepharoptosis were examined to ascertain which type of operation gave the best results. An external (skin) approach gave better exposure and yielded better results than an internal (conjunctival) approach for retrieving a retracted levator severed in the eyelid. These operations, however, were useless when the levator muscle was paralyzed. In such cases the blepharoptotic eyelid had to be suspended from the frontalis or from the superior rectus muscle with, however, a less satisfactory outcome.

A Crawford fascia lata operation is indicated for patients with unilateral traumatic blepharoptosis only when the levator muscle is paralyzed. The external approach is the procedure of choice for retrieving a severed levator muscle when the levator function is 3 mm or more from downgaze to upgaze. Gross amounts of over- or undercorrection can be avoided by this approach only when the surgeon positions the blepharoptotic eyelid on its cornea at operation so as to compensate for a greater postoperative lift of the eyelid when the levator function is good than when it is poor.

# EXOPHTHALMOS AND POSTERIOR FRONTOCELE WITH FIBROUS WALL ON ORBITAL SIDE

ALY MORTADA, M.S.
*Cairo, Egypt*

Frontocele with exophthalmos is usually of the anterior type where there are the following characteristic signs: (1) The globe is pushed down and out. (2) There is a palpable mass below the upper, inner orbital margin. (3) In gigantic frontocele, there may be a bulging of the forehead.[1] (4) The diagnosis can be made clinically without difficulty by an otolaryngologist, especially by transillumination. (5) Characteristic changes are seen on x-ray examination of the skull: There is bone condensation around the mucocele,[2] affection of the superior orbital margin accompanied by opacity of the affected frontal sinus, and there may be a fluid level. There is usually a widening of the orbital cavity in very large frontoceles. Skull x-ray films after Lipidol injection of the affected sinus are impressive.

Exophthalmos that results from an early posteriorly placed fronocele usually does not show any of these characteristic signs when it is surrounded on the orbital side by fibrous tissue (the bone having been absorbed). In skull x-ray films, the absorbed bone is overshadowed by the surrounding orbital bones. A small palpable mass deep in the upper or upper-inner part of the orbit that is found to be pushing the globe slightly downward is not diagnostic.

Two cases of posteriorly placed frontocele with exophthalmos were found among 50 cases of radiographically and surgically proven frontoceles with exophthalmos. These are described here because the condition is very rare. If the mucocele is deep, not palpable externally, the proptosis is usually diagnosed as of uncertain etiology, and such cases may not receive proper treatment. The two cases described herein were not correctly diagnosed until orbital exploration.

## EXAMINATION AND FINDINGS

The first patient (Case 1) was a 40-year-old man with right proptosis, 21 mm in degree, of three years' duration (Fig. 1). The second patient was a 35-year-old woman whose proptosis was on the left side, 20 mm in degree, and was of four years' duration (Fig. 2).

In both cases, proptosis was unilateral and had progressed gradually over several years. There was no important family history and no history of trauma or past x-ray therapy. Neither patient showed signs of endocrine dysfunction, and there was no enlargement of the thyroid, liver, or spleen. Chest and abdominal examinations revealed no abnormality. There were no cafe-au-lait areas of

Fig. 1 (Mortada). Case 1. Right proptosis of three years' duration due to a surgically proved posterior frontocele.

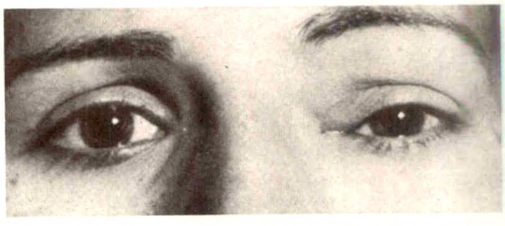

Fig. 2 (Mortada). Case 2. Left proptosis of four years' duration due to a surgically proved posterior frontocele.

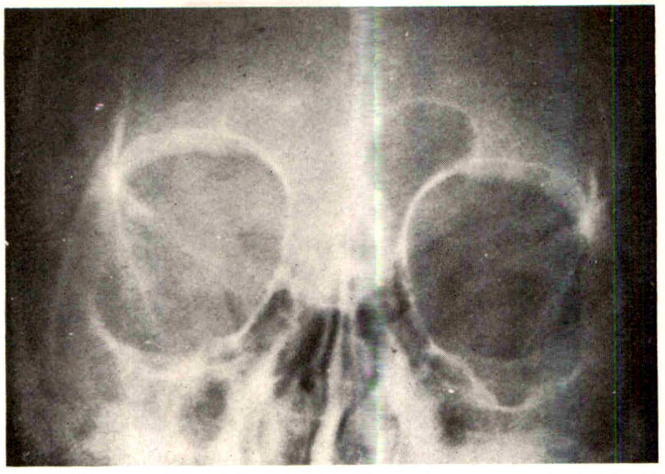

Fig. 3 (Mortada). Case 1. Postero-anterior skull x-ray taken with 20° tube tilt showing intact right superior orbital margin. The right frontal sinus is opaque, and the opacity is continuous with upper part of nasal cavity. There is no radiologic evidence for right orbital frontocele. The left frontal sinus is clear.

skin pigmentation, no nodules, no hemangiomas, no tumors.

Temperatures, pulse, blood pressure, urine, feces, blood total and differential counts, bleeding and clotting times were within normal limits. Tuberculin tests, the Wasserman, and the Casoni test for hydatid cyst all proved negative. Basal metabolic rate and $^{131}I$ uptake were within normal limits. All roentgenogram studies except those of the skull revealed bone structure to be normal.

The proptosis was neither intermittent nor pulsating, and neither case showed signs of an acute inflammatory process. In the first case, there was no palpable orbital mass; in the second, a small mass was palpable deep in the pper medial part of the orbit. In both patients, the unaffected eye was normal. In each, there was upward limitation of ocular movement, but the fundi and visual acuity (6/9) were not affected. Examination showed only an opaque frontal sinus on the affected side in each case.

Additional skull roentegographic studies were undertaken as follows to further examine the orbital bones and surrounding sinuses: occipital views for the frontal and maxillary sinuses; postero-anterior views (taken at a tilt of 20°) for frontal, maxillary, and anterior ethmoidal sinuses and nasal septum; two oblique views for posterior ethmoidal sinuses and optic canals; lateral views for the frontal, maxillary, and sphenoid sinuses; and views of the base of the skull for the ethmoid and sphenoid sinuses.

## Results

In the first case, the postero-anterior x-ray view of the skull shows an intact right superior orbital margin (Fig. 3). The right frontal sinus is opaque, and the opacity is continuous with the upper part of the nasal cavity. There is no definite radiologic evidence for a right orbital frontocele. The left frontal sinus is clear.

In the second case, the postero-anterior x-ray view of the skull shows an intact left superior orbital margin (Fig. 4). The left frontal sinus is opaque, but there is, again, no definite evidence for a left orbital frontocele. A dense linear sclerosed bone condensation is present in the middle of the left frontal sinus, perhaps representing the upper side of the mucocele.

*Surgical exploration*—In both cases, orbital exploration revealed a cyst of approximately 2 × 2 cm in the upper medial part of the orbit continuous with the frontal sinus. Each cyst contained a dark green, thick mucoid fluid with a few degenerated polymorphonuclear cells and no hairs. Histopathologically, these cysts were composed of fibrous tissue with mononuclear infiltration. The

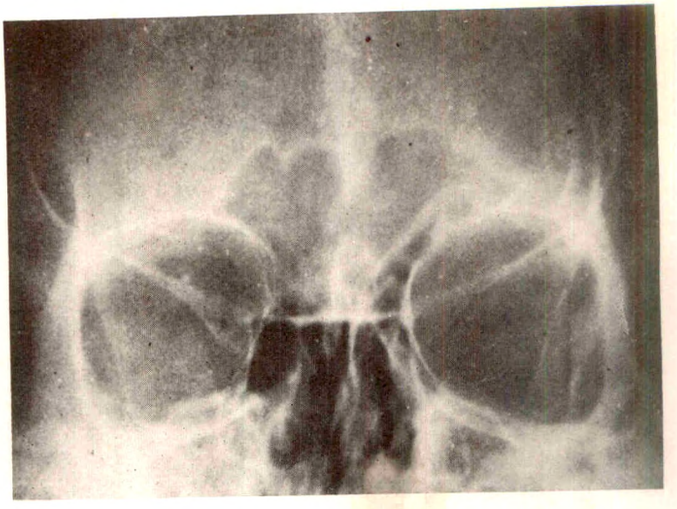

Fig. 4 (Mortada). Case 2. Postero-anterior skull x-ray taken with 20° tube tilt showing intact left superior orbital margin. The left frontal sinus is opaque. There is no definite radiologic evidence for left orbital frontocele. A dense linear sclerosed bone condensation is present in the middle of the left frontal sinus, perhaps representing the upper side of the mucocele.

walls were lined in some areas by columnar epithelium. There was no skin lining, no sebaceous glands, nor hair follicles. The diagnosis in each case was frontocele.

## Comment

The two frontal sinuses vary in size in different individuals. Occasionally, they extend backward into the roof of the orbital cavity as far as the optic foraminae. The potential extent of a frontal mucocele depends on the original size, extent, and pneumatization of the affected sinus. All or part of the sinus may be affected, and the size of the mucocele also depends upon the density of the boney wall of the sinus and how it reacts to the presence of infection and to the degree of pressure created by the fluid within the mucocele. The expanding mucocele may thus produce pressure atrophy, thinning, or sclerosis of the bony wall of the sinus,[3] with corresponding variations in the radiographic picture.

In an earlier paper,[4] I described 30 cases of frontocele with exophthalmos and classified these according to the status of the superior orbital margin as seen on skull roentgenograms. In cases in which the superior orbital margin is affected, there may be (1) complete affection by absorption, or by sclerosis and depression, or there may be (2) partial affection by depression. The depressed area may be thin and not visualized, it may be sclerosed, or it may be unchanged in density. The affected area may involve the inner one-third, the middle third, or the medial half of the margin. Mucoceles affecting only a part of the superior orbital margin are usually seen in a younger age group than those affecting the complete margin.[5]

In cases in which the superior orbital margin is not affected, this is due to the fact that the frontocele extends posteriorly. In such cases (1) the mucocele may be evident on skull roentgenograms, being surrounded by bone condensation, or (2) it may not be visualized, being surrounded by thinned or absorbed bone and thus overshadowed by the surrounding orbital bones. This was the case in the two patients described in this paper. If the mucocele is deep and there is no externally palpable mass, as in the first of the two cases presented herein, it is impossible to demonstrate clinically the cause of the proptosis.[6]

## Summary

In two patients with slowly increasing proptosis, posterior orbital frontocele proved to be causative on surgical exploration, but this cause could not be demonstrated preoperatively. In each case, the lesion was surrounded on the orbital side by fibrous tissue,

the bone having been absorbed, and thus these frontoceles could not be visualized on skull x-ray examination because they were overshadowed by the surrounding orbital bones. Since these cysts are deep and may not be palpable externally, as in the first of these two cases, the proptosis may be diagnosed as of uncertain etiology and proper treatment may not be instituted. Only orbital exploration, with histopathologic examination of the wall of the mucocele and the fluid it contains, are diagnostic.

## Ophthalmic miniature

"A devil of a man," said Robert Poussepain. "He shows himself; he's a hunchback. He walks; he's bowlegged. He looks at you; and he has only one eye. You speak to him; but he is deaf. Why, what does this Polyphemus do with his tongue?"

"He speaks when he wishes," said the old woman. "The ringing of the bells has made him deaf. But he's not dumb."

"So that is lacking to him?" observed Jehan.

"And he has one eye too many," added Robert Poussepain.

"Not so," said Jean judiciously. "A one-eyed man is much more incomplete than a blind man, for he knows what it is that's lacking."

# NEW APPROACH TO THE TREATMENT OF SELECTED RETINAL DETACHMENTS SECONDARY TO VITREOUS LOSS AT CATARACT SURGERY

EDWARD W. D. NORTON, M.D., AND ROBERT MACHEMER, M.D.
*Miami, Florida*

A typical retinal detachment may develop in some aphakic patients as a result of massive vitreous incarceration in the cataract wound. The lower half of the retina is elevated, often including the nonpigmented epithelium of the pars plana, and there may be inferior breaks. Vitreous extends from its attached base below to the cataract wound above (Fig. 1). This sheet of vitreous apparently shrinks gradually pulling the inferior retina into the pupillary area. The extent of the retinal detachment is determined by the location of associated retinal breaks.

When a single strand of vitreous extends up to the wound, this has sometimes been cut and a conventional buckling procedure successfully carried out, but a large sheet of vitreous pulling the retina to the wound above presents a much more difficult problem.[1,2] In the past, we have not attempted to cut the vitreous free from the wound. Rather, we have utilized a high segmental or encircling buckle to attempt to establish contact between the choroid and retina. In some successful cases the buckle has been high enough to obstruct the function of the posterior polar area.

With the introduction of an instrument to cut and remove vitreous, in situ, via the pars plana—the vitreous infusion suction cutter (VISC)[3]—it became apparent that a new approach to this type of complicated detachment would be to cut and remove the vitreous from the anterior segment. Vitreous traction is immediately relaxed and the retina falls back towards its normal position. A conventional buckling procedure may then be carried out.

This paper presents the results of this surgical technique in four eyes. A single case is reported in greater detail to better illustrate the problem and this method of its management.

## CASE REPORT

*Case* 1—A cataract extraction performed August 2, 1965, on the left eye of this patient was complicated by extensive vitreous loss and iris incarceration in the wound. On August 9, a disrupted wound was repaired. The patient was first seen at the Bascom Palmer Eye Institute on December 23, 1965. Best visual acuity was 20/25 in the right eye, 20/40 in the left. The inferior retina and the thin ciliary epithelium was elevated by a dense vitreous condensation extending from the vitreous base be-

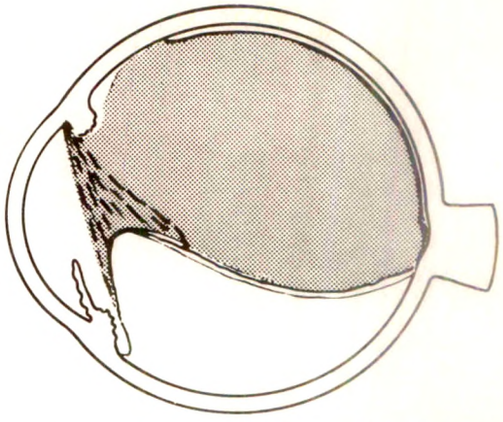

Fig. 1 (Norton and Machemer). Schematic drawing of an eye with vitreous incarceration into the cataract wound and secondary retinal detachment.

low to the cataract wound above. The ciliary epithelium was so thin that initially it was misinterpreted as a dialysis extending from three to 8:30 o'clock.

On December 27, a scleral buckling procedure was performed. Since it seemed impossible to reattach the retina and ciliary epithelium anterior to the equator, it was decided to place a buckle so that the retina would be attached in the region of the equator or slightly posterior to it. Therefore, a scleral undermining was done inferiorly from 2:30 to 10 o'clock. Diathermy applications and a silicone plate were placed in the undermined bed and a 360-degree band was used. Postoperatively, the retina was attached on and posterior to the buckle. Anteriorly, however, the retina remained elevated in the inferior half where there was extensive traction by the vitreous. On January 14, 1966, because of increasing elevation of the retina anterior to the buckle, photocoagulation was placed to the crest of the buckle. On January 31, it was evident that the detachment had extended across the buckle and the lower half was detached. The macula was still attached with a visual function of 20/70. No further surgery was planned, since it appeared impossible to release the vitreous traction.

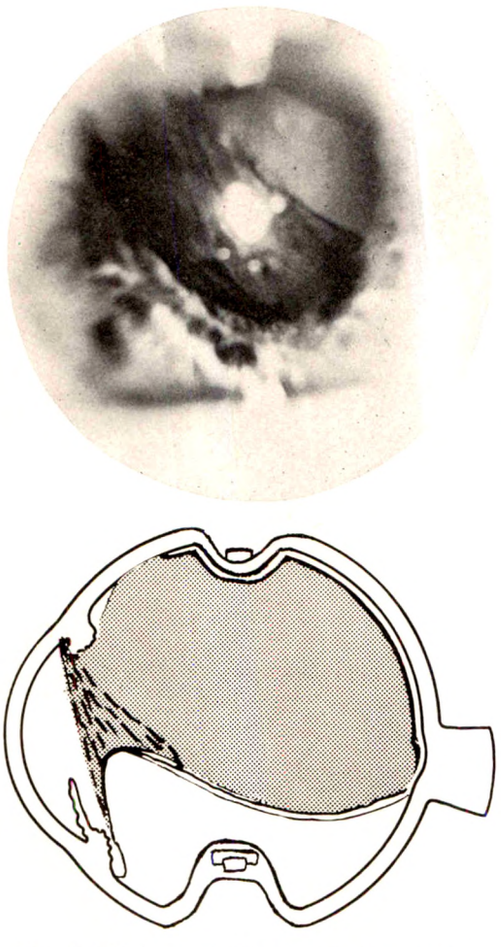

Fig. 2 (Norton and Machemer). Case 1. Top: Preoperative photograph. Vitreous is incarcerated in the cataract wound and pulls on the inferior pars plana and retina. Pars plana epithelium is visible in the pupillary area on retrograde illumination. Bottom: Schematic drawing of same eye showing encircling buckle from which the retina became loose because of further shrinkage of incarcerated vitreous.

During the subsequent four and one-half years, the patient was followed and noted to have a gradual increase in the elevation of the inferior retina with further shrinking of the vitreous membrane. Associated with this, visual function dropped to counting fingers at four feet. At this point it should be noted that the retinal ciliary epithelium was drawn up so that it was visible in the pupil (Fig. 2).

On October 19, 1970, the vitreous infusion suction cutter was introduced into the eye via the pars plana temporally. The vitreous membrane was cut out of the anterior chamber along with a moderate amount of the vitreous occupying the posterior chamber. This resulted in a prompt mobility and flattening of the detached retina and ciliary epithelium. The previously placed buckle was revised and retreated with cryotherapy without shortening the encircling element. Air was injected into the vitreous cavity. Except for a small fold in the macular region, the retina has remained attached postoperatively (Fig. 3). Best visual acuity is 15/400.

## Clinical experience

Four cases were treated in the manner outlined above. Beside the patient whose case is reported, one other had also had a previous unsuccessful primary buckling procedure. In both of these cases, failure resulted from the inability to produce firm chorioretinal adhesions because of the immobility of the highly elevated retina and progressive vitreous shrinkage. Following removal of vitreous, the retina became mobile and was reattached with an encircling buckle.

In the other two cases, vitreous surgery was undertaken as the primary procedure. In one, the retina became so mobile an attempt was made to reattach it by intraocular air tamponade[4] and cryotherapy, without a buckling element. The retina became detached again within three weeks from a small superotemporal dialysis even though it had been recognized and treated at the time of the original surgery. Reoperation with a

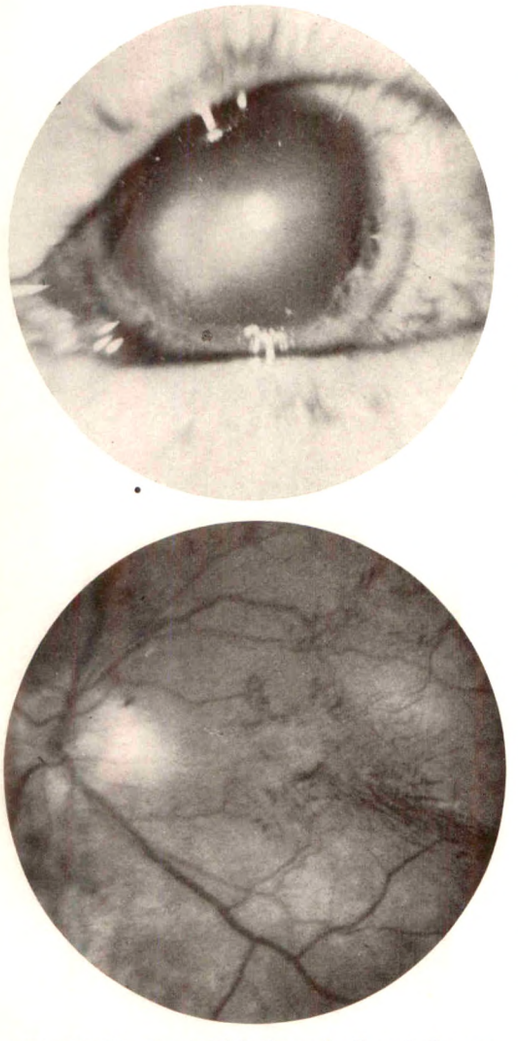

Fig. 3 (Norton and Machemer). Case 1. Postoperative photograph. Top: Retrograde illumination shows a red reflex from the pupil after vitrectomy. Bottom: Fundus photograph with retina attached.

360-degree buckle resulted in retinal reattachment. Because of this experience. the fourth case was treated initially by vitrectomy combined with a 360-degree buckle and cryotherapy. This resulted in immediate reattachment.

## Summary

Vitreous removal, utilizing the vitreous infusion suction cutter, combined with a scleral buckling procedure, was the method of management in four cases of retinal detachment associated with extensive vitreous incarceration in the cataract wound. Two of these patients had undergone previously unsuccessful primary buckling procedures. Failure in these two cases was due to the presence of extremely elevated and immobile retina and progressive vitreous shrinkage. This combination of circumstances prevented the achievement of firm chorioretinal adhesions. In the other two cases, vitreous surgery was undertaken as the primary procedure. Successful re-attachment was achieved in all four patients.

# TROPICAL AMBLYOPIA IN NIGERIANS

BENJAMIN O. OSUNTOKUN, M.R.C.P., AND OLABOPO OSUNTOKUN, M.B.
*Ibadan, Nigeria*

The syndrome of tropical nutritional neuropathy has been described in many parts of the tropics and in prisoners-of-war camps.[1–5] It is frequently referred to as tropical ataxic neuropathy because of the marked sensory ataxia demonstrated by patients with this syndrome. In parts of Nigeria, the prevalence of the disease among adults is as high as 14-26 per 1000.[6–8] It is a major cause of blindness in Nigeria, as amblyopia is usually a feature, and often the presenting sign of the disease. In 1952, Degazon[9] labeled the ophthalmologic deficit tropical amblyopia, a term indicating that the condition is predominantly a disorder of warm countries. Recently, a causal relationship was demonstrated between chronic cyanide intoxication of dietary origin and tropical nutritional neuropathy.[5,7,10]

In this paper, the ophthalmic findings in 360 Nigerians with this syndrome are reported in detail.

## MATERIAL AND METHODS

The subjects of this study are 360 Nigerian patients with tropical nutritional neuropathy, more often referred to as tropical ataxic neuropathy because of the marked sensory ataxia in these patients. In Nigerians, the syndrome is comprised of bilateral optic atrophy and sensorineural deafness, panmyelopathy, and peripheral neuropathy. The diagnosis is usually made when any two of these four components are present.[5] Of these patients, 132 were investigated in University College Hospital (UCH); the rest were seen and investigated during neurologic surveys of two villages, Epe and Ososa, situated in Southern Nigeria, an endemic focus of the disease.

Detailed clinical evaluation, and full neurologic and otologic assessment (including tuning fork tests, audiometry, and determination of threshold drift) were carried out.

Biochemical investigations were directed towards determining the nutritional status with regard to protein-calorie deficiency, mineral and vitamin nutrition, assessment of renal and hepatic function, and exclusion of diabetes mellitus. In order to assess chronic cyanide intoxication concentrations of cyanide and thiocyanate (the major detoxification product of cyanide) in the plasma, and thiocyanate in 24-hour urine, and serum $B_{12}$ levels were estimated as previously described.[5,11]

Cerebrospinal fluid was examined in hospitalized patients, and in a number of these patients, anterior tibial nerve biopsies were done and subjected to histologic examination, single nerve fiber preparation, and electron microscopy. Also, many patients were studied with electrocardiography, electromyography, and by determination of motor nerve conduction velocity. Urine was examined for albuminuria, porphobilinogen, and schistosoma ova. Estimation of plasma protein-bound iodine, $^{125}I$ tri-iodothyronine red blood cell uptake, Kay's augmented histamine test meal, tests to exclude malabsorption, examination of blood films stained to show malaria parasites, and serologic tests for syphilis (Kahn's test and Venereal Diseases Laboratory Research slide tests) were also done.

*Ophthalmic investigations*—Tests of visual acuity were carried out (Snellen). Central and peripheral visual fields were examined by the confrontation method. During field surveys, scotomas were easily demonstrated, when present, by confrontation, using 5 mm white and red test objects. Perimetry and examination by a 2 meter Bjerrum

screen (using white test objects of 2, 5, and 10 mm) were done in a third of the patients, mostly those who were hospitalized. Refraction was also carried out in the hospitalized group.

## Findings

In parts of Southern Nigeria where cassava forms the staple diet, there are well known foci where the disease is endemic, with males and females affected equally. The highest incidence is in the fourth and fifth decade (Table 1). All the patients gave a history of poor diet in which the staple food was cassava, eaten usually three times a day. Cassava (Mannihot) contains a cyanogenetic glycoside, linamarin, from which hydrocyanic acid is released on enzymatic or acid hydrolysis. The patients belonged to the poorer socioeconomic classes. In 41% of the patients, there was a history of another family member similarly affected. In 50% of familial cases, husbands and wives were affected. In 30 of the patients, a history was obtained of preceding febrile illness occurring one to eight weeks before the onset of symptoms. In 18 female patients, the illness began during the last two trimesters of pregnancy. In 13 other females, onset of symptoms coincided with lactation. Smoking of tobacco and drinking of alcoholic beverages were uncommon habits, occurring in moderation in about 10%, as these patients were poor.

Usually, patients presented at the hospital long after onset of their disease. None presented within four months of onset of symptoms. They finally sought treatment because of increasing ataxia of gait, weakness of legs, or worsening vision; 65% had had symptoms for more than three years before seeking medical care.

As far as ataxia and weakness were concerned, mode of onset was usually gradual. Impairment of vision, however, was sometimes sudden. A history of intermittency in severity of symptoms was obtained in 8%, with symptoms such as paresthesia being worse during the rainy season, pregnancy, lactation and febrile episodes. Two patients described complete remissions; this was confirmed in one, who was seen during remission. In the rest of the patients, the illness was progressive initially, subsequently becoming static.

TABLE 1

AGE AND SEX DISTRIBUTION IN 360 NIGERIAN PATIENTS WITH TROPICAL ATAXIC NEUROPATHY

| Age in Years | Males | Females | Total |
|---|---|---|---|
| 0–9 | 0 | 4 | 4 |
| 10–19 | 11 | 13 | 24 |
| 20–29 | 18 | 28 | 46 |
| 30–39 | 34 | 54 | 88 |
| 40–49 | 43 | 49 | 92 |
| 50–59 | 48 | 21 | 69 |
| 60–69 | 26 | 8 | 34 |
| 70 and over | 2 | 1 | 3 |
| Total | 182 | 178 | 360 |

The most common symptoms encountered in this study were various forms of paresthesia or dysesthesia, usually confined initially to the lower limbs (87%); impaired vision or blindness (80%); ataxic gait (50%); tinnitus and impaired hearing (45%); and weakness in lower limbs (33%). A third of the patients complained of recurrent stomatoglossitis.

Neurologic examination showed posterior column sensory loss (perception of vibration, joint position sense, and two-point discimination), usually in lower limbs. This was associated with sensory ataxia in 80%, and with bilateral perceptive deafness in 40%. It was associated with weakness and wasting of the distal musculature of the lower limbs, and occasionlly of the upper limbs, with glove and stocking sensory loss of superficial sensations (touch, pain, and temperation) in 25% of the patients. Tendon reflexes were commonly absent; they were exaggerated, however, in a few patients in whom hypertonia was present. Occasionally, signs of cerebellar degeneration and disease of the basal ganglia were present. Details of

the clinical picture have been presented elsewhere.[5,7]

In 80 per cent of the patients, ophthalmologic examination showed abnormalities.

*Ophthalmic symptoms*—Early visual symptoms consisted of blurring of vision and loss of details at a distance; familiar faces were not recognizable unless they were very near, and students complained of inability to see the writing on the blackboard. Four patients complained especially of night blindness. In 18 patients all under 30 years of age, blurring of vision was the initial symptom, antedating other symptoms by intervals varying from one month to five years.

Although impairment of vision was usually gradual, a history of sudden onset of blurring of vision was obtained in six patients, five females and one male, all under 30 years of age. In four of them, sudden onset of blurring of vision was preceded by paresthesia in the lower limbs for periods of one, three, four, and seven years. In two other patients, sudden visual impairment occurred early in the morning and was followed by paresthesia in lower limbs one and three months later, respectively. In three of these six patients, transient diplopia and vertigo accompanied the sudden onset of blurred vision, but they were not seen by us during the acute stage. All the patients subsequently developed other symptoms of the disease such as tinnitus and deafness. Only one of these patients was seen before several years had elapsed, and presumably they had episodes of retrobulbar neuritis. The only patient who was seen a week after the sudden onset of blurring of vision was a girl, aged 16 years. She showed evidence of retrobulbar neuritis, with pain in the eyes that was made worse by movement of the eyeballs, severe impairment of visual acuity (less than 6/60 in each eye), slightly dilated pupils with sluggish light reflex, large bilateral paracentral scotomas (easily demonstrable on confrontation and further confirmed by examination on a Bjerrum screen), and pink suffused optic disks with slightly blurred margins on ophthalmoscopy. There was no other neurologic deficit. Six months after onset of visual symptoms, examination of her fundi showed bilateral optic atrophy. In addition, there was evidence of severe bilateral nerve deafness, myelopathy with predominant involvement of the posterior columns, and motor polyneuropathy.

*Ocular findings*—Loss of visual acuity was symmetrical in all but six patients. Among those whose loss was the same bilaterally, nine patients (2.5%) were virtually blind with almost no perception of light. In 130 (36%), visual acuity in both eyes was less than 6/60 and vision was reduced to counting fingers at 18 inches. In 82 patients visual acuity in both eyes was 6/36, and another 58 it was 6/18. In six patients, loss of visual acuity was 6/18 in one eye and 6/60 in the other (with ophthalmoscopic evidence of retrobulbar neuritis in one eye and early optic atrophy in the other). In the patients who were virtually blind and in those with pale white disks, the pupils were large and did not react to light stimulus.

Marked bilateral temporal pallor of the optic disk (Fig. 1) was found in 148 (41.1%). In 22 of these patients, there was

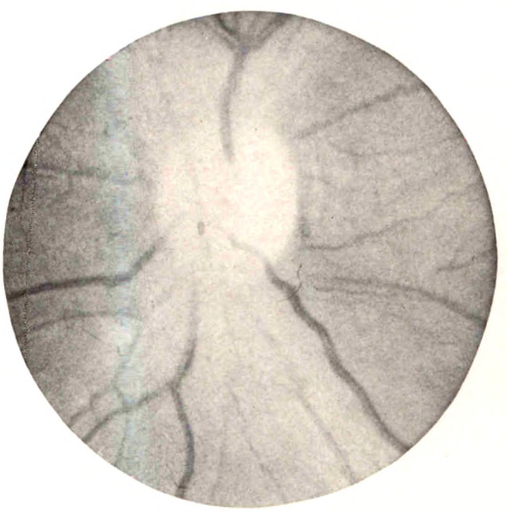

Fig. 1 (Osuntokun and Osuntokun). Temporal pallor (early optic atrophy) in tropical amblyopia in Nigerians.

no history of visual symptoms, but reduction in visual acuity was present. In six patients who had had visual symptoms, bilateral temporal pallor of the optic disk was present, but visual acuity was normal. In the advanced cases the disks were pale white, and atrophic or small, with clear well-defined margins; the retinal arteries appeared attenuated (Fig. 2). This advanced optic atrophy was found in 147 (41%) of patients. Widespread choroidoretinitis with diffuse punctate or patchy pigmentation was observed in both fundi in 12 (3.3%) patients. In 14 (3.8%) patients who complained of blurring of vision, and who showed demonstrable loss in visual acuity, the fundi were surprisingly normal.

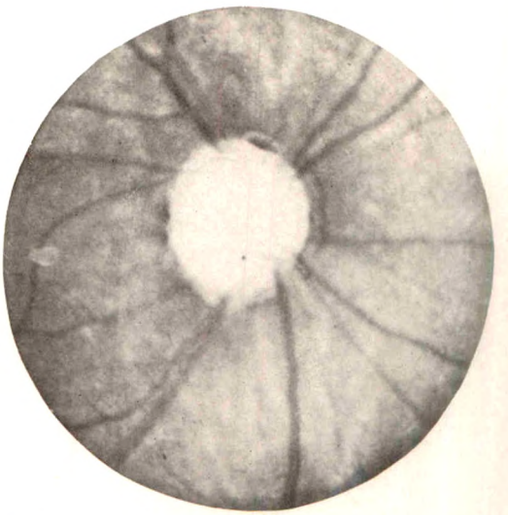

Fig. 2 (Osuntokun and Osuntokun). Advanced optic atrophy in tropical amblyopia in Nigerians.

Concentric diminution of the visual fields (Fig. 3) was the commonest finding and was present in 99 (84%) of the 118 patients in whom the visual fields were examined by perimetry. This presumably progressed to tubular vision (Fig. 4). Central or paracentral scotomas were found in only 16 patients.

*Other findings*—The results of the biochemical, electrophysiologic, and histologic investigations have been presented in detail elsewhere.[5,7,12,13]

There was no biochemical evidence of protein-calorie deficiency. Apart from diminished urinary excretion of riboflavin, the biochemical evidence available suggests that the intake of thiamine, nicotinic acid, and folic acid was adequate.

Cerebrospinal fluid showed no abnormality. Histologic examination of peripheral nerves showed segmental demyelination. Reduced motor nerve conduction velocity was found even in patients who had no clinical evidence of polyneuropathy.

There was biochemical evidence of increased exposure to cyanide in the patients.

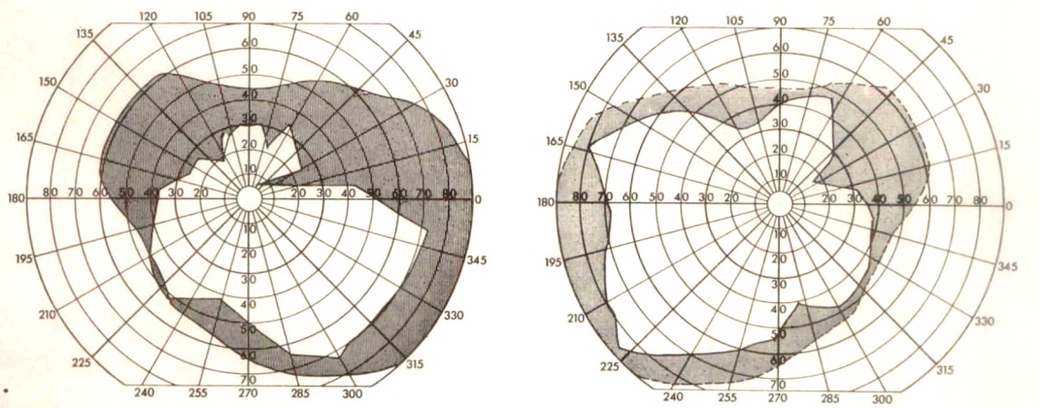

Fig. 3 (Osuntokun and Osuntokun). Example of constriction of peripheral visual fields in tropical amblyopia in Nigerians. Left: Right eye. Visual acuity 6/9. Right: Left eye of same patient. Visual acuity 6/18.

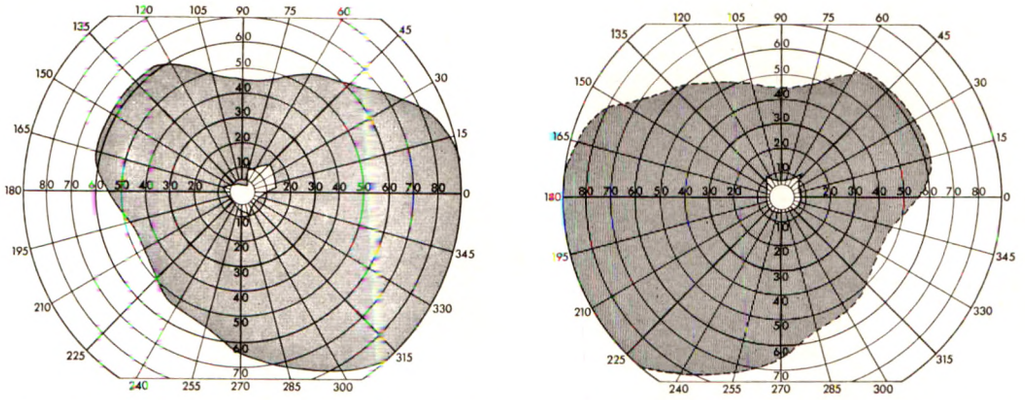

Fig. 4 (Osuntokun and Osuntokun). Example of tubular field in tropical amblyopia in Nigerians. Left: Right eye. Visual acuity 6/60. Right: Leyt eye of same patient. Visual acuity 6/60.

The plasma thiocyanate, cyanide, and urinary excretion of thiocyanate were raised (Table 2). These levels fell (Table 3) and this was accompanied by clinical or symptomatic improvement when patients were fed a hospital diet which contained cassava meals only twice a week. The levels rose again when the patients returned to a cassava diet (Table 4).

There were qualitative changes in the serum $B_{12}$ components which suggested increased exposure to cyanide,[5,7,8] for vitamin

TABLE 3

FALL IN PLASMA THIOCYANATE AND CYANIDE AND URINARY THIOCYANATE IN 67 PATIENTS WITH TROPICAL AMBLYOPIA AFTER SIX WEEKS ON HOSPITAL DIET*

| | On Admission | After Six Weeks of Hospital Diet |
|---|---|---|
| Plasma thiocyanate*† | 11.1+0.4 | 2.8 +0.1 |
| Plasma cyanide*† | 0.09+0.004 | 0.03+0.001 |
| Urinary thiocyanate*‡ | 2.4+0.1 | 0.7+0.03 |

* The differences between the concentration on admission and after six weeks on hospital diet are statistically significant ($p<0.001$ for each variant).

† In micromoles/100 ml (mean plus standard error).

‡ In micromoles/kg/24 hours (mean plus standard error).

$B_{12}$ is involved in the detoxication of cyanide.[14-23] The concentration of serum hydroxocobalamin (which probably adsorbs cyanide, and is thereby converted to cyanocobalamin) was reduced in patients. The concentration of cyanocobalamin was raised.

In the plasma of patients, there was an absence or a reduced level of the sulphur-containing amino acids (cysteine, cystein, and methionine)[12]—these are the main donors of thiol groups which combine with cyanide to form thiocyanate, and cystine itself reacts spontaneously with cyanide.[24-28]

TABLE 4

PLASMA THIOCYANATE AND CYANIDE IN 35 PATIENTS WITH TROPICAL AMBLYOPIA ON ADMISSION, SIX WEEKS AFTER ADMISSION (ON HOSPITAL DIET), AND 12 WEEKS AFTER DISCHARGE AND REVERSION TO CASSAVA MEALS

| | Plasma Thiocyanate* | Plasma Cyanide* |
|---|---|---|
| Within 48 hours of admission | 11.9+0.8 | 0.1 +0.006 |
| Six weeks hospitalization and on hospital diet | 2.8+0.3† | 0.025+0.002† |
| Twelve weeks after discharge and return to cassava meals | 12.8+0.9 | 0.11 +0.07 |

* In micromoles/100 ml (mean plus standard error).

† The difference between this figure and the one above it and below it is significant at the $p < 0.0001$ levej. The differences between determinations made upon admission and six weeks after discharge are not significant.

Concentrations of serum calcium, phosphate, sodium, chloride, bicarbonate, and potassium and tests of throid, liver, and renal function were normal. Amino acids and porphobilinogen were absent in the urine. Occasionally schistosoma ova were found in urine of young people. There was no malabsorption. Glucose tolerance tests were not significantly abnormal. Histamine-fast achlorhydria was rare.

Serologic tests for syphilis, typhoid, and typhus gave usually normal results. There was no increased prevalence of infections with malaria in patients.

Electrocardiographic examination usually showed normal results, although sinus tachycardia and nonspecific T-wave changes were occasionally encountered.

## DISCUSSION

The ophthalmic findings in Nigerian tropical ataxic neuropathy are interesting in that the commonest visual field loss was peripheral constriction, although this was often asymmetrical and bizarre. Paracentral and central scotomas were less frequently demonstrable. However, undoubtedly classical retrobulbar neuritis can occur in the Nigerian tropical ataxic neuropathy. In such cases, constriction of peripheral visual fields is not found but paracentral scotoma is easily demonstrable. It is speculative to suggest that the high frequency of contriction of peripheral visual field is due to a higher susceptibility to damage (by a diffusible toxin such as cyanide) of the peripheral receptors in the retina, which are unprotected by an overlying layer of nerve fibers. It has been suggested that cyanocobalamin may act as a "Trojan horse" in the visual system, as cyanide released from this compound by photolysis or electromagnetic waves in the visual spectrum may then accumulate in the vitreous and damage the retinal receptors and especially the macula.[29,30] It is also possible that cyanide may be present in relatively high concentration in the vitreous because of secretion by the ciliary epithelium or because of an affinity of cyanide for an ion such as potassium present in the vitreous.[29] The severe loss of visual acuity frequently encountered in this disease may also be explained by damage to the macula which is also relatively unprotected. Damage to the papillomacular bundle may explain the frequency of temporal pallor in this disease Progressive and continuous damage leads to complete optic atrophy. Combination of damage to papillomacular bundle and the peripheral retinal receptors may be expected to occur.

Demyelination occurs in the peripheral nerves in Nigerian tropical ataxic neuropathy[7,13] and probably also in other parts of the nervous system—especially the optic and auditory nerves and the spinal cord. Demyelination in optic nerves will explain the occasional finding of retrobulbar neuritis in the Nigerian patients. Chronic cyanide intoxication in experimental animals can produce demyelination.[7,13,19,31,32]

The ophthalmic findings in Leber's hereditary optic atrophy, subacute combined degeneration with optic atrophy, and tobacco

amblyopia, although vaguely similar in some respects, are in many ways different from those found in Nigerian ataxic neuropathy. It is worth recalling that there is some evidence suggesting that the visual impairment in these diseases is due to chronic cyanide intoxication.[11,33-35] However, ophthalmic findings similar to those described in the Nigerians with ataxic neuropathy have been described in tropical amblyopia in Jamaicans,[9] and in Jamaican neuropathy,[36] of which the former is probably a fragmentary form. Jamaican neuropathy is in many ways similar to the Nigerian ataxic neuropathy, although there are some subtle differences.[37] Recently,[29] bizarre and atypical visual field defects were described in Jamaican amblyopia, and although they were mostly unlike those described in tobacco amblyopia, in some cases there was some similarity. McKenzie and Phillip[29] (1968) state that there is no clear line dividing tobacco amblyopia from Jamaican amblyopia and nutritional amblyopia. The common factor may be chronic cyanide intoxication.

The evidence available at present does not suggest that the Nigerian ataxic neuropathy is related to disseminated sclerosis and neuromyelitis optica.[5] The former is virtually unkown in Nigerians; the latter, although quite frequently seen among Nigerians, is remarkably different in its clinical manifestations, presenting usually as acute retrobulbar neuritis preceding or following acute transverse myelitis.

Other causes of retrobulbar neuritis or optic atrophy associated with lesions elsewhere in the neuraxis were excluded in the Nigerians by the appropriate investigations. The list of possibilities is extensive and includes juvenile-onset diabetes with optic atrophy, acanthocytosis, Refsum's disease, Leber's hereditary optic atrophy, neurosyphilis, para-infectious encephalomyelitis, the heredofamilial spinocerebellar ataxais, peroneal musclar atrophy, familial opticoacoustic nerve degeneration and polyneuropathy,[38] and oculo-otocerebro-renal syndrome.[39]

Deficiency of thiamine, nicotinic acid, and riboflavin may produce the same abnormal biochemical end result in oxidative metabolism and in transfer or electron to molecular oxygen, as cyanide-induced inhibition of cytochrome oxidase, and hence may produce a similar neurologic picture. However, on clinical and biochemical evidence in the Nigerian patients with tropical ataxic neuropathy there is no deficiency of thiamine and nicotinic acid. Riboflavin deficiency, though it exists* in the Nigerian patients,[40] is so far not recognized nor has it been proved clinically or experimentally as a cause of polyneuropathy, myelopathy, and deafness,[41] although it may cause retrobulbar neuritis. Pernicious anemia is virtually unknown in the Nigerians,[42] and although there may be cyanide-conditioned deficiency of physiologically active vitamin $B_{12}$ in the Nigerian patients, this has no association with absence of an intrinsic factor.

The ophthalmic findings in Nigerian tropical amblyopia or tropical ataxic syndrome are consistent with the hypothesis that the major factor is a toxin. This toxin appears to be cyanide.

## Summary

In Nigerians, tropical amblyopia is a major component of a syndrome of tropical ataxic neuropathy which comprises bilateral optic atrophy, sensorineural deafness, myelopathy, and polyneuropathy. In a series of 360 Nigerian patients with this disease, more than 80% had visual signs and symptoms. In 18 patients, visual symptoms antedated other manifestations of the disease.

Severe impairment of visual acuity, sometimes progressing to complete blindness, bilateral temporal pallor, and complete optic atrophy were common findings. The commonest visual field loss was peripheral constriction (in 84%). Central or paracentral scotomas were uncommon. These suggest that retrobulbar neuritis was uncommon and

* New evidence confirms deficiency of riboflavin as determined by measurement of serum riboflavin.

that relatively unprotected retinal receptors in the periphery and the macula were damaged by a diffusible toxin. In the Nigerians, such a toxin is probably cyanide of dietary origin (from cassava meals).

ACKNOWLEDGMENT

We thank Mrs. C. A. Piper for secretarial assistance and the Medical Illustration Unit, University of Ibadan, for the figures. Dr. Ian Brockington kindly allowed us to use his retina camera to photograph the fundi.

OPHTHALMIC MINIATURE

Sherlock Holmes welcomed her with the easy courtesy for which he was remarkable, and, having closed the door and bowed her into an armchair, he looked her over in the minute and yet abstracted fashion which was peculiar to him.

"Do you not find," he said, "that with your short sight it is a little trying to do so much typewriting?"

"I did at first," she answered, "but now I know where the letters are without looking." Then, suddenly realizing the full purport of his words, she gave a violent start and looked up, with fear and astonishment upon her broad, good-humoured face. "You've heard about me, Mr. Holmes," she cried, "else how could you know all that?". . . .

Sherlock Holmes clapped his hands softly together and chuckled.

"'Pon my word, Watson . . . . As you observe, this woman had plush upon her sleeves, which is a most useful material for showing traces. The double line a little above the wrist, where the typewritist presses against the table, was beautifully defined. The sewing-machine, of the hand type, leaves a similar mark, but only on the left arm, and on the side of it farthest from the thumb, instead of being right across the broadest part, as this was. I then glanced at her face, and, observing the dint of a pince-nez at either side of her nose, I ventured a remark upon short sight and typewriting, which seemed to surprise her."

# HYPERPLASTIC PERSISTENT PUPILLARY MEMBRANE

S. MERIN, M.D., J. S. CRAWFORD, M.D., AND J. CARDARELLI, M.D.
*Toronto, Ontario, Canada*

A thick, persistent pupillary membrane covering the whole or most of the pupil is uncommon as a congenital anomaly. Most cases are sporadic. One author reports a pair of twins who were both affected.[1] This anomaly was transmitted by the autosomal dominant mode in three families.[2-4] In all of these the anomaly was associated with other ocular abnormalities such as cataract,[2-4] microcornea,[3] megalocornea,[4] nystagmus, either in the same individual or members of his family.

We describe a fourth family whose members have the same congenital anomaly (Fig. 1), but unassociated with any other ocular abnormality, except in one instance where the proband also had high myopia.

## CASE REPORT

The proband, a seven-year-old girl, was sent to our Eye Clinic by a school nurse because of poor vision in both eyes. The examination revealed severe myopia. Her corrected vision (—8.00 sph. in each eye) was 20/30 in the right eye and 20/60 in the left eye. There was an intermittent exotropia of 10 degrees. The pupils of both eyes were covered by a thick, raised, and slightly pigmented membrane (Fig. 2). The membrane consisted of a central area, about 4 mm in diameter and multiple peripheral strands, connecting this area to the collarette (Figs. 3 and 4). The lens itself appeared normal. The fundus viewed with the strong light of the indirect ophthalmoscope was normal.

### DESCRIPTION OF FAMILY MEMBERS

The proband's eldest sister had similar membranes covering the pupils of both eyes. Her best corrected vision was 20/80 in the right eye (correction: +1.75 sph.⊃+4.00 cyl. ax. 90°) and 20/30 in the left eye (correction: +1.00 sp.⊃+2.00 cyl. ax. 90°). She had an alternating exotropia of —10 degrees with a left hypertropia of two degrees. The lens and fundus were normal. At the age of eight years a sector iridectomy was performed on the right eye at the 12 o'clock position. Immediately the membrane shrank, leaving a wide open pupil (Fig. 5). Visual acuity was not improved by the operation. A postoperative iritis caused synechiae between the membrane and the lens.

The proband's three-year-old brother had similar pupillary membranes in both eyes. The visual acuity could not be measured, but no other ocular abnormalities were seen.

The mother, too, had similar pupillary membranes. Her visual acuity was 20/80 in the right eye, 20/30 in the left eye. All other members of the family examined including a maternal grandparent of the proband were normal.

## DISCUSSION

The four affected members of the family suffered from a condition called sometimes persistent pupillary membrane, or hyperplasia of the anterior layer of the iris stroma,[5] or hyperplasia of the iris.[6] The pupillary membrane, which normally exists during the third to the sixth month of fetal life is much thinner than that seen in this condition. Since there is no assurance that the condition is hyperplasia of the whole anterior layer of the iris, we suggest the term hyperplastic persistent pupillary membrane to distinguish it from "ordinary" persistent membrane which, though common, rarely has a familial inheritance.[7,8]

The thickness of the membranes and their

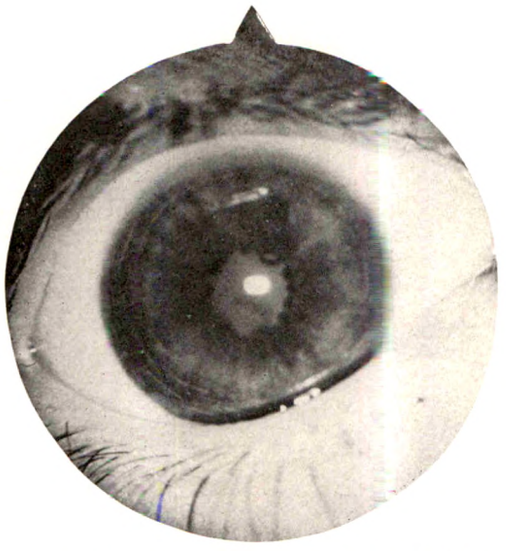

Fig. 2 (Merin, Crawford, and Cardarelli). Right eye of proband showing thick membrane covering almost the whole undilated pupil. The left eye was similar.

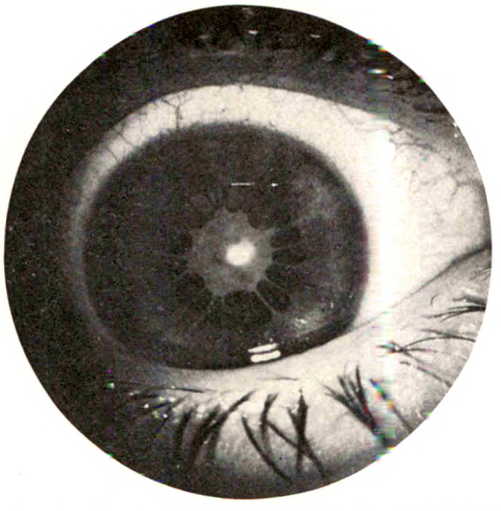

Fig. 3 (Merin, Crawford, and Cardarelli). Right eye of proband under maximum mydriasis.

opacity were striking, though visual acuity was remarkably good, ranging from 20/30 in the best eye to 20/80 in the worst.

Our one attempt to improve visual acuity by iridectomy failed. The results of a similar operation reported by Levy[9] are difficult to compare since preoperative visual acuity was unaided. Postoperative corrected visual acuity was 20/30 and 20/60, similar to that of our patients. Probably the condition should not be treated surgically except in very young children, before amblyopia develops.

The pedigree in our family points to an autosomal dominant mode of transmission of this anomaly, starting as a new mutation in the mother. Contrary to the other reported

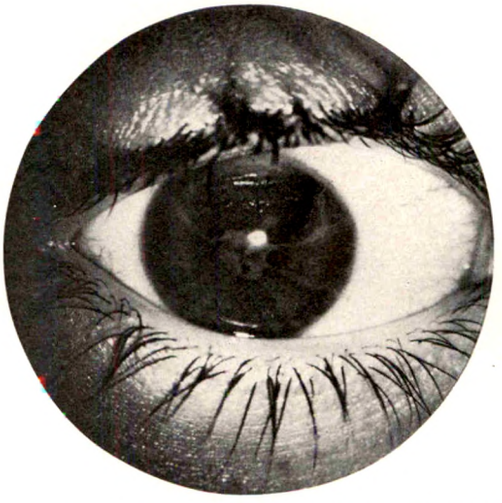

Fig. 5 (Merin, Crawford, and Cardarelli). Right eye of proband's eldest sister, showing optic iridectomy and shrunken membrane. Operation did not improve visual acuity.

families,[2-4] the anomaly in our family is isolated and not connected with corneal or lenticular abnormalities.

## Summary

A family is described with four members suffering from a condition termed as hyperplastic persistent pupillary membrane. This is the fourth description of a family with this condition. In all four the heredity was of the autosomal dominant mode. This is the first family reported without associated corneal or lenticular lesions.

# PIGMENTARY RETINOPATHY OF MYOTONIC DYSTROPHY

MICHAEL G. BETTEN, M.D., DONALD C. BILCHIK, M.D., AND MORTON E. SMITH, M.D.
*St. Louis, Missouri*

The common ocular findings in myotonic dystrophy include lenticular changes, blepharoptosis, extraocular muscle abnormalities, hypotony, and abnormalities of dark adaptation and the electroretinogram. Less frequently, pigmentary anomalies of the macula and peripheral retina are seen.[1-4] Histopathologic examination of the retina has been limited to investigations of specimens from six autopsies,[5-9] three of which demonstrated retinal pigmentary abnormality.[5,6] This paper presents the histopathologic findings in the retina of a patient with myotonic dystrophy and raises questions concerning possible pathogenetic mechanisms.

## CASE REPORT

A 44-year-old white woman was hospitalized at the Washington University Medical Center because of a left intraocular tumor. The patient had myotonic dystrophy for 20 years. She had taken a total of approximately 4700 g of quinine to the present time, but had none of the known toxic manifestations.

Examination revealed a best corrected visual acuity of 20/30 in the right eye and 20/70+1 in the left eye. There were multicolored posterior subcapsular opacities and normal intraocular pressures in both eyes. Both maculas showed pigmentary streaking. The fundi contained many clumps of pigment throughout the entire periphery. The pigment was not located adjacent to vessels nor did it resemble bone corpuscles. There was a large nonpigmented mass located in the inferior temporal quadrant of the left eye with an exudative retinal detachment inferiorly. Laboratory studies, including a VDRL, were normal. A diagnosis of malignant melanoma was made and the left eye was enucleated.

### HISTOPATHOLOGY

*Gross*—The specimen consists of a firm left eye measuring 22 × 22 × 24 mm with 6 mm of optic nerve attached. Transillumination reveals a poorly defined shadow at the insertion of the inferior oblique muscle. The globe is opened from 10 to four o'clock. The anterior segment appears normal. Scattered round pigment clumps in the retina are seen anterior to the equator (Fig. 1). There is a partially pigmented 7 × 7 × 6 mm tumor in the inferior temporal choroid.

*Microscopic*—The anterior segment is unremarkable except for thickening of the basement membrane of the ciliary epithelium. The lens is in place and shows posterior migration of subcapsular epithelial cells, bladder cell formation, and morgagnian globules. Arising from the temporal choroid between the equator and the optic nerve is a partially pigmented almond-shaped tumor composed of epithelioid cells and nucleolated spindle cells. The overlying retinal pigment epithelium is hyperplastic while the overlying retina is disorganized and contains cystoid spaces. There is a serous detachment of the neuroepithelium surrounding the tumor. The remaining choroid, sclera, and optic nerve appear unremarkable.

There is an artifactual detachment of the retina. The temporal retina anterior to the choroidal tumor and the nasal retina anterior to the equator exhibit diffuse cystoid degeneration and marked disarray of the layered architecture (Fig. 2). There is a loss of

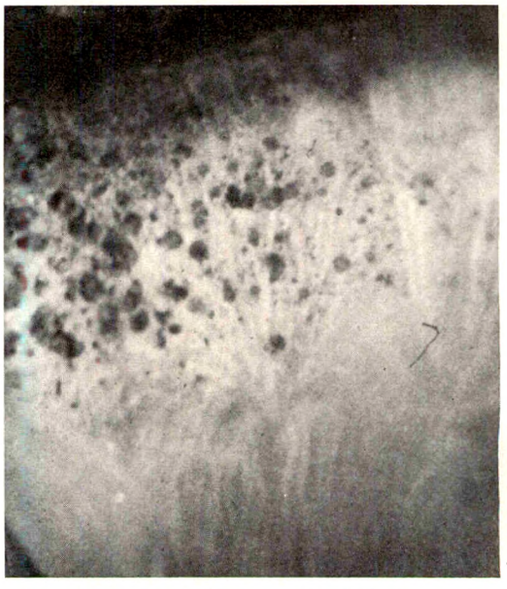

Fig. 1 (Betten, Bilchik, and Smith). Gross photograph showing clumps of pigment in the peripheral retina.

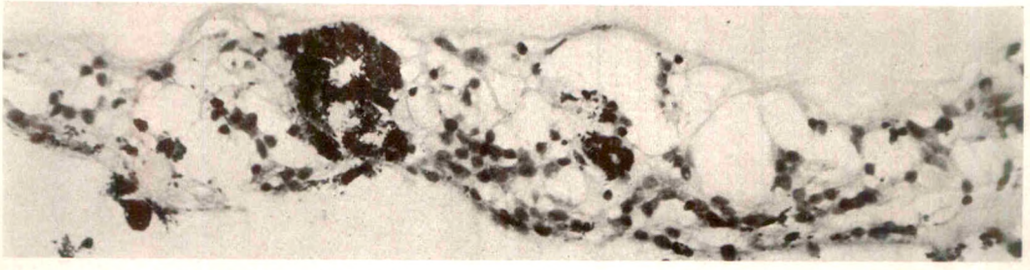

Fig. 2 (Betten, Bilchik, and Smith). Photomicrograph of peripheral retina demonstrating marked disorganization, cystoid spaces, loss of photoreceptors, and pigment migration. The pigment epithelium is artifactually detached (hematoxylin-eosin, ×350).

photoreceptors and, temporally, a reduction in the thickness of the inner plexiform layer. Foci of extracellular pigment and hyperplastic pigment epithelium are present within the retina frequently juxtaposed to areas where the retinal pigment epithelium is degranulated (Fig. 3). The intraretinal pigment is distributed throughout all retinal layers and is not located adjacent to vessels. There are foci of pigmented cells in the outer plexiform layer of the macula, which is otherwise intact (Fig. 4). Drusen of Bruch's membrane are scattered throughout the peripheral retina.

*Diagnosis*—Malignant melanoma of the choroid, peripheral pigmentary retinal degeneration, rare pigment migration into the macula, and cataractous lens.

## Comment

Verwey and Legras[10] first noted a pigmentary maculopathy in a patient with myotonic dystrophy. Since then, others[1-4] have encountered macular changes which often consist of streaks of pigment arranged in a stellate fashion. In some cases, reduction of visual acuity has been attributed to the macular changes.

A pigmentary abnormality of the peripheral retina in a patient with myotonic dystrophy was first described clinically by Gotfredsen.[11] His report, as well as subsequent papers,[1-4] describe a noncorpuscular, haphazard pigmentation in the retinal periphery.

Burian and Burns[1] studied 25 patients with myotonic dystrophy. Six patients had definite macular pigmentary changes and four of 13 examined with the indirect ophthalmoscope had pigment clumping in the periphery. Slatt[2] reviewed 17 patients with myotonic dystrophy. Four patients had grayish-white macular stippling but none had peripheral pigment deposition. Junge,[3] in a study of 52 patients with myotonic dystrophy, found pigmentary abnormalities in the macula of two patients and in the periphery of one patient. Babel and Tsacopoulos[4] reported the retinal findings in 12 patients with myotonic dystrophy. Eleven patients had a wide-meshed pigmentary network between the equator and ora serrata, and five patients had deep macular pigmentation.

Manschot[5] described the peripheral retinal histopathology in an autopsy specimen of a 48-year-old patient with myotonic dystrophy. His examination was limited by severe postmortem changes. There was marked atrophy of the external retinal layers and proliferative folds of pigment epithelium which extended into the retina. Hyaline material continuous with the thickened lamina vitrea filled the spaces within the pigment epithelial folds. There were numerous drusen of Bruch's membrane. Based upon these findings, Manschot hypothesized that pigment epithelial proliferation was the first stage in the retinal abnormality of myotonic dystrophy. However, his photomicrographs also

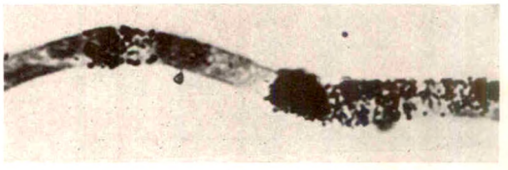

Fig. 3 (Betten, Bilchik, and Smith). Photomicrograph of peripheral retinal pigment epithelium showing areas of pigment degranulation (hematoxylin-eosin, ×720).

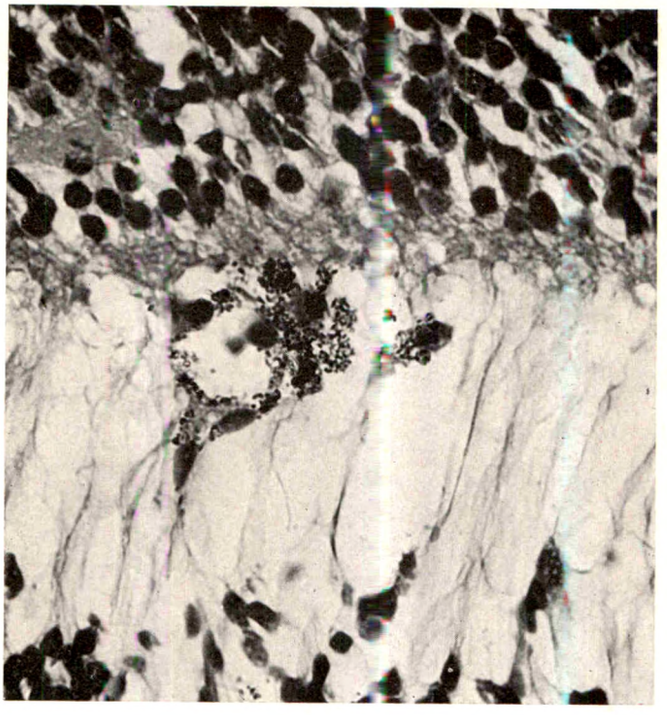

Fig. 4 (Betten, Bilchik, and Smith). Photomicrograph showing a focus of pigment cells in the outer plexiform layer of the macula (hematoxylin-eosin, ×720).

showed retinal degeneration in the areas of pigment epithelial proliferation.

Houbert and Babel[6] studied autopsy specimens from two patients with myotonic dystrophy. They found peripheral retinal degeneration and intraretinal pigmentary proliferation, as well as hyalinosis and microthrombosis of the peripheral retinal vessels.

Burns[7] found drusen of Bruch's membrane and central serous retinopathy in an autopsy specimen from a patient with myotonic dystrophy. The other two histopathologic studies in the literature[8,9] reported no retinal abnormalities.

The pathologic features in our case are generally similar to those described by Manschot[5] and Houbert and Babel.[6] In addition, we have observed areas of degranulation of an otherwise normal appearing retinal pigment epithelium and foci of pigmented cells in the outer plexiform layer of the macula.

On the basis of our observations, we cannot come to any definite conclusion concerning pathogenesis. The question which still remains is: Are these findings due to a primary neuro-epithelial disorder or are they secondary to a pigment epithelial disturbance? Another question is whether the retinal findings are indeed an intrinsic part of this multiphenotypic disease—i.e., myotonic dystrophy—or whether they are due to some other cause.

Since many patients with myotonic dystrophy take variable quantities of quinine during their life, is it possible that quinine may be responsible for the retinopathy? The idiosyncratic and overdose ocular reactions to quinine are an amblyopia with optic nerve atrophy, narrowed arterioles, and markedly constricted visual fields.[12] The pathogenesis of this toxic effect is not fully understood, but quinine, as discussed by Almeida,[13] is thought to either have a direct toxic effect on the retinal ganglion cells or an arteriolar narrowing effect leading to secondary retinal and optic nerve atrophy.

Quinine, by similar or perhaps different pathophysiologic mechanisms, may produce

other manifestations, such as those reported here, when the drug is taken steadily over a long period of time. One possible mechanism may involve binding of quinine or one of its breakdown products to melanin, with the subsequent development of retinal degeneration. It is known, however, that quinine is rapidly absorbed, degraded, excreted, and not accumulated in the body.[14] Yet, rapid handling and the lack of significant storage does not preclude sequestration of small amounts in selected tissues, e.g., the pigmented tissue of the eye. In support of this mechanism, Potts[15] found that quinine dihydrochloride, as well as a whole host of other resonating aromatic compounds, is bound in vitro to uveal melanin granules. To the best of our knowledge, an in vivo study of the affinity of quinine for melanin-containing tissue has not been done.

The chemical similarity of quinine and chloroquine,[14] the large accumulated dose of chloroquine necessary to produce retinopathy,[16] and the somewhat comparable histopathology observed in chloroquine retinopathy and our case (retinal localization differs),[17] further suggests to us that quinine may cause a tapetoretinal disease.

Clinical and laboratory studies seem indicated to probe this area of speculation. Investigation of the drug histories of patients with myotonic dystrophy with and without pigmentary retinopathy should help resolve the issue. Also, studies of patients taking other long-term quinolones (e.g., quinidine, the isomer of quinine) might also be informative.

## Summary

Gross examination of a surgically enucleated eye from a patient with myotonic dystrophy disclosed pigment clumps in the retina anterior to the equator. Microscopic study of the peripheral retina showed extensive pigmentary degeneration of the neuroepithelium and areas of proliferation and degranulation of the pigment epithelium. Rare foci of pigmented cells were observed in the macula. The possible role that quinine may have in producing this pigmentary retinopathy is discussed.

## Acknowledgment

Dr. Glen Johnston provided the clinical information in this case.

# CONGENITAL AMAUROSIS OF RETINAL ORIGIN

## (LEBER)

WILLIAM C. EDWARDS, M.D., WILLIAM D. PRICE, M.D.,
AND RODERICK MACDONALD, JR., M.D.
*Louisville, Kentucky*

In 1869, Leber[1] described a disorder which included: (1) congenital amaurosis or highly imparied vision, (2) a fundus picture in infancy often showing marked discrepancy between this and the visual function, and (3) a recessive heredity. Subsequently an extinct, or nearly extinct, electroretinogram was described.[2] The ocular fundus in infancy may be either normal or demonstrate diffuse fine pigmentation. The condition often progresses to abnormalities such as those seen in retinitis pigmentosa.

The patients whose four case histories are described in this report are from a family of nine children. The mother was 36 years of age when the last child was born. There was no known consanguinity. Neither parent described a family history of mental retardation or eye problems. The first five children ranged from 16 to 21 years of age and were not available for eye examinations. They were described as normal, however, and although two of them had minor difficulties with schoolwork, they passed all school visual screening tests, obtained driver's licenses, and are gainfully employed without ocular complaints.

The four younger children all showed congenital retinal blindness associated with varying degrees of other ocular defects and mental retardation. In each of these cases, pregnancy and delivery were unremarkable.

From the Department of Ophthalmology, University of Louisville School of Medicine, Louisville, Kentucky. This research was supported in part by Public Health Service Training Grant EY 00023 and Research Grant 00432 from the National Eye Institute, and a grant from Research to Prevent Blindness, Inc.

Reprint requests to William C. Edwards, M.D., Department of Ophthalmology, University of Louisville School of Medicine, 301 East Walnut Street, Louisville, Kentucky 40202.

### CASE REPORTS

In all four of the cases described below, the following studies were performed and the results were declared normal: complete blood count, urinalysis, urine for amino acids, bilirubin, urine for reducing agents, and chromosomal karyotypes. Skull x-rays were also performed and these were also considered normal.

*Case* 1—This boy was born May 13, 1958. By the time he was six weeks of age, blindness was suspected by his parents. At three months of age he developed a "turned-in eye and jerking eye movements." He was first seen by our department at the age of seven years.

Ocular examination revealed normal eyelids with enophthalmos and minimal microphthalmos. Cornea, irides, and lenses were normal in appearance. Ophthalmoscopy revealed normal disks with slightly attenuated arterioles (Fig. 1). A repeat examination at the age of 10 years revealed a cataract in the left eye. Another examination was performed when he was 12 years of age revealed very fine retinal pigmentation which was not described in the early examinations.

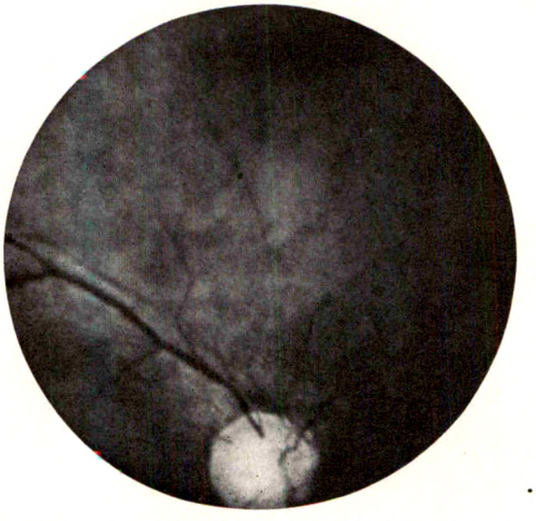

Fig. 1 (Edwards, Price, and Macdonald). Case 1. Left fundus illustrating attenuation of retinal arterioles and fine background pigmentation.

General physical examination revealed a child below the third percentile in height and weight with a borderline normal head circumference. There was a prominence along the sagittal suture. Muscle tone was generally increased. The remainder of the physical examination was unremarkable. An electroencephalogram revealed an irritative lesion in the left temporal area. Testing demonstrated low-normal intelligence. An electroretinogram, performed when he was 12 years of age, was extinguished. Shortly after his seventh birthday he was enrolled in the Kentucky School for the Blind where his over-all performance has been termed adequate.

*Case* 2—This boy was born April 29, 1960. Blindness was suspected by his parents at an early age. He was seen in consultation when he was five years of age. Ocular examination revealed enophthalmos. His right eye demonstrated a dense leukoma with adherent iris and flat anterior chamber. It was felt that this represented a perforated keratoconus. The left pupil reacted sluggishly to light. A moderately dense left cataract was present. The fundi were poorly visualized, but the disks appeared pale. At seven years of age he was re-evaluated and found to have bilateral dense cataracts. The fundi could no longer be seen.

General development was markedly delayed. The patient did not sit alone until the age of four years. Physical examination revealed a small child below the third percentile in height and weight. The head circumference was small with a prominence along the sagittal suture. Muscle tone was generally increased. The remainder of the physical examination was unremarkable. The only positive laboratory tests were a serum carotene level of 682 mg% and a blood sugar of 52 mg% reported at the age of five years. An electroencephalogram was moderately dysrhythmic. Evaluation at seven years of age revealed profound mental retardation.

*Case* 3—This girl was born July 12, 1961. Blindness was suspected by her parents by the age of two months. She was first seen in consultation at the age of four years. Eye examination revealed no fixation or following of light. Enophthalmos and microphthalmos were noted. The eyelids, corneas, irides, and anterior chambers appeared normal. The pupils showed hippus, but no light reaction. There was peripheral spoking of the lenses with cortical opacities. The disks appeared pale. She was re-examined at the age of seven years and found to have bilateral dense cataracts with no visualization of the fundi.

General development had been non-progressive after the age of one year. Physical examination revealed a small child with height, weight, and head circumference below the third percentile. There was generalized increased muscle tone, with the development of a positive Babinski sign on the right by seven years of age. The remainder of the physical examination was unremarkable. As in Case 2, blood chemistry revealed a markedly elevated serum carotene of 640 mg% and a blood sugar of 59 mg. An electroencephalogram revealed an irritative focus in the left frontal temporal region. Evaluation confirmed the impression of profound mental retardation.

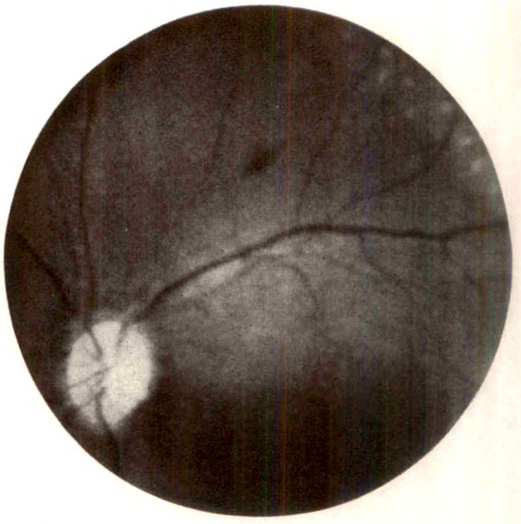

Fig. 2 (Edwards, Price, and Macdonald). Case 4. This photograph illustrates marked attenuation of retinal arterioles consistent with amaurosis congenita. The posterior pole appears normal. Adjacent is the abrupt commencement of the white punctate retinopathy.

*Case* 4—This girl was born May 12, 1964. Blindness was suspected by the age of one month. She was first seen in consultation at the age of 14 months. Eye examination revealed no fixation or following of light. Enophthalmos and minimal microphthalmos were evident. The eyelids, corneas, irides, anterior chambers, and lenses were normal. Fundus examination revealed normal disks and vasculature. Repeat eye examination at the age of four years showed fundi with attenuated arterioles and many small, discrete, flat, white, punctate lesions at the equator (Figs. 2 and 3). Some were irregular in shape. When she was re-examined at age six years of age, the punctate lesions were found to be yellow-white in color and tended to be larger and more irregular. The fundus appeared similar to a case reported by Krill.[6]

This child's general development was reported to be normal. Physical examination revealed height, weight, and head circumference below the third percentile. There was a prominence along the sagittal suture. In contrast to her three siblings, there was generalized hyporeflexia. An electroencephalogram showed an irritative focus in the left temporal region. An electroretinogram at the age of six years was extinguished. Evaluation revealed a probable low-normal intelligence. At the age of five years she was enrolled in the Kentucky School for the Blind where her progress has been good.

Fig. 3 (Edwards, Price, and Macdonald). Case 4. Area of left fundus showing areas of white punctate retinopathy.

## Discussion

In Leber's initial report[1] of this condition (1869), now termed amaurosis congenita, he described several children in an institution for the blind were he was the consulting ophthalmologist. He noted that the affected children were blind at birth or soon thereafter. The children also evidenced photophobia and nystagmus. A most interesting finding was that in the first few months of life no significant fundus abnormality could be seen. Later in life these children usually developed a fine pigmentation of the fundus. A few developed the typical bone spicule formation of retinitis pigmentosa, whereas a small number retained apparently normal fundi. Most of the patients, regardless of the background fundus picture, developed attenuation of the arterioles and the appearance of optic atrophy. Cataracts were noted in some of the older patients.

In the 100 years since Leber's report, others have added further relationships to the basic condition of congenital blindness of retinal origin. A significant proportion of the affected individuals are now known to have keratoconus or keratoglobus.[4-8] Alstrom and Olson[7] report an incidence of 33% in their oldest age group. A small series by Gillespie[8] reports an incidence of 100%. Leber[1] himself reported the low incidence of only 1% in a series of cases in young patients. Most authors feel the frequency of this association increases with age.

Electroretinographic study of these children is found to be severely abnormal, either extinct or characterized by minimal responses.[2,5,9,10,11] The digito-ocular phenomenon wherein blind children attempt manual retinal stimulation by pressure on their own globes is also seen in this condition.[12]

The family in this report illustrates that true congenital blindness of retinal origin is evident in early infancy. In each of these four children, blindness was suspected by the age of three months, and as early as the age of six weeks in one. Unfortunately, only one of these children (Case 4) was seen by us while still an infant. At that time, however, her fundus examination revealed no abnormality. The other three siblings had already developed fundus changes consistent with early optic atrophy by the time their initial eye examination was performed. All three had varying degrees of arteriolar attenuation associated with pale disks. One child (Case 1) has shown increasing fine pigmentation of the fundus without any clumping.

Retinitis punctata albescens has been described as part of the broad group of tapetoretinal degenerations. It has been suggested by Forsuis and Erikson[11] that it is part of a continuum between congenital retinal blindness and retinitis pigmentosa. These investigators state, however, that there is no report of retinitis punctata albescens appearing in a patient whose siblings have congenital blindness of retinal origin, as is the case in this family. In Case 4 in this report, as well as the case cited by Krill,[3] yellow-white spots are observed which are not necessarily related to retinitis punctata albescens or fundus albipunctatus.

The three eldest children in this study have developed cataracts (Fig. 2). In Case 1,

a unilateral cataract was found on examination at 10 years of age which was not present at the earlier examination when the child was seven years of age. In Case 2, cataract was present in one eye at the age of five years and was present bilaterally by the age of seven years. In Case 3, bilateral cataracts were developing at the age of four years and these had progressed to become dense by the age of seven years. Development of cataract seems related to age,[6,7,11] and our family confirms this concept. It is of interest that the two children who developed cataracts earliest are the two who are most severely retarded (Cases 2 and 3).

In various reports of keratoconus and keratoglubus[4-8] it appears that this disorder, like cataracts, becomes more evident with increasing age. One of our patients (Case 2) showed the probable aftermath of perforated keratoconus in one eye, demonstrating very clearly that it is possible to have corneal degeneration together with a typical fundus picture of congenital amaurosis.

Central nervous system disorders are variably reported in congenital amaurosis of retinal origin. Dekaban and Carr[10] felt that since the eye was intimately related to the brain developmentally, significant central nervous system defects might also be expected to occur with this entity. They presented seven affected children from four families and found only one to be normal mentally. Thee had epilepsy and two had abnormal electroencephalograms. Incidence of mental retardation and neuropsychiatric problems has ranged in various reports from 13% to 33%.[6] Some larger studies have excluded mentally retarded subjects and those with neuropsychiatric problems.[8] In this report, two of the four children affected are severely retarded (Cases 2 and 3), but all four of the children had abnormal electroencephalograms. Three of the children also demonstrate muscular hypertonicity while Case 4 demonstrates muscular hypotonicity.

In this family, the most severe eye problems (i.e., cataracts, keratoconus) were associated with profound mental retardation. The other two children, both of whom who are functioning well at the Kentucky School for the Blind (Cases 1 and 4), have clear media and minimal structural changes of anterior ocular segments. Waardenburg and Scappert-Kimmijser[13] made similar observations are made in their report of three sisters. However, there are several articles in which this parallel is not seen. Of the six retarded children presented by Dekaban and Carr[10] none had significant structural changes of the globe at the time of examination. In a family described by Gillespie,[6] four members had marked structural changes in the form of significant keratoconus, but none was mentally retarded. This points out the variability of expression of the gene of congenital retinal blindness, not only between affected families, but also within the affected families.

There have been several histopathologic descriptions of eyes with a clinical diagnosis of congenital retinal amaurosis. Aubineau[14] mentioned disorganization of the outer granular layer with loss of the receptive elements. He also described alteration of the pigment epithelium with pigment migration into the retina, thinning of the retina, and pronounced atrophy of the choriocapillaris. Sorsby and Williams[6] described "non-characteristic extensive degeneration of all retinal layers" in a 16-year-old patient. These authors felt that histopathologic examination of material from a younger patient would be needed to incriminate a specific retinal layer. Babel noted two specimens with extensive degeneration of the neuroepithelium and atrophy of the choroid in one eye.[15] What appeared to be an agenesis of rods only was described by Vrabec.[16] Waardenburg[4] reported an essentially normal neuroepithelium. In another paper, Gillespie[7] found a retina with no perceptive elements and peripheral areas with pigment migration, gliosis, and destruction of Bruch's membrane. In the posterior pole no rods or cones were seen, instead there was a "layer of cuboidal cells."

Congenital amaurosis of retinal origin is well accepted as a genetic entity. This family is compatible with the generally recognized autosomal recessive mode of inheritance.

There has been one instance of autosomal dominant inheritance reported. Sorsby and Williams[6] described a family in which members of three successive generations demonstrated congenital amaurosis of retinal origin.

Of interest is the report by Waardenburg and Shappert-Kimmijser[13] of a family in which both parents were affected with congenital amaurosis of retinal origin. They had two children, one boy and one girl, both of whom had normal eyes. These authors state that multiple alleles may be involved in determining the expression of congenital retinal blindness. This might explain the variability of expression between affected individuals.

Forsuis and Erickson[11] feel that congenital amaurosis of retinal origin and retinitis pigmentosa represent a continuum of tapetoretinal degenerations. They suggest, from their studies of tapetoretinal degenerations on the Åland Islands, that the various degrees of expression in that population may be due to a single genetic mutation hundreds of years ago.

## Summary

A family with four affected siblings demonstrates the variability of the fundus picture seen in congenital amaurosis of retinal origin. The four siblings in this study showed early severe decrease in visual function and attenuation of retinal arterioles. Of the two children who could be tested, both showed an extinguished electroretinogram. Two of the siblings revealed pigmentary changes of the retina. The unusual occurrence of a white punctate retinopathy in one child is thought to be part of the spectrum of congenital amaurosis. Three of the four siblings showed lenticular opacities and one demonstrated corneal degeneration. The progressive nature of both the fundus findings and the lens opacities in this syndrome is evident in this study, as is the association of mental retardation and congenital retinal blindness. Finally, this family illustrates the variability of both ocular and central nervous system defects in a sibship with diverse phenotypic expressions of this disorder.

### Acknowledgments

We thank Theodore Lawwill, M.D., for the electroretinograms in this study, Mr. Thomas Van Cader for the photographs, and Mrs. Linda Ballard for her secretarial assistance. We acknowledge with gratitude the assistance of the University of Louisville Child Evaluation Center and the Kentucky School for the Blind.

# PERIPHERAL RETINAL ALBINOTIC SPOTS

DONALD A. SCHLERNITZAUER, M.D., AND W. RICHARD GREEN, M.D.
*Baltimore, Maryland*

The pigment epithelium of the retina is one of the most reactive structures of the eye, and alternations in it are commonly seen in diseases and degenerative processes in the eye. The purpose of this report is to record the observation of a retinal pigment epithelial abnormality noted in the Eye Pathology Laboratory of The Johns Hopkins Hospital.

The abnormality was noted during the routine processing of autopsy eyes. One eye was from a 59-year-old white man who died of squamous-cell carcinoma of the esophagus, while the other eye was from a 64-year-old white man who died from complications of atherosclerosis. After the eyes were opened, it was noted that a round area of hypopigmentation was located inferonasally at the equator in one eye, and inferotemporally at the equator in the other. In each case, the fellow eye did not show similar abnormalities. The involved areas were characterized by a loss of pigmentation, a more distinct choroidal pattern, and by fairly well demarcated borders (Fig. 1). There was no juxtaposed area of pigmentary hyperplasia as is usually seen in old chorioretinal scars.

In each eye, only a single area was so involved. The spot measured 4 mm in diameter in one eye, and 4.5 mm in diameter in the other. Except for peripheral cystoid degeneration in both of the eyes and cobblestone degeneration in one eye, no other gross abnormalities were noted.

On microscopic examination of the involved areas, the cells of the retinal pigment epithelium were slightly flatter than in the uninvolved areas, as were the nuclei of the involved cells. These flattened cells had lost virtually all of their pigment granules. The few remaining pigment granules at the borders of the lesions appeared to have the lancet shape characteristic of the retinal pigment epithelium. A Fontant stain showed only the pigment which was obvious with other stains. In the areas directly bordering the lesion, the cells of the retinal pigment epithelium appeared entirely normal, the transition being a rather abrupt one (Fig. 2). Bruch's membrane, the choriocapillaris, and the remainder of the choroid directly underlying the lesions appeared normal. The overlying receptor elements and remaining retina were also normal. In one eye, drusen of Bruch's membrane were present in the hypo-

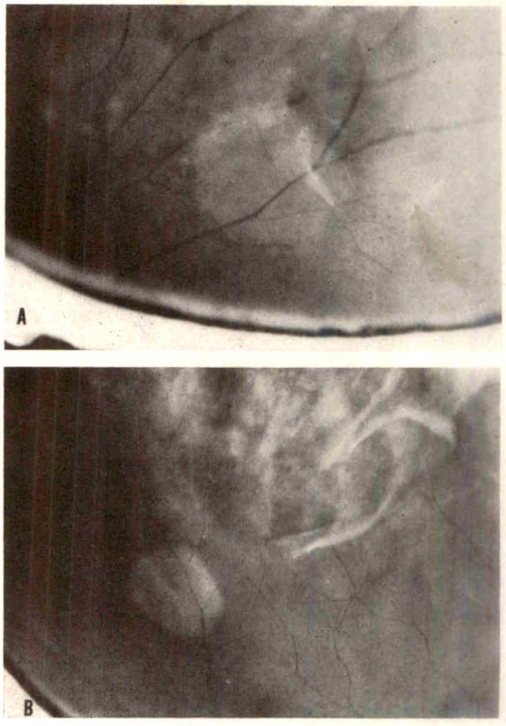

Fig. 1 (Schlernitzauer and Green). Gross photographs of the hypopigmented area noted in two autopsy eyes. Top: Eye of 59-year-old man. Bottom: Eye of 64-year-old man.

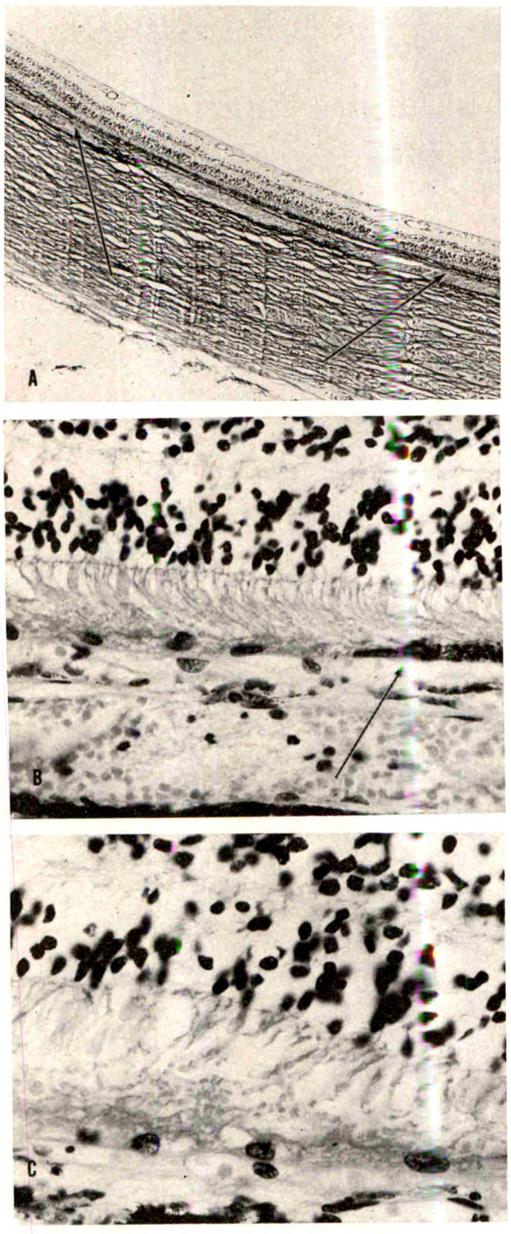

Fig. 2 (Schlernitzauer and Green). Photographs of the retinal pigment abnormality. Top: Overall view showing the extent of the lesion (arrows indicate the borders) (PAS, ×45). Center: Higher-power view of the border of the lesion, showing the abrupt transition from normal-appearing retinal pigment epithelial cells to the abnormal cells (arrow) (hematoxylin and eosin, ×575). Boston: View of the center of a lesion showing the somewhat flattened retinal pigment epithelial cells which lack pigment and which rest on a normal-appearing Bruch's membrane and choriocapillaris (hematoxylin and eosin, ×800).

pigmented area as well as in the uninvolved areas. The remainder of the eye was normal in both instances, except for mild arteriolarsclerosis of the retinal and choroidal vessels, and the peripheral cystoid degeneration and cobblestone degeneration noted above.

Although we are unable to make a clinicopathologic correlation at present, the clinical appearance of such focal areas of hypopigmentation might be similar to those depicted in Figure 3. These lesions were observed in six of 842 individuals examined during a mass screening of members of a small Maryland community.[1]

## Discussion

In 1921, Kraupa[2] reported on a variety of fundus lesions and he included a clinical drawing of a peripheral lesion which appears to be exactly the same as those we have observed. He was of the opinion that the lesion was most likely due to an acquired defect in the retinal pigment epithelium. In the same paper, however, he reported the occurrence of considerably smaller areas of pigment abnormality in the periphery, and he considered these to be probable congenital defects in the retinal pigment epithelium.

The unexplained absence of pigment granules in the retinal pigment epithelium was noted by Klien[3] in 1958 and was termed "depigmentation in situ." This designation was also used by Kurz and Zimmerman[4] in 1962 when they reported on vagaries of the retinal pigment epithelium. The process described by Klien, however, was in relation to diseases of the macula, and her paper does not note the occurrence of "depigmentation in situ" in the periphery. The histologic findings she described, however, are very similar to those reported in this paper. Klien suggested that this process—in which she had noted gradually expanding, ill-defined areas in which the choroidal vasculature became increasingly distinct over a period of months to years—may be a precursor of senile macular degeneration.

When areas of hypopigmentation occur in the periphery, on the other hand, as in the

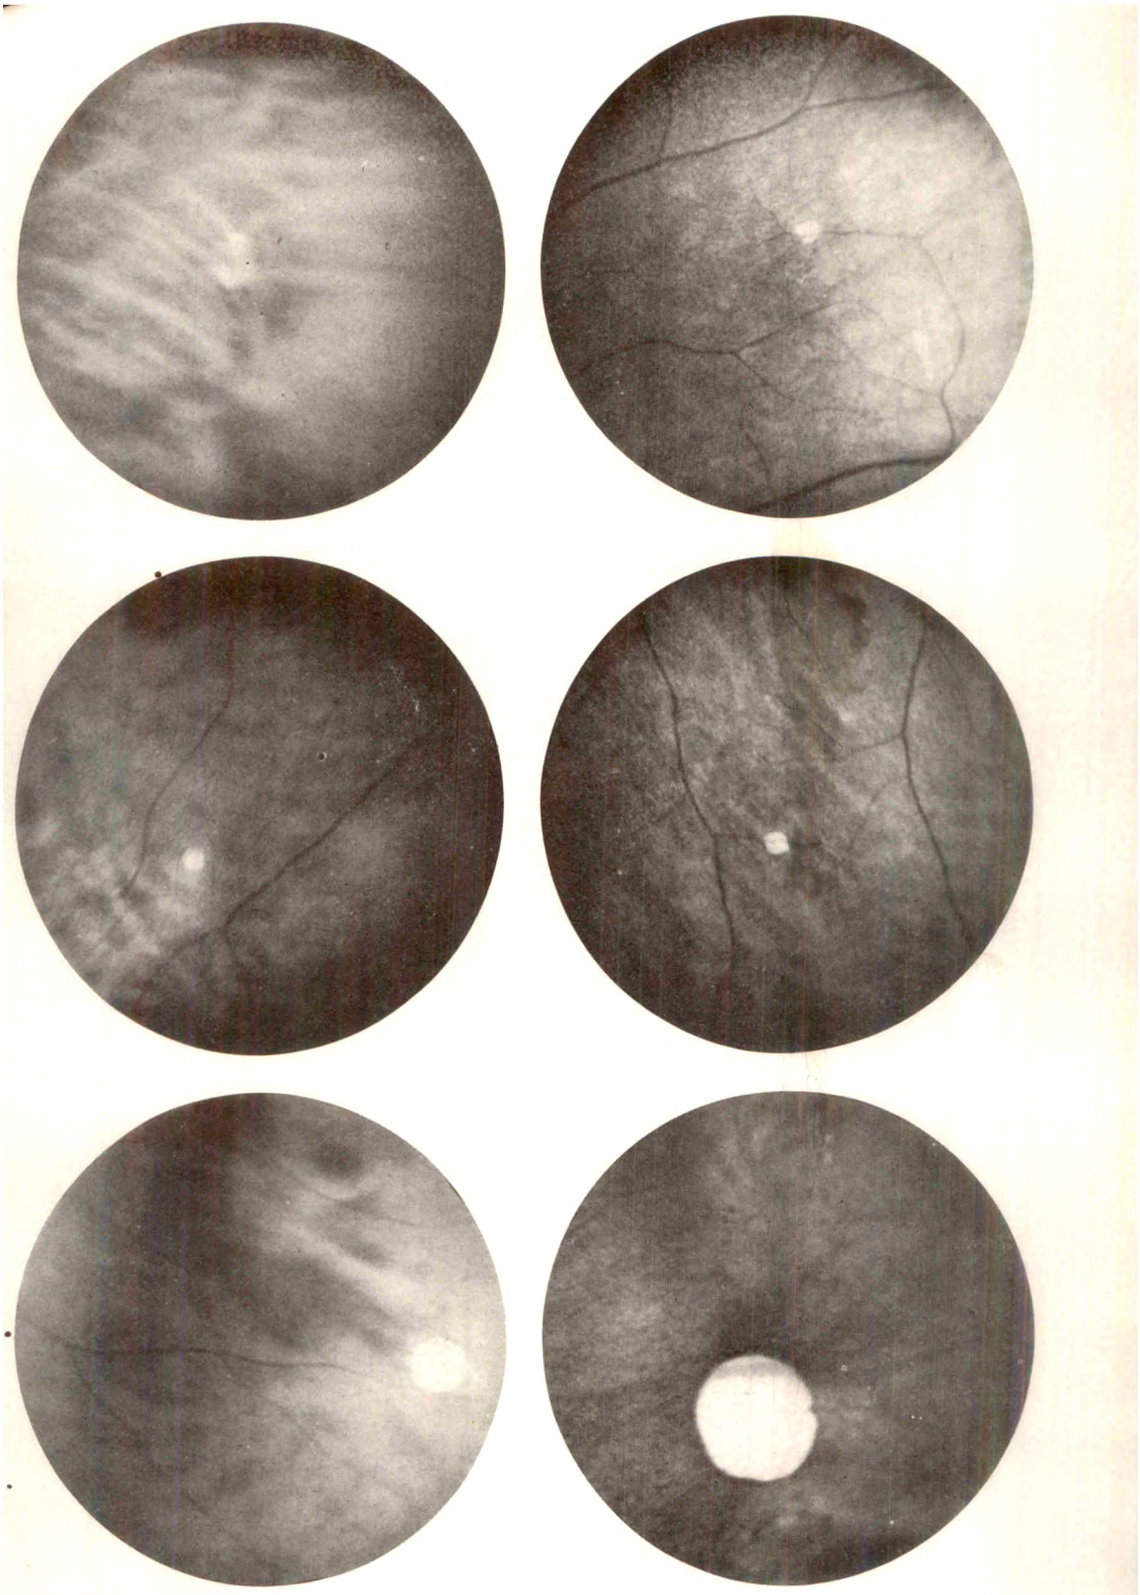

Fig. 3 (Schlernitzauer and Green). Photographs of the peripheral fundus in six patients showing well-demarcated, hypopigmented spots in which the choroidal vascular pattern is more prominent.

two cases reported here, it is difficult to project their evolution into any of the known peripheral lesions. Light microscopic evaluation of our specimens also leaves unanswered the question of the possible etiology of these changes. One of the more likely etiologies, perhaps, would be a localized vascular insufficiency, but no evidence has been found thus far to support this conjecture.

Realizing that in our two cases the development of the lesion had not been observed clinically, one cannot exclude the possibility of a congenital defect in the retinal pigment epithelium. It would therefore seem that until their pathogenesis has been ascertained it would be more suitable to use a term such as "peripheral retinal albinotic spots" to refer to this interesting (although perhaps not too significant) lesion of the retinal pigment epithelium.

## Summary

A peripheral area in the retinal pigment epithelium which was essentially devoid of pigment granules was noted during the routine processing of two autopsy eyes. A light-microscopic description of the abnormality is presented, but no conclusion as to the etiology of the lesion is offered. Since the possibility exists that these lesions are congenital rather than being degenerative, it is suggested that they be termed "peripheral retinal albinotic spots" to distinguish them from histologically similar lesions which have been observed to develop in the posterior pole by a process that has been termed "depigmentation in situ." Probable clinical counterparts of the peripheral retinal lesions reported here have been observed.

# EFFECTS OF TOXOPLASMA GONDII TOXIN ON THE RABBIT EYE

M. J. Hogan, M.D., and G. B. Moschini, M.D.
*San Francisco, California*
AND
O. Zardi, M.D.
*Rome, Italy*

Weinmann and Klatchko[1] first observed in 1950 that a toxin probably is present in the peritoneal fluid of mice previously infected with the RH strain of Toxoplasma gondii. They gave an intravenous injection of 0.1 ml of supernatant fluid from centrifuged peritoneal exudate to healthy Swiss mice. This resulted in severe respiratory symptoms, convulsions, and death. However, a dose of five times this amount injected intraperitoneally was tolerated by the mice.

Weinmann[2] later observed this toxin had no hemolytic or anticholinesterase activity and no antigenic properties and that it was thermostable. He also demonstrated that a similar ascitic fluid induced by chemical (lactic acid) or biologic (killed streptococci, tumor grafts) means produced no disease when injected intravenously in mice.

Varela and co-workers[3] believed that the toxic action of the centrifuged fluid resulted from the presence of a substance resembling the diethyl-amide of D-lysergic acid, while Pettersen[4] believed that the toxic effect was nonspecific and that it was caused by substances that originated in the mice.

According to Nozik and O'Connor,[5] the lethal effects produced in mice by the supernatant fluids from Toxoplasma-induced mouse peritoneal exudates can be positively correlated with the viscosity and surface-tension characteristics of this fluid.

Zardi recently was able to obtain and report on a purified preparation of the toxin of Toxoplasma gondii by a newly developed method.[6] This toxin was found to have the biologic actions of a true toxin. We are reporting here some clinical and histologic studies of the effects of this toxin on the rabbit eye after it was injected into the anterior chamber and the vitreous humor.

## Materials and methods

*Preparation of toxin and control*—Two-month-old white Swiss mice, each weighing about 20 g, were injected intraperitoneally with 15 million organisms of the LP strain of Toxoplasma gondii. This strain originally was isolated from the hypothalamus of a newborn hydrocephalic human infant and was maintained in mice by intraperitoneal inoculation. The virulence and antigenic properties of this LP strain are similar to those of the RH strain. After five days the peritoneal exudate was removed and subjected to ultracentrifugation at 31,000 × G. The supernatant fluid containing the toxin was adsorbed with trypsinized anti-mouse guinea pig spleen cells in order to remove proteins of mouse origin. The nitrogen content of the supernatant fluid measured by the micro-Kjeldahl method was 2.45 g/100 ml before the adsorption and 1.86 g/100 ml afterward. No mouse protein could be detected in this supernatant fluid by immunodiffusion against rabbit anti-mouse serum. The fluid was lyophilized at − 30°. and then resuspended to a concentration of 400 mg/ml in sterile distilled water buffered with phosphate at pH 7. The solution was then dia-

TABLE 1

SCHEDULE OF ENUCLEATION IN 19 RABBITS RECEIVING ANTERIOR CHAMBER INOCULATION

| No. Rabbits | Time Elapsing before Sacrificing (in days) |
|---|---|
| 3 | Retained |
| 3 | ½ |
| 3 | 1 |
| 3 | 1½ |
| 2 | 2 |
| 1 | 3 |
| 1 | 4 |
| 2 | 7 |
| 1 | 27 |

lyzed through one-fourth inch Visking tubing against the same amount of distilled water; this procedure was repeated three times. The dialysate at the end of this procedure was tripled in volume: it was again lyophilized, then resuspended at a concentration of 400 mg/ml in distilled water buffered with phosphate at pH 7. The solution had a viscosity of 1.23 centipoises at 20°C.

The same procedure was adopted for preparation of the control peritoneal exudate which was produced by injecting 0.5 ml of sterile culture broth, 0.5 ml of a solution of sterile tapioca powder at the concentration of 1.0g/100 ml or 0.2 ml of a streptococcal extract prepared in the following way: five billion beta hemolytic streptococci per ml of sterile distilled water were heated for 15 minutes at 100°C and then centrifugated at 2000 × G for 20 minutes. The supernatant was injected into the peritoneal cavity. The control peritoneal exudate was centrifuged, adsorbed and lyophilized as described for the Toxoplasma induced exudate. The lyophilized powder was dissolved at a concentration of 400 mg per 100 ml in sterile distilled water buffered with phosphate at pH 7.

There was no difference in the morphology of the cells of the exudate produced by Toxoplasma gondii and that produced by broth, tapioca or streptococcal extract. No mouse proteins were detected in the control peritoneal exudate after absorption with trypsinized anti-mouse guinea pig spleen cells, when tested by immunodiffusion with rabbit anti-mouse serum.

*Anterior chamber injection*—Nineteen pigmented rabbits, each weighing about 2.5 kg, were inoculated with 0.1 ml toxin in the anterior chamber of the right eye and with 0.1 ml of control fluid in the left eye. The eyes were enucleated according to the schedule shown in Table 1.

The rabbits were anesthetized with pentobarbital sodium and given a retrobulbar injection of carbocaine in 1.5% solution. A 7-0 black silk suture was placed intracorneally near the upper limbus, and a 27-gauge needle then was passed through an intracorneal track, superficial to the suture, into the anterior chamber. Aqueous humor was removed and replaced with 0.15 ml of toxin or control fluid. As the needle was withdrawn from the chamber, the intracorneal suture was tied, preventing loss of fluid. The rabbits were examined daily with a flashlight, ophthalmoscope and slit lamp microscope.

*Vitreous injection*—Twenty rabbits were inoculated with 0.1 ml of toxin in the vitreous of the right eye and with 0.1 ml of control fluid in the left eye. The eyes were enucleated according to the schedule shown in Table 2. The rabbits were anesthetized, and the anterior chamber was emptied of aqueous humor with a syringe and 27-gauge needle. Using another syringe and 27-gauge needle, the toxin and control fluids were injected either into the anterior or posterior vitreous through a puncture in the superior pars plana region. A silk suture was inserted at the injection site for identification at the time of histologic study. The rabbits were examined daily with the slit lamp and ophthalmoscope.

All eyes were enucleated shortly after sacrifice, fixed for 48 hours in neutral 10% formalin solution and washed for 24 hours in running tap water. Large nasal and tiny temporal calottes were then removed and the eyes were processed in the usual manner in paraffin. Step sections were studied at various levels in the two calottes and the central

portion. Mallory and van Gieson stains were applied to some sections, but routine sections were stained with hematoxylin and eosin. Occasionally, sections from the eyes given an anterior chamber injection were stained with PAS to show the changes in the iris and deep corneal stroma.

## Results

### Clinical findings

*Anterior chamber injection of toxin*—Within three to six hours there was some chemosis with cells and flare and a fibrin clot in the anterior chamber. This increased up to 24 hours and was accompanied by a variable amount of corneal edema. Posterior synechias of the iris to the lens invariably occurred. The signs persisted for three to four days, then slowly subsided. By the seventh to tenth day the inflammation was gone and synechias, iris atrophy and anterior subcapsular cataractous changes in the lens were observed. Glaucoma and keratectasia occurred in one-third of the eyes.

*Control eyes*—The control eyes showed a mild iridocyclitis for one to two days and then became quiet.

*Vitreous injection of toxin*—Within 24 hours there was some iridocyclitis but no fibrin clot or chemosis. The anterior or posterior vitreous showed a gray, hazy opacification so that the retina was difficult to see. This grayness often was more intense in the inferior vitreous. In a few eyes, small vitreous hemorrhages occurred because of the ciliary body necrosis. The vitreous haze usually cleared during the subsequent one to two weeks, at which time there were pigmented chorioretinal scars. The scars were usually more severe inferiorly, but quite often they were found to be diffuse. A cataract secondary to the inflammation developed in eight eyes.

*Control eyes*—The control eyes showed some cells in the vitreous and a few tiny hemorrhages, but there was no important inflammatory reaction and the vitreous remained quite clear. Slit lamp examination of the anterior eye was always negative.

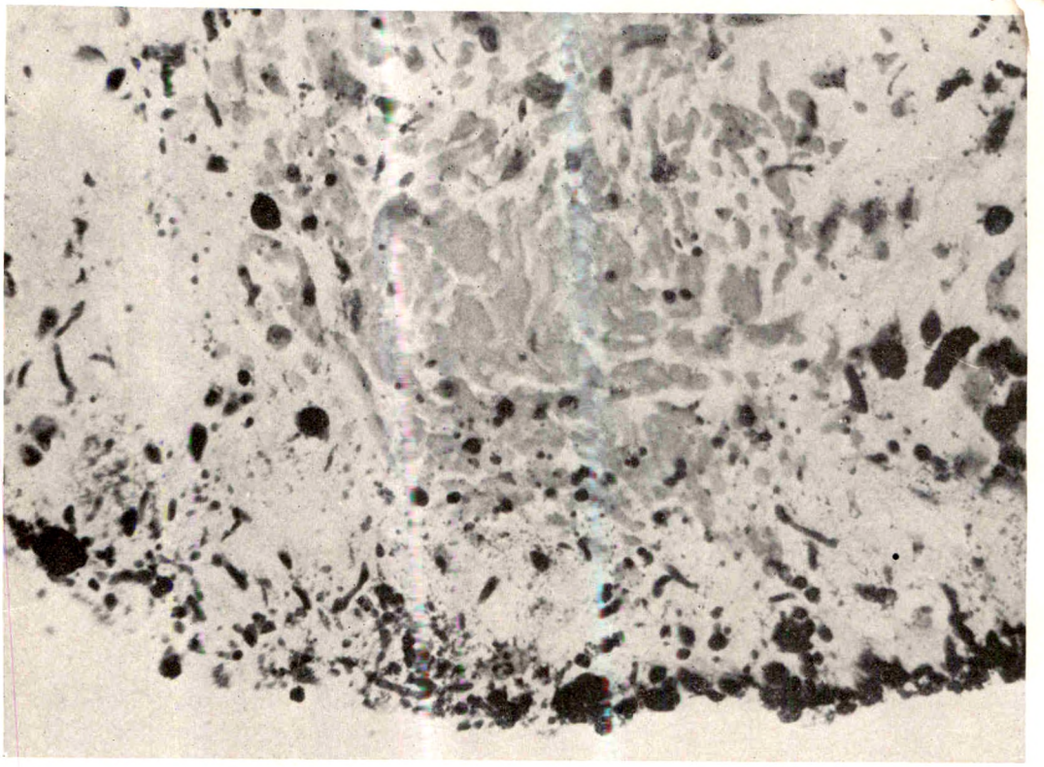
### Histopathologic findings

*Anterior chamber injection of the toxin.* The following changes were seen in eyes removed 12 hours to three days after inoculation. Within 12 hours there was a diffuse or localized keratoconjunctivitis and episcleral, scleral and trabecular inflammation. These tissues showed edema and infiltration of polymorphonuclear leukocytes. Some eyes showed a large fibrin clot containing polymorphonuclear leukocytes in the anterior chamber.

The anterior iris layers were involved earliest (Figs. 1 and 2). There was stromal edema and the melanocytes were swollen and rounded. The vessels were quite congested and their lumina often were occluded by thrombi (Fig. 1). The vascular endothelial cells were swollen and pale; their nuclei were absent or stained poorly. The vessel walls also showed edema and disruption (Figs. 1 and 2). Hemorrhage into the stroma of the pupillary and ciliary portions of the iris and into the stroma of the ciliary processes was frequent (Fig. 1). Polymorphonuclear leukocytes often were seen in the anterior half of the edematous stroma. The epithelial layers of the posterior iris and anterior ciliary body almost always showed



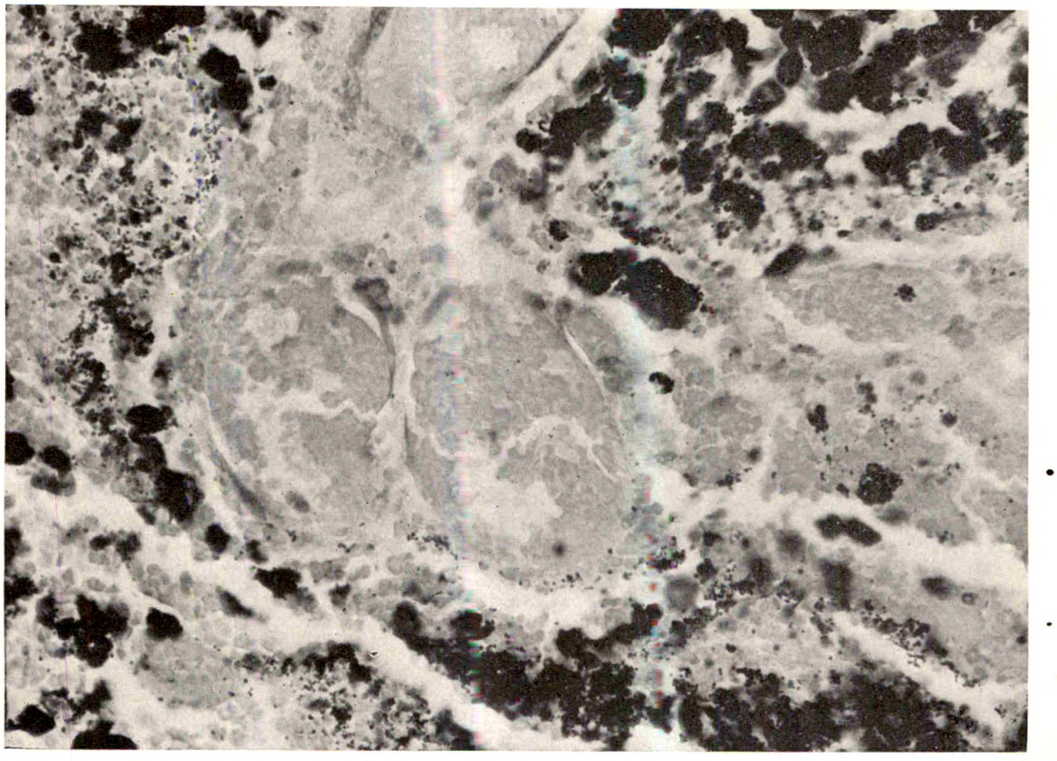


Fig. 1. (Hogan, Moschini, and Zardi). Acute iritis with stromal necrosis, hemorrhage, and degeneration of the posterior epithelial layers (×100).

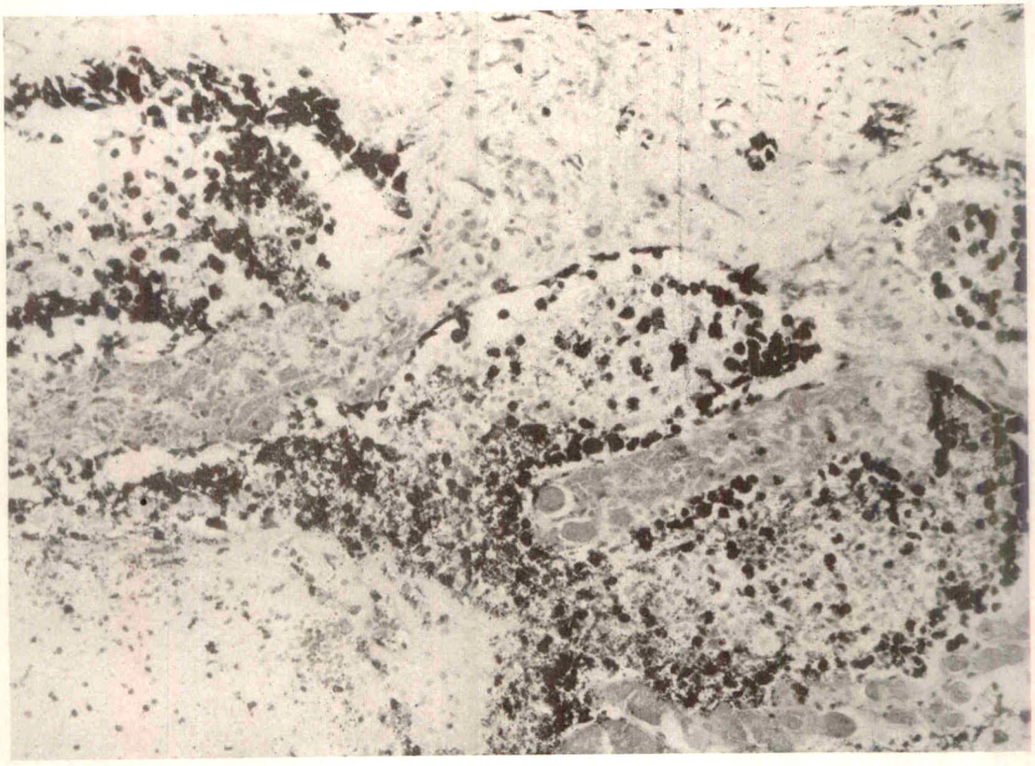

Fig. 3 (Hogan, Moschini, and Zardi). Acute cyclitis with necrosis of the ciliary processes, vascular destruction, thrombosis and stromal hemorrhage. There is marked destruction of the epithelial layers with pigment dispersion (×40).

edema and degeneration and frequently were separated from the stroma.

Many eyes showed similar vascular and stromal changes in the ciliary body. Hemorrhage was frequent in the disintegrating ciliary processes and posterior chamber. In some eyes the stromal and epithelial necrosis in the ciliary body was so marked that only engorged, thrombosed vessels remained. Pigment from the disintegrated stromal melanocytes and epithelium was dispersed in fine granules through the affected stroma and ciliary processes (Figs. 3 and 4).

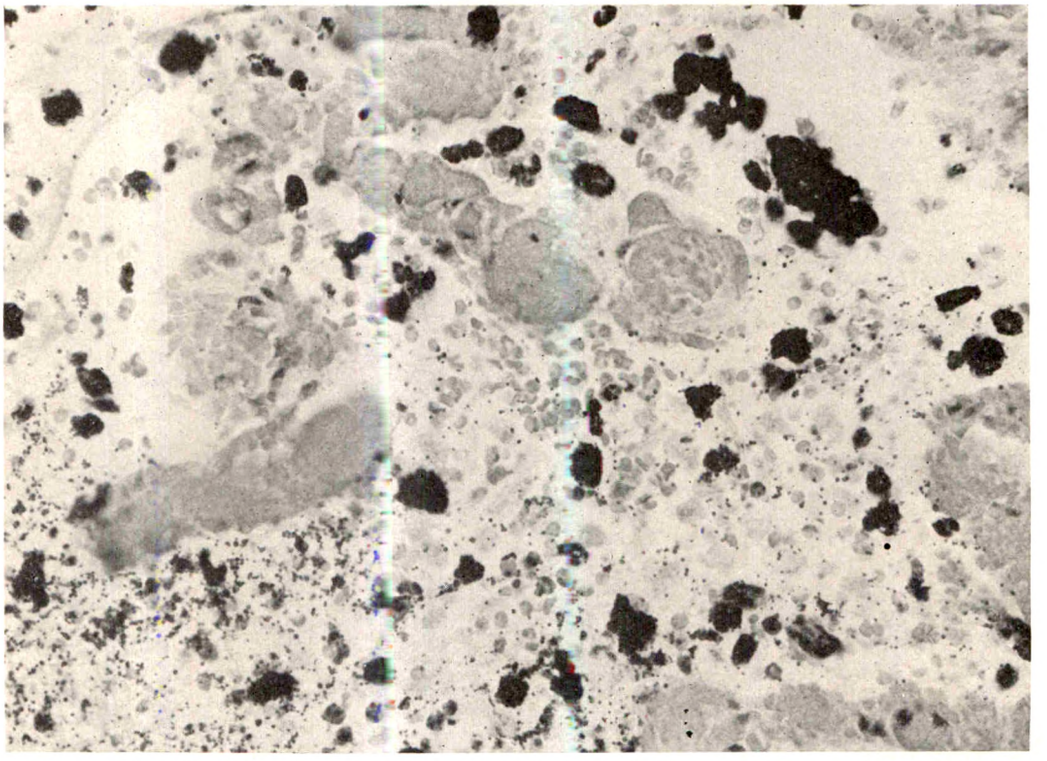
Cataract occurred in many eyes, but the changes are believed to be caused by the adjacent inflammation. Reparative changes were found after the first three days. The anterior third of the iris stroma became less vascular and more fibrosed, and a characteristic group of large, rounded pigmented macrophages or damaged melanocytes occupied this area (Fig. 5). The ciliary body showed marked degenerative changes in the processes and stroma with pigment dispersal in the posterior chamber (Fig. 6).

*Vitreous injection of toxin*—The following changes were seen in eyes removed 12 to 36 hours after inoculation:

1. *Anterior vitreous injection*—If the Toxoplasma toxin was placed in the anterior vitreous, a short distance behind the lens, the principal effects in the ciliary body was similar to those after anterior chamber injection. The retinal changes varied; in some areas

←

Fig. 2 (Hogan, Moschini, and Zardi). Same as Figure 1. Destruction of the vessel walls, stromal hemorrhage, pigment and stromal cellular destruction (×100).



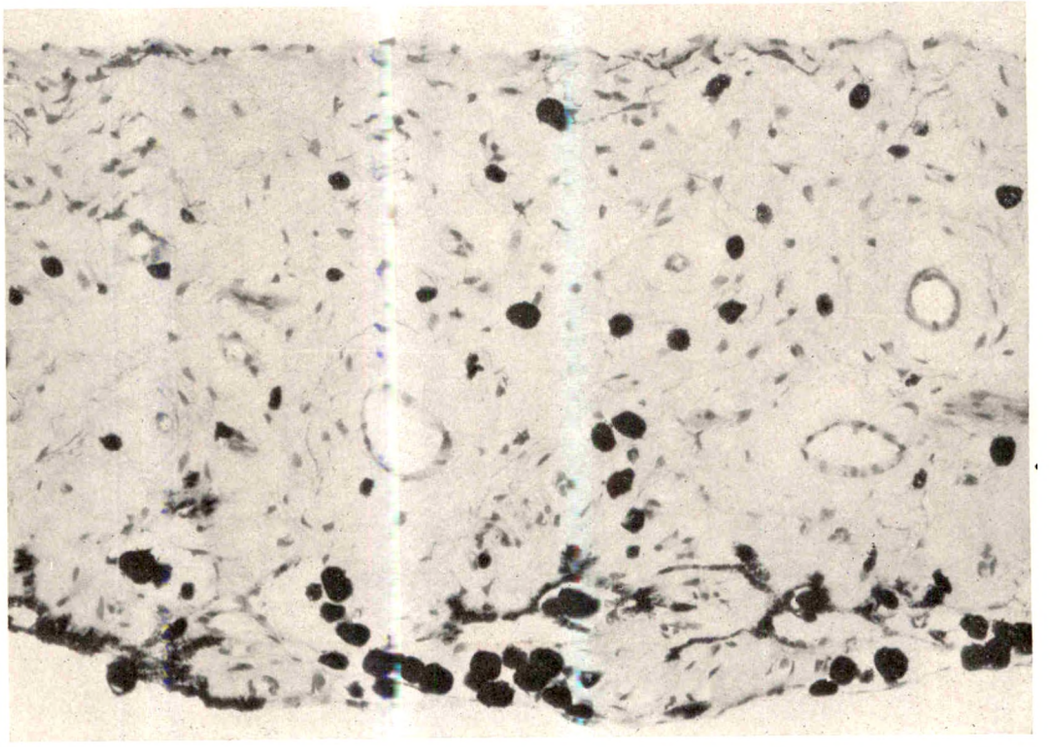


Fig. 4 (Hogan, Moschini, and Zard). Same as Figure 3, showing the vascular and stromal damage (×100).

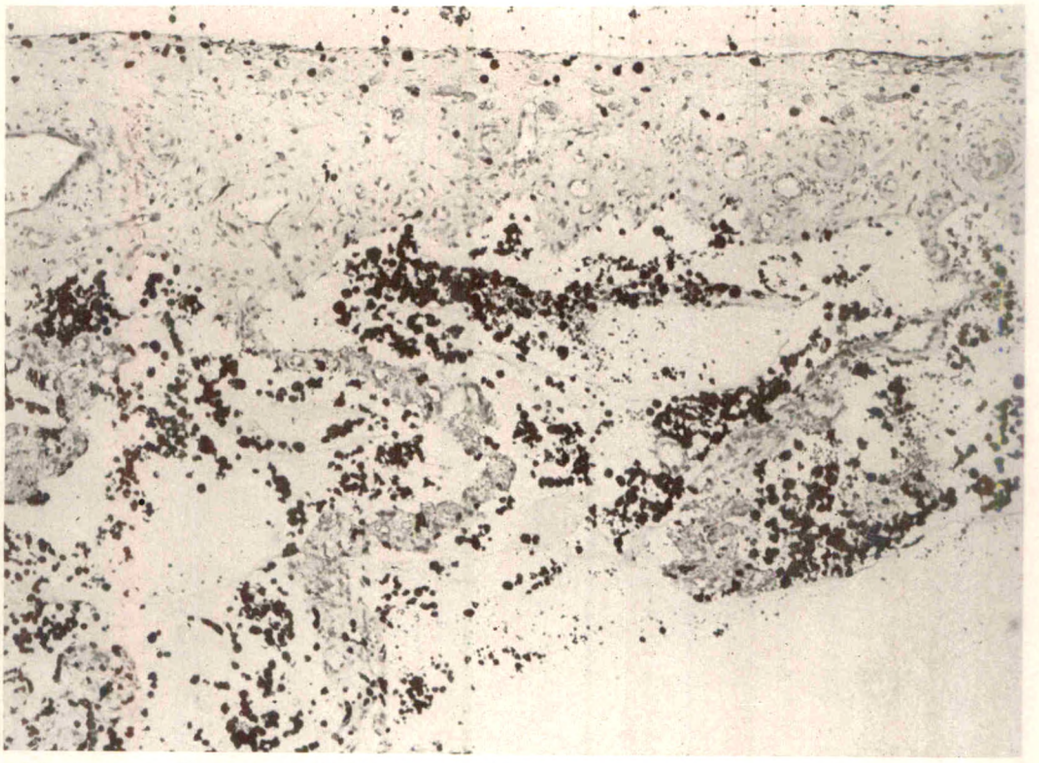

Fig. 6 (Hogan, Moschini, and Zardi). Healed iris and ciliary body lesions. There is severe damage to the ciliary processes with loss of epithelium and blood vessels (×22).

the innermost layers of cells and nerve fiber layer were severely damaged and infiltrated with polymorphonuclear leukocytes and lymphocytes being replaced by scattered inflammatory cells. In other areas the entire retina including the pigment epithelium showed severe destruction. The nuclear layers were swollen, and their nuclei were more basophilic. The outer segments of the receptors were replaced by a granular debris and the pigment epithelial cells were swollen, misshapen and dislodged from their normal position (Fig. 7).

The choroidal vessels were distinctly congested, and the stroma frequently contained hemorrhages. In the posterior eye the retinal vessels showed few changes; there was no congestion and very little infiltration with inflammatory cells. After the first two to three days there was no progression of the inflammatory process and formation of chorio-retinal scars soon became apparent (Fig. 8).

2. *Posterior vitreous injection*—In most eyes the injection was at a site just posterior to the center of the vitreous. In these eyes, the changes were localized to the choroid and retina, except for ciliary congestion in a few eyes. The changes in the retina and choroid were identical to those seen when the injection was made into the anterior vitreous, ex-

Fig. 5 (Hogan, Moschini, and Zardi). Late reparative phase in the iris. There is stromal and epithelial pigment cell loss, and stromal scarring. Some vessels have been obliterated, while others have a reduced caliber (×50).

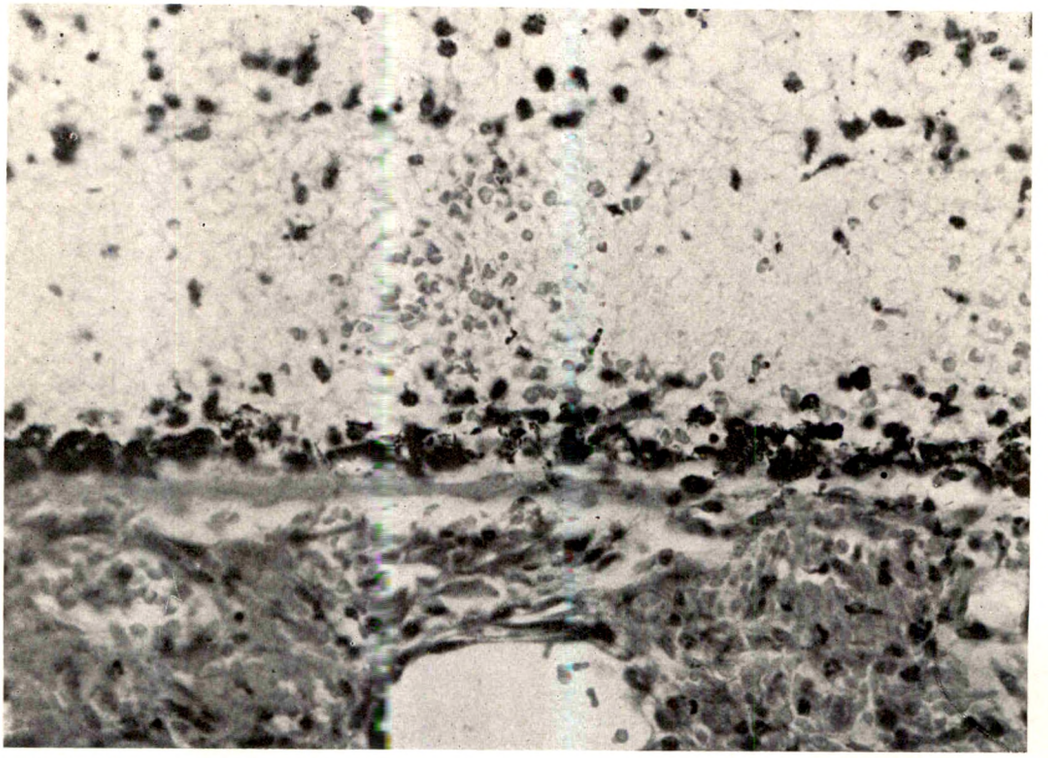

Fig. 7 (Hogan, Moschini, and Zardi). Acute chorioretinitis. The retina shows marked cellular destruction with hemorrhage. The pigment epithelium is degenerating. The choroid shows marked congestion and some stromal hemorrhage (×100).

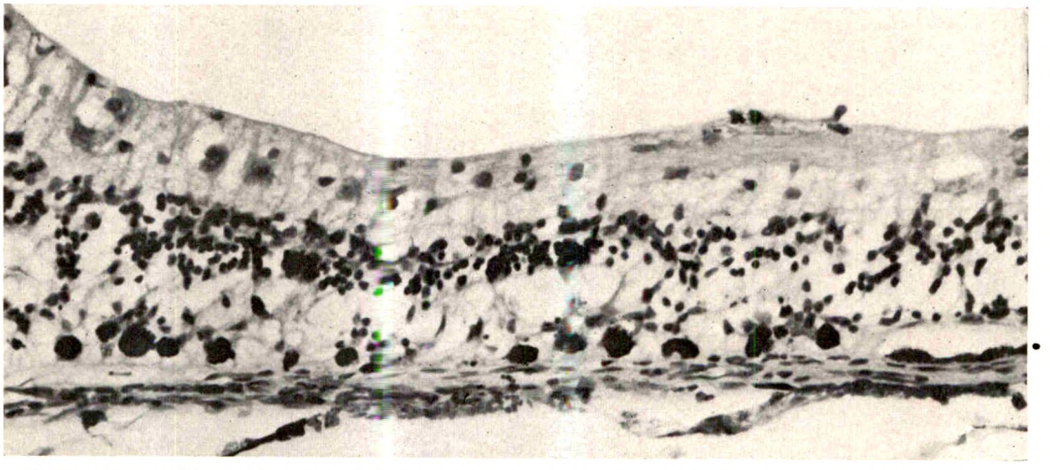

Fig. 8 (Hogan, Moschini, and Zardi). Healed chorioretinal lesion. The retina shows marked degenerative changes and is united to the choroid by cellular scar tissue. The internal choroid also shows some scarring (×64).

cept for involvement of the vessels on the inner retinal surface and disc region. These vessels showed more congestion and perivascular polymorphonuclear leukocytic infiltration. In the healed stage, a variable amount of retinal and choroidal destruction with scar formation was seen.

The amount of involvement of the retina and choroid seemed to depend on the exact placement of the injected fluid and the eventual distribution of the toxin; the entire area of these two tissues rarely was involved.

*Control eyes*—All of the control eyes were unremarkable. Some inflammatory cells were observed in the vitreous for two to three days after vitreous injection of the control fluid.

## Discussion

The histologic findings in these eyes show that when this product of Toxoplasma gondii-induced peritoneal fluid is injected into the rabbit eye the vascular and cellular effects suggestive of a real toxin are observed. In common with other known toxins, this preparation produces an irreversible alteration of the cell structure either by changes in the cell membrane or cell metabolism. It is well known that every toxin has a different mechanism of action. Pappenheimer,[7] for instance, has accumulated evidence that the toxicity of diphtheria toxin results from its interference with the cytochrome system of the cells of susceptible animals. The toxin of Clostridium perfringens is a lecithinase, an enzyme which cleaves phospholipid substrates to yield phosphorilcholine and diglycerides, thus altering the cell metabolism.[8]

In the present series of experiments, the vascular endothelium of the iris and ciliary body was found to be most severely affected. The vascular changes were characterized by thrombosis and disruption of the vessel walls. The dose of toxin administered here probably is greatly in excess of that which would be produced by the Toxoplasma organisms in the ordinary toxoplasmic lesion. Nevertheless, the cytologic effects on the cells is similar to that seen in tissue cultures where nonparasitized cells are affected by some product of the proliferating organisms.

The ocular tissue changes produced by the toxin injected into the vitreous are similar to those seen in toxoplasmic infections of the retina. It may be that the severe necrosis that occurs in toxoplasmic infections is caused by the liberation of toxoplasma toxin.

The elucidation of the biochemical mechanism of the action of Toxoplasma gondii toxin was not among the aims of our report; further studies are required in this area.

## Summary

A toxic material was prepared from Toxoplasma-infected peritoneal fluid of white mice by ultracentrifugation, absorption with anti-mouse guinea pig spleen cells, and repeated lyophilization and dialysis against distilled water. It was finally suspended in distilled water as a clear, nonviscous sterile solution. Control peritoneal fluid was produced by peritoneal injection of sterile broth, tapioca, or streptococcal extracts and treated in the same way. Anterior chamber and vitreal injection of this toxin produced necrosis of the vascular endothelium of the iris and ciliary body. It also destroyed fibroblasts, melanocytes, neuronal and glial cells, and bleeding occurred as a result of vascular changes. Control fluids produced no such changes. The cellular effects are those of a toxin and are similar to the necrotizing lesions seen in acute toxoplasmosis.

## Ophthalmic miniature

Every schoolboy knows that the termination *-itis* indicates inflammation, and it is rather a shock to those of them who become medical students, when they start pathology, and have inflammation described to them in great detail, to find that a lot of -itises (or itides) are by no means inflammatory. It is not merely conditions like chronic nephritis, appendicitis, and cholecystitis, which (though they commonly have no persisting inflammatory element) have at least the excuse that they are usually the sequelae of active inflammation, but there are conditions such as osteoarthritis, osteitis deformans, and osteitis fibrosa cystica in which there is no pretence of any inflammatory element. It is all very confusing for the student.

The odd thing is that etymologically speaking osteoarthritis is just as correct as peritonitis. To quote O.E.D.: "Greek *itis,* properly forming the feminine of (certain) adjectives, but often used substantively . . . as in Lake Asphaltis; (also) in Greek, used to qualify (disease) of the joints, etc." So in saying osteoarthritis, we are, strictly speaking, indicating the presence only of disease of bone and joint together, not of inflammation.

This piece of history should not, however, have any influence at all on our opinions as to present usage. We have established that *-itis* refers to inflammatory conditions, and we ought to stick to this. At least it is unlikely that anyone will knowingly coin any new noninflammatory uses. Where there are sound alternatives, as with osteitis deformans and cystica, we ought to prefer them. Where it is possible without confusion, we might encourage a shift to the neutral *-osis*—perhaps even osteoarthrosis. For old scarred organs, we might prefer such a term as fibrosis of the appendix to the implication of chronic inflammation. It is a mistake to try to reform a language overnight, but there is no harm in encouraging a process of attrition.

Reflections of a Lexicographer

# ANEURYSM OF THE OPHTHALMIC ARTERY WITH DRUSEN OF THE OPTIC NERVE HEAD

RICHARD D. CUNNINGHAM, M.D., AND J. JAY SEWELL, M.D.
*Temple, Texas*

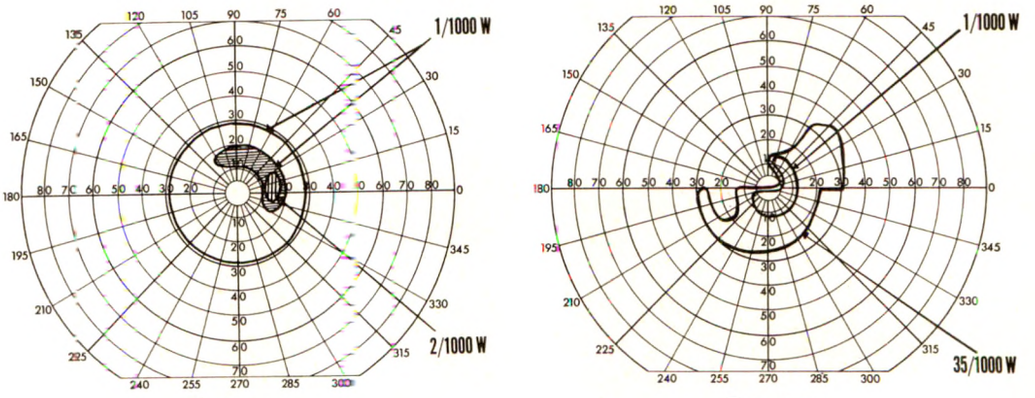
Drusen (hyaline bodies) in the optic nerve head may be responsible for defects in the visual fields,[1] and rarely, they are associated with tumors and other diseases of the intracranial structures.[2-4] Although extensive investigation usually seems unnecessary when hyaline bodies accompany visual field defects, some authors[2-4] have emphasized diagnostic discretion in these patients. The following report illustrates how an aneurysm of the ophthalmic artery might have been overlooked because of the presence of drusen in the optic nerve head.

## CASE REPORT

A 37-year-old woman had excellent health until May, 1967, when she began to have episodes of blurred vision with a "skim" over her eyes. In July, 1967, she experienced a period of complete amaurosis of the left eye, followed by a gradual return of diminished vision. During that episode, she was seen at another hospital and was told that she had optic atrophy and drusen of the optic nerve head. Her visual acuity progressively decreased, and she reported to Scott and White Clinic for the first time on November 28, 1967.

When she was first examined, visual acuity in the right eye was 20/20, and in the left, 20/70 with correction. The pupils were equal in size, but a Marcus Gunn pupillary response was noted in the left eye. Intraocular pressure was 14 mm Hg in each eye. The visual field examination of the left eye revealed a superior altitudinal defect with an arcuate scotoma extending inferiorly from the blind spot. The right eye had a relative superior arcuate scotoma (Fig. 1). Muscle balance and ocular rotations were normal. Numerous hyaline bodies were seen in both optic disks, and the left optic disk was moderately atrophic (Figs. 2 and 3). Spontaneous venous pulses were absent bilaterally. Hertel exophthalmometry was 12 mm Hg in both eyes. Retinal artery pressures were not recorded preoperatively.

The results of general medical and neurologic examinations were not remarkable. Kline, Kahn, and VDRL serologic tests were negative. The erythrocyte sedimentation rate (Wintrobe) was 30 mm in one hour, with a hemoglobin concentration of 13 g/100 ml. Glucose tolerance was within normal limits. An electroencephalogram and skull roentgenograms, including optic foramina views, did not demonstrate abnormalities. Percutaneous transfemoral selective left carotid angiography revealed a saccular aneurysm of the proximal portion of the left ophthalmic artery, beginning at the anterior aspect of the carotid siphon. The aneurysm had a wide mouth, a diameter of 4 mm, and was 10 mm in length (Fig. 4). A selective right carotid angiogram was interpreted as normal.



On December 4, 1967, a Silverstone clamp was applied and closed on the left internal carotid artery. Postoperatively, the only neurologic change was a transient blepharoptosis of the left eyelid. The clamp was removed on April 17, 1968. Ophthalmic examination on August 1, 1968, did not show progression of the visual field defects. The visual acuity in the right eye was 20/20, and in the left eye, 20/40-1. Ophthalmodynamometry revealed measurements of 76/28 mm Hg in the right eye and 16/5 mm Hg in the left eye. Intraocular pressure remained normal (14 mm Hg in each eye). The atrophy of the left disk was unchanged. A follow-up examination on February 5, 1970, did not reveal additional findings.

## COMMENTS

Aneurysms rarely occur in the ophthalmic artery—only 30 cases have been reported previously, and almost all of these lesions arose from the junction of the internal carotid and ophthalmic arteries. Most patients had visual field defects and decreased vision. The symptoms progressed slowly, and the course of the disease usually was benign.[5]

Drusen in the optic nerve head occur sporadically or in a heredofamilial, irregular dominant pattern based on an autosomal gene.[4,6] These hyaline excrescences have accompanied angioid streaks in pseudoxanthoma elasticum, corneal dystrophy, juvenile diabetes mellitus, Friedreich's ataxia, status dysraphicus, pituitary tumor, meningioma, and Wilson's disease.[4,6] They are also found in the atrophic optic nerves of patients with glaucoma, retinitis pigmentosa, and syphilis.[4] No other report of drusen in the optic nerve head in a patient with an aneurysm of the intracranial vessels was found.

RIGHT EYE LEFT EYE

Fig. 1 (Cunningham and Sewell). Preoperative visual fields. Left eye demonstrates a dense superior altitudinal defect. There are bilateral arcuate scotomas.

Rucker,[1] and Chambers and Walsh,[7] have reported seeing patients with enlarged blind spots as we noted in our patient's right eye. These authors also described nerve fiber bundle defects such as in our patient's left eye. In these reports, the preponderance of peripheral contraction of the visual fields in the lower nasal portion was in contrast to the superior altitudinal defect noted in our patient. Although several reports show progression of visual field defects associated with drusen of the optic nerve head, opinions differ as to whether or not these hyaline bodies may cause decreased visual acuity. Stiefel and Smith,[2] in an excellent review of their cases, concluded that if central visual acuity is significantly reduced, as it was in our patient, careful neurologic and ophthalmic evaluation should be carried out before attributing the visual loss to the hyaline

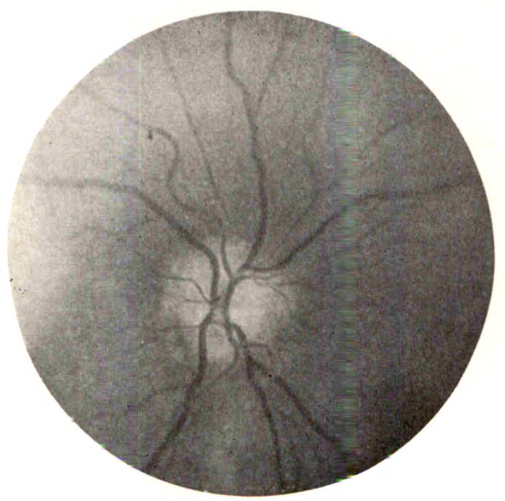

Fig. 2 (Cunningham and Sewell). Fundus (right eye) showing structural fullness of right disk and hyaline bodies of the optic nerve head.

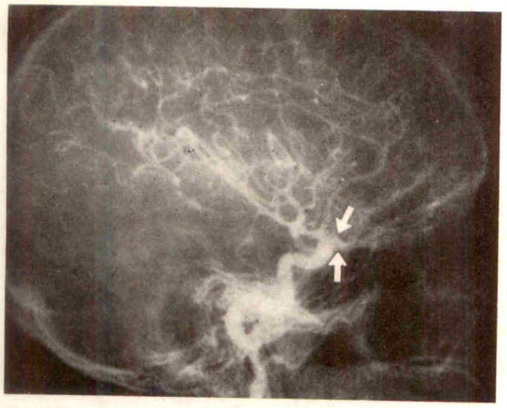

Fig. 4 (Cunningham and Sewell). Arteriogram (left carotid) demonstrating aneurysm of proximal portion of the left ophthalmic artery.

bodies alone. Optic atrophy without an obvious cause also warrants further clinical investigation.

## Summary

A 37-year-old woman with a significant decrease of visual function exhibited an aneurysm of the ophthalmic artery and drusen of the nerve head. To our knowledge, the coexistence of these conditions has not been reported previously.

Drusen usually do not cause abnormal pupillary responses and progressive loss of central acuity. Patients with such findings deserve careful ophthalmic and neurologic evaluation to screen out more serious underlying defects.

# ACHROMATOPSIA IN PINGELAP ISLANDERS

## Study of a Genetic Isolate

Ronald E. Carr, M.D., Newton E. Morton, Ph.D., and
Irwin M. Siegel, Ph.D.
*New York, New York*

Patients with congenital achromatopsia (total color blindness, rod monochromatism) typically complain of poor visual acuity and aversion to bright lights, since these symptoms are produced by their widespread loss of functioning retinal cones.[1] The incidence of this unusual vision disturbance is much lower than the commonly occurring forms of sex-linked color deficiencies, and affects males and females in equal numbers. The high rate of ancestral consanguinity (31% in Europe and 75% in Japan) in pedigrees with affected members indicates that the mode of inheritance is autosomal recessive.[2] Holm and Lodberg,[3] in their study of seven generations, including about 300 people, all from a small island off the coast of Denmark, found 20 persons with achromatopsia. Pedigrees such as this permit the study of phenotypic variations as well as a great many known carriers with a view towarl detecting carrier signs.

For two weeks we studied a group of South Pacific Islanders, the Pingelapese, who, according to a preliminary survey,[4] showed a high incidence of a condition closely resembling achromatopsia. Fortunately, a large number of Pingelapese have emigrated to the island of Ponape, some 190 miles from Pingelap, where the availability of electricity and hospital facilities allowed thorough examination.

From the Department of Ophthalmology, New York University Medical Center, and the Population Genetics Laboratory, University of Hawaii, Honolulu, Hawaii. This investigation was supported by USPHS Grants NB 2589, GM 1173, and EY 35004, and a Grant-in-Aid from Fight for Sight, Inc.

### History

Pingelap atoll is located in the Eastern Caroline Islands which are part of the huge archipelago known as Micronesia. This three-million square mile area of the Pacific Ocean includes the Caroline, Marshall, and Mariana island groups, and since the end of World War II is known collectively as the Pacific Trust Territory of the United States. Over a period of 250 years, many nations, including Spain, England, Germany, Japan, and America have instituted cultural and social changes on these islands, but it was a natural catastrophe two centuries ago which brought about the high incidence of achromatopsia in the Pingelapese. In the late 18th century a typhoon of great intensity struck the tiny atoll. Deaths from injuries, disease, and starvation reduced the population from about 500 inhabitants to about 20 persons. The survivors lost little time in rebuilding and repopulating their community, and by the early 1900s they numbered several hundred. At this time, the (German) administrators of the district, to alleviate overcrowding on Pingelap, assigned more than 100 natives to the large island of Ponape. Many other Pingelapese followed these early migrants, and it is now estimated that there are about 900 on Ponape and 600 remaining in Pingelap. Although this island contains several groups of immigrant populations, each engages in endogamous marriage practices, so that even in contemporary times the Pingelapese maintain in their population a high frequency of the gene for achromatopsia. The original survey[4] showed that the incidence of affected persons in the Pingelap Island population was 6%. Using the Hardy-Weinberg formula,[5] the calculated incidence

of the carrier state in this group is 37%. In a general population, on the other hand, one out of 30,000 persons was reported to be affected with achromatopsia,[6] and only 1% are carriers for the disorder.

## Materials and methods

*Routine testing*—With the help of Peace Corps volunteers who were fluent in Pingelapese and local dialects, we were able to obtain histories and perform subjective testing. Every patient was tested on the standard Snellen eye chart or illiterate E test at a distance of 20 feet. For children and those adults with severely reduced vision, the flash-card vision test of the New York Association for the Blind was used at a distance of five feet. Refractions were performed on any whose acuity was less than 20/30. Direct and indirect ophthalmoscopy was routinely done on all patients after dilatation, and photographs were taken with a portable (Model PRV Olympus Corp.) fundus camera.

*Color vision*—The Ishihara and the Hardy-Rand-Rittler pseudoisochromatic tests were administered under standard illumination by placing a Macbeth Illuminant "C" filter in front of a 100 watt frosted tungsten bulb. Patients with color defects were further tested with the Farnsworth D-15 panel, and Sloan achromatopsia strips.

*Special testing*—Determination of final dark adapted thresholds and electroretinography (ERG) were performed on patients with unusual visual problems, those suspected of being achromatic, and those known to be achromatopsia carriers. The ERG was recorded using a slightly modified Cambridge Model VS III portable electrocardiograph machine. A small solid state amplifier allowed the "sync-out" pulse from the Grass PS-2 photostimulator to activate the marker pen whenever the flash tube was pulsed, thus obtaining a stimulus mark on the record. In addition, the response to low frequencies was reduced to eliminate pen drift by inserting an appropriate R-C network into the accessory jack receptacle. Electrical shielding of the patient was not necessary because the amplification system receives the ERG signal plus background, and returns the inverted common mode signal to the subject through the ground lead. This inverted "driven ground" signal, while allowing amplification of the differential signal, tends to eliminate in-phase activity such as AC hum. After mydriasis and anesthetization of the cornea, a Burian-Allen type contact lens electrode containing a drop of Isopto Alkaline, was placed on the patient's eye. Metal disk reference and ground electrodes were fixed to the forehead and wrist with saline paste. For optimum recording, it was important to thoroughly cleanse and slightly abrade the skin area to which electrodes were attached with alcohol-soaked gauze sponges.

Final dark-adapted thresholds were obtained with a small box containing a light source powered by the ophthalmoscope transformer, a camera shutter set at 1/25 second, removable neutral density filters, and a pair of polaroid plates which could be varied to obtain small changes in stimulus intensity. A small red fixation light ensured that the stimulus, which subtended an angle of about 4.5°, fell 15° temporal to the fovea. Typically, the patient would have his right eye dilated and securely patched for at least one-half hour before the test. During this period of dark adaptation the examiner would explain the nature of the test and demonstrate what would be required. There was little difficulty obtaining reliable data once the patient understood the task. The object of this test was simply to establish the sensitivity of the subject's retinal rods relative to normal subjects; therefore, final thresholds are listed as higher (+) or lower (−) than averaged normal values in log units (Table 1).

## Results

A brief summary of the findings for the 26 affected patients is given in Table 1. Without exception, the affected individuals

TABLE 1

SUMMARY OF FINDINGS IN PATIENTS WITH ACHROMATOPSIA

had absent color vision and a best corrected acuity of 20/70 or less. In 13 patients on whom ERGs were done, there was an extinguished response to an intense 30 cps flickering light, a finding indicating that cone function in these patients was severely impaired. Normal rod function is, of course, as much a sine qua non of achromatopsia as generalized cone malfunction, and the results of several other tests must be scrutinized before a definitive diagnosis can be made.

Qualitatively, the results of the Farnsworth D-15 panel demonstrated that the scotopic system in these patients subserves vi-

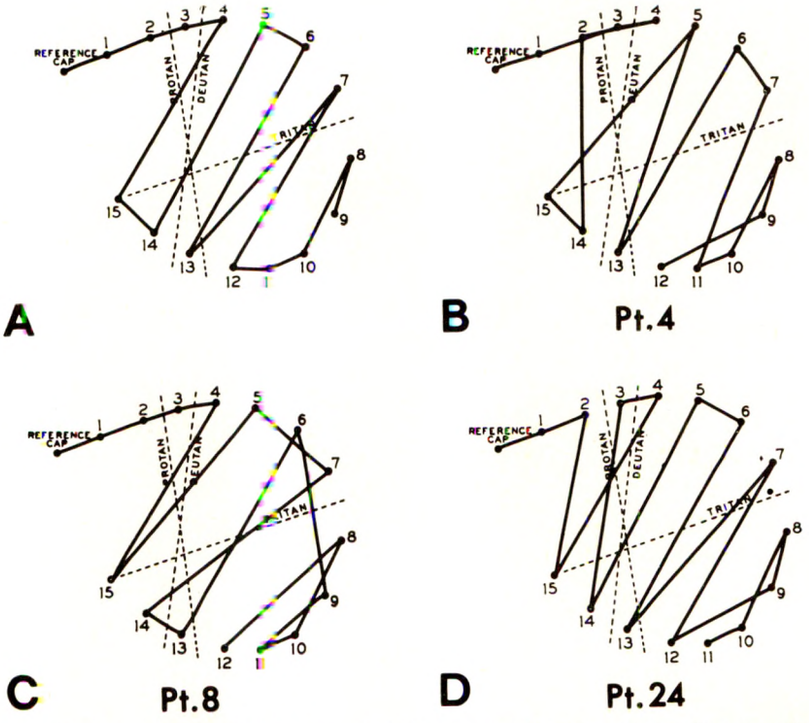

Fig. 1 (Carr, Morton, and Siegel). Farnsworth D-15 panel test results. If the disks are aligned on the basis of their scotopic brightness values, pattern A is obtained. It is clear that the achromatic patients Nos. 4 (B), 8 (C), and 24 (D), whose patterns were typical, use rod vision even at moderately bright light levels.

sion even at moderately bright light levels. Figure 1-A shows how the colored disks would be ordered on the basis of their scotopic brightness as computed by Sloan.[7] For comparison, actual patterns made by three affected patients are shown in Figure 1-B, C, and D. The test patterns of the different patients are remarkably similar and their approximation to the scotopic arrangement unmistakeable.

Two other tests of great importance in this regard are the dark-adapted (scotopic) ERG, which gives information about the massed electrical response of millions of rods, and the more sensitive test of dark adaptation. Ideally, the latter procedure should include the measuring of thresholds in several areas of the retina; however, our portable device allowed only measures of the final absolute threshold (not rate of adaptation) in one area of the retina. The results of both these tests are abnormal for the majority of affected patients (Table 1). But before advancing the notion that both cones *and* rods were affected, it should be noted that the majority of these 26 patients are myopic. Sixteen of them (62%) range from −5.00 to −16.50 diopters and all show pronounced fundus changes commonly associated with myopia. For the sake of brevity, refractive errors in Table 1 are given as spherical reductions; few of the patients had astigmatic errors greater than about two diopters, and none higher than 3.50 diopters. Including all degrees of myopia, it is seen that about 80% of the affected subjects have both achromatopsia and nearsightedness. It was precisely the highly myopic patients who showed low amplitude ERGs and raised (+) final thresholds, whereas emmetropic or mildly myopic patients (e.g., Patients 5, 9, 24, 25, and 26) gave normal responses to the low intensity

($S_1$blue) flash, the stimulus usually used to demonstrate rod function. Higher intensity flashes would be expected to be lower than normal since they also elicit a cone contribution to the response which of course would be lacking in these patients.

Figure 2 shows ERG recordings of a normal subject, one with six diopters of myopia, a patient (No. 25) who is affected but nearly emmetropic, and a patient (No. 4) who has both achromatopsia and high myopia. Clearly, the myopic patients have reduced b-waves, and the myopic patients with achromatopsia have the lowest responses of the whole group. It is not expected, however, that myopia itself invariably produces decreased ERGs since Franceschetti and associates[8] have shown that although b-waves from the affected eyes of patients who are unilateral myopic are very often much lower than their normal fellow eye, exceptions are not unusual (e.g., our Patient 8). Although high myopia affects rod function (which in uncomplicated achromatopsia is normal) a clear distinction can be made on the basis of ERG responses, final thresholds,

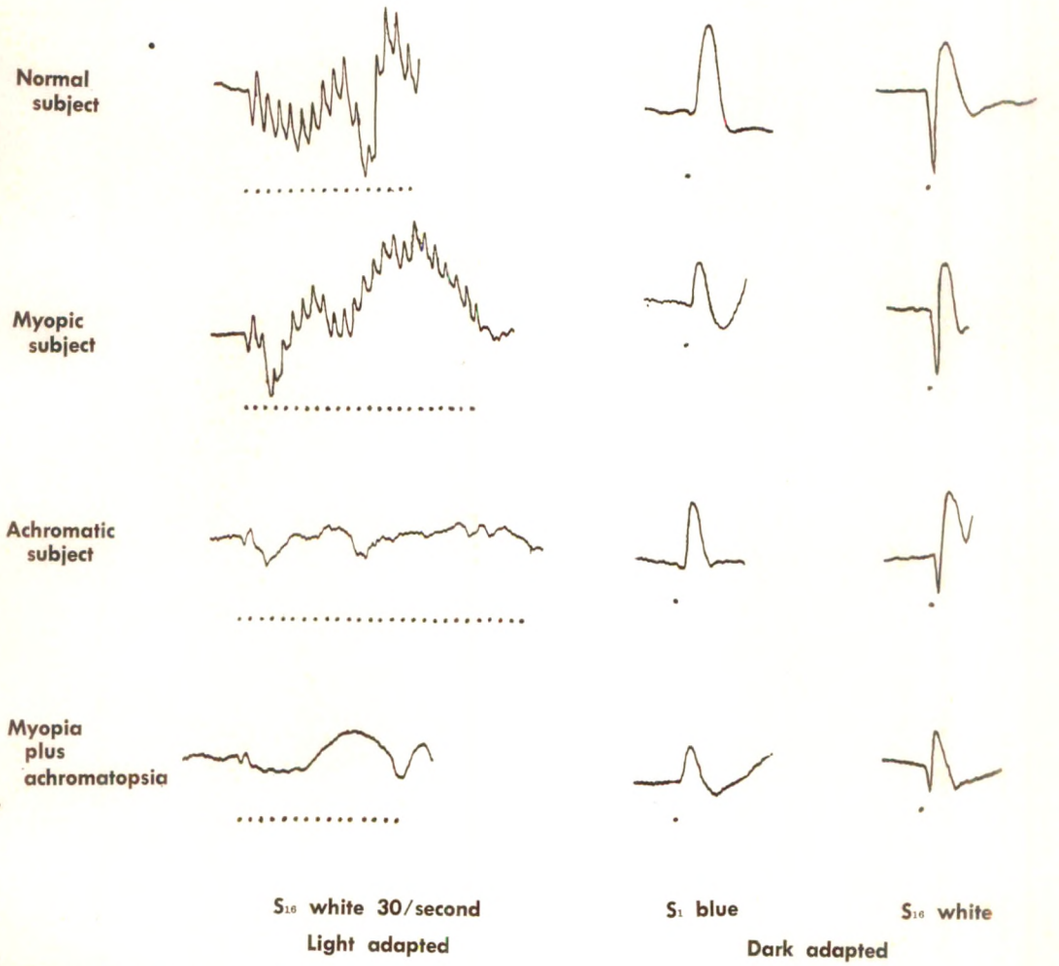

Fig. 2 (Carr, Morton, and Siegel). ERG tracings obtained using the equipment described in the text. The stimuli values $S_1$ and $S_{16}$ refer to the weakest and most intense flashes produced by the photostimulator. To produce maximal rod responses the eye was dark adapted for 10 minutes and then the low intensity $S_1$ flash with a (Grass Co.) blue filter was used.

and fundus appearance, between this group with myopia-achromatopsia and certain forms of generalized retinal degenerations in which symptoms relating to the cone impairment predominate, (e.g., the group III cone-rod dysfunction of Goodman and associates[9]).

Most of the affected patients had nystagmus. This is a variable finding in achromatopsia, however, and can range (as Table 1 shows) from no visible nystagmus to marked movement. There appears to be little relation between degree of nystagmus and any other finding.

Photophobia, or more accurately in the case of achromatopsia, aversion to light, was present to some degree in all of the affected patients. Several patients wore (plano) sunglasses, but the majority preferred not to, though it was obvious that they avoided open sunlight and continually looked downward to prevent dazzling.

Most completely achromatic subjects show lack of foveal reflex and the macular region often has a granular appearance.[9] Many of those affected showed macular abnormalities, and those having high myopia also showed fundus pathology associated with that disorder. Several patients had retinal changes that were independent of the achromatopsia and myopia. For example, Patient 10 had severe peripapillary choroidal sclerosis, generalized retinal pigmentation, and heavy lattice degeneration in the periphery. The very low scotopic ERG amplitudes in this patient reflected the extensive retinal pathology. Patient 3 presented lesions that appeared to be the result of congenital toxoplasmosis.

Ocular examinations were performed on 24 known carriers (i.e., persons who had one affected parent or women who had affected children). Of these, all but one older patient had a corrected acuity of at least 20/30 and many could read the 20/15 line with ease. Color vision as tested with the Ishihara and H-R-R plates was normal in all these patients. Electroretinography performed on several carriers showed, with the exception of the one patient noted below, completely normal photopic and scotopic responses.

Ophthalmoscopic examination revealed a variety of retinal changes, most of which are found in the general population as a result of aging. Of particular note was the finding of angioid streaks in three of the older carriers. In two patients this was associated with reduced vision and macular degeneration. These latter changes were, however, more typical of the senile form of macular dystrophy. About a third of the carriers show Gunn's dots[10] (hyaline verrucosities of the internal limiting membrane), which gave a pinpoint refractile appearance in the peripapillary area. Due to the superficial nature of these tiny nodules and their common occurrence in otherwise normal eyes, no significance can be attributed to them.

Of the younger carriers, one subject (No. 46) showed very marked fundus pathology, apparently of a vascular nature. Both eyes demonstrated extensive venous sheathing and several atrophic areas throughout the peripheral retina; the central areas appeared granular but otherwise normal. We were completely unprepared, therefore, to find a virtually extinguished ERG response to the flicker stimulus. This woman's photopic and scotopic ERG records are presented in Figure 3 along with responses from another normal carrier of about the same age for comparison. The scotopic ERG amplitudes were also smaller in Subject 46 than that of the other carriers, but this could have been due either to her extensive retinal changes or simply to the loss of the cone contribution to these responses, as in achromatic individuals. Of particular interest here is the fact that in spite of this marked cone dysfunction, visual acuity and color vision were normal in this woman. Obviously, the foveal cones were spared, since the small number of receptors in that region (1 or 2% of all the cones in the retina), while contributing little to the photopic ERG response, could nonetheless remain completely normal. But it is the generalized loss of cone function in this known carrier of achromatopsia that holds our at-

tention. Can her defect be considered a "carrier sign" of the disorder? This appears unlikely, since many of the other carriers who were tested had normal flicker ERGs. Moreover, this patient had obvious fundus pathology, which strongly suggests that the selective impairment of the cone system was a *secondary* involvement. This patient's functional findings are remarkably similar to Siegel and Smith's[11] Patient A with acquired achromatopsia, a 33-year-old woman whose visual acuity and color vision were only mildly affected, but in whom there was massive loss of cone activity as evidenced by an extinguished flicker ERG and gross constriction of her color (naming) fields. Interestingly, our patient evinced no photophobia, whereas a severe "dazzle effect" was a pronounced feature of Siegel and Smith's case. However, the presence of some functioning cones in this patient, as evidenced by a small photopic response (observable in the ERG record from the right eye) perhaps accounts for her lack of discomfort in bright lights. Because of the ophthalmoscopically visible pathology, we examined the medical background of our unusual carrier. She gave birth to her three children at the hospital, but the delivery and postpartum course in each case was uneventful. There was no indication of her having a systemic disease serious enough for hospitalization or intensive treatment during the 10-year period covered in the record. Specific tests done at the time of each admission included Kahn, sputum for AFB, CBC, urinalysis, and chest x-ray studies. These were normal or negative.

## Discussion

Pedigree analysis of the Pingelap population with regard to several genetic traits is in preparation and indicates that in so far as

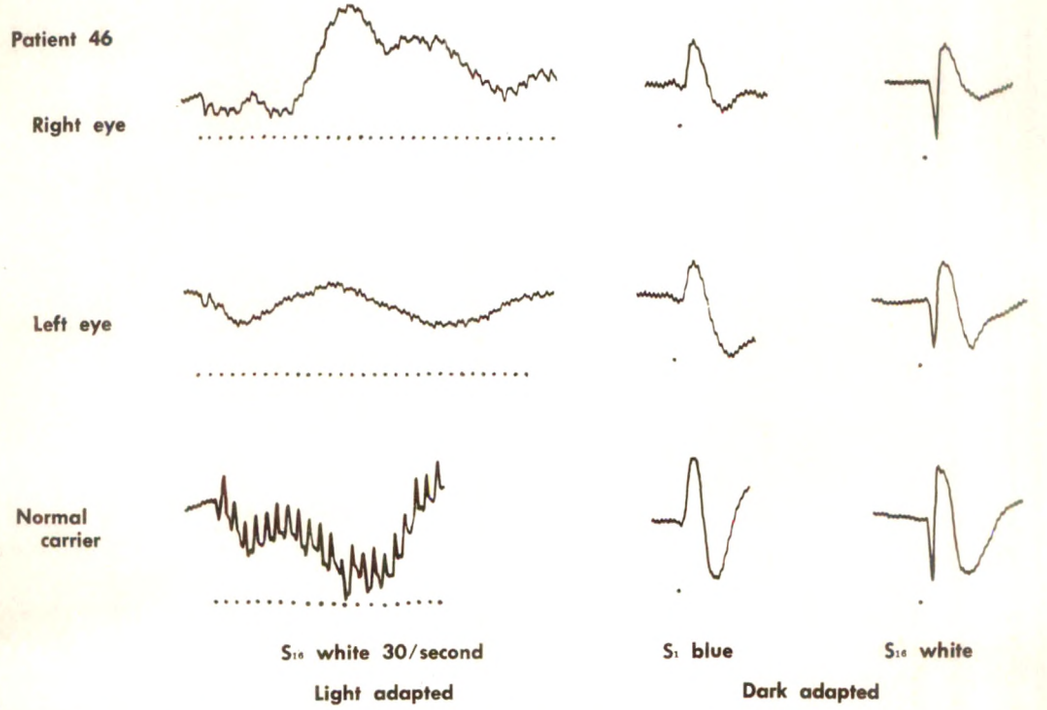

Fig. 3 (Carr, Morton, and Siegel). ERG recordings from the right and left eyes of Patient 46, a carrier with fundus pathology, predominantly of vascular origin, but who had good acuity and normal color vision. The reduction of cone function is most marked in the left eye, while rod responses in both eyes are within the lower limits of normal. Another carrier (Patient 48) is presented for comparison.

the ocular disorder is concerned, the mode of transmission is autosomal recessive. Typically, affected offspring had unaffected parents, who themselves had parents with achromatopsia or who had affected siblings. Usually, consanguinity of some degree between parents of affected children could be proven.

One of the outstanding features of our achromatic population is the large percentage of associated high myopia. This was not noted by Holm and Lodberg,[3] in the literature review by François and associates,[12] or in the 50 patients representing complete and incomplete forms of the syndrome studied by Goodman and his colleagues.[9] We are therefore reluctant to assume that high myopia is an effect of the gene for achromatopsia, although this possibility cannot be excluded. There seems little doubt that high degrees of myopia are transmitted as an autosomal recessive,[13] and if these genes are present in a highly inbred population such as the Pingelapese, the incidence should be much greater than in the general population.

It is of interest to pursue this relationship between achromatopsia and myopia in this group. Any discussion of the genetic probabilities must be theoretical, however, since matings between affected individuals never occur in this population. Thus, it is impossible to know the answers to such questions as: (1) Did matings of two affected individuals with both high myopia and achromatopsia ever produce an offspring with only achromatopsia? or, (2) Did matings of two affected individuals with only total color blindness ever result in an offspring with both disorders? The extensive pedigree analyses made during this trip and an earlier one show no instances of mating between affected individuals and in all cases there is a strict autosomal recessive pattern of heredity.

There is strong evidence against the gene loci for achromatopsia and myopia being on different pairs of chromosomes. Such an arrangement would result (according to the Mendelian law of independent assortment) in the following: Double heterozygotic parents (i.e., those carrying single genes for each of the conditions) could have 9/16 offspring who were phenotypically normal, 3/16 offspring with achromatopsia, 3/16 who were myopic, and 1/16 having both myopia and achromatopsia. The actual incidence of the different types is far from this prediction, making the possibility of independent gene action very unlikely. A more probable explanation is that the gene loci for myopia and achromatopsia exist as a linked pair on one chromosome. This pair of linked genes could have two configurations in the double heterozygote: (1) coupled (Fig. 4-left), in which both recessive alleles are on the same chromosome; or (2) in repulsion (Fig. 4-right), where the deleterious genes (a and m) are on opposite chromosomes. Two parents of the genotype shown in Figure 4-left can have normal and doubly affected (myopic and achromatic) children in the ratio 3/4:1/4 as shown in Figure 5-top. Two parents with the deleterious genes in repulsion (Fig. 4-right) can have myopic, normal, or achromatic children in the proportions 1/4:2/4:1/4, but *no* doubly affected children. Therefore, the coupled gene arrangement serves to explain most of the association between the two disorders. However, to completely account for the presence of those individuals

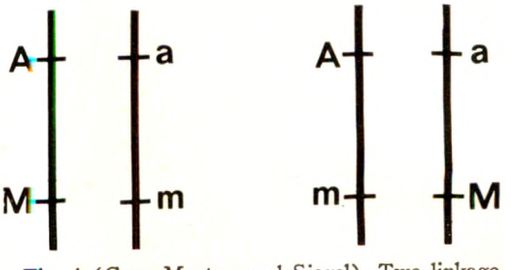

Fig. 4 (Carr, Morton, and Siegel). Two linkage arrangements of the achromatopsia gene (a) and the myopia gene (m) in the double heterozygote. The genes could be coupled (i.e., on the same chromosome) as on the left, or in repulsion, shown on the right. Parents of the genotype shown at the left can have normal children or children who have linked genes in repulsion. Parents of the genotype shown at the right can have normal children, achromatic children, or myopic children.

who were achromatic with no significant degree of myopia, recombination or crossing over, a process whereby material is reciprocally exchanged between members of a chromosome pair must be considered.

The further apart two gene loci are on a chromosome pair, the greater the likelihood of an exchange occurring. If the genes are very far apart and recombination occurs as much as 50% of the time, the number of gametic types produced will not be distinguishable from two genes located on different chromosome pairs which can assort independently during meiosis. For the chromosome pair shown in Figure 5-top, the possible offspring are a homozygote normal, two carriers, and a doubly affected child. If chromosome breakage and recombination occurs between the two genes in one or both parents, it is possible to produce new genotypes: achromatic *or* myopic individuals (Fig. 5-bottom) in addition to the non-recombinative forms. The schema of recombinative genotypes also shows that there is just as much chance of uncomplicated high myopia occurring as achromatopsia without myopia. We did not find any "pure" high myopia among any of the subjects examined, although only about a third of all the affected individuals noted in the original survey were seen.

Since poor vision was the only criterion used in selecting the majority of our subjects, our selection of patient material was not biased in favor of those having both conditions. Many of the children on whom subjective testing could not be done, and the several hundred natives living on the island of Pingelap, where lack of electricity made detailed testing difficult, were in a sense excluded from consideration, and perhaps further investigation of these persons will reveal some with high myopia. Absence of "pure" high myopia in this population would argue strongly against two linked genes with a detectable recombination rate. Since high myopia is not produced by the gene for achromatopsia in other populations, and evidence of recombination between the two

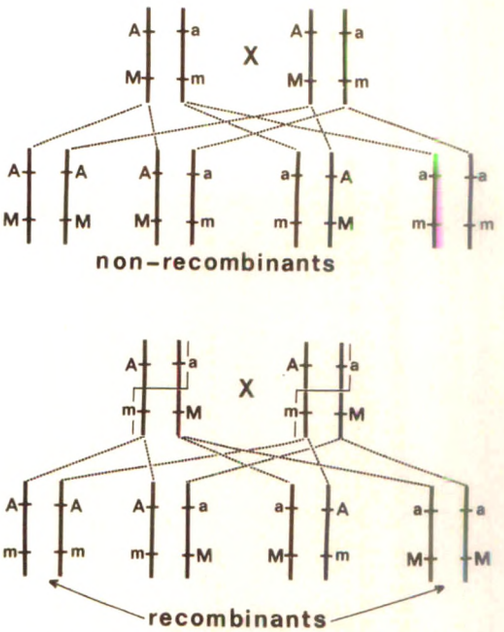

Fig. 5 (Carr, Morton, and Siegel). Possible offspring of double heterozygotes, where the genes are coupled on the same chromosome, are shown in the top figure. The affected offspring are both achromatic and myopic. All others have at least one normal allele (A and M) to produce a normal individual. If the exchange of chromosomal material takes place between the two gene loci as shown in the lower figure, offspring may be achromatic or myopic.

genes is incomplete, what other mechanisms would account for the close association of these defects among the Pingelapese? One possibility is a single mutational event (such as an inversion, unequal crossover, or deletion) which simultaneously affects two linked genes. Then the probability of recombination could be negligible, and we would not expect to find "pure" high myopia. Unfortunately, this hypothesis is not distinguishable by genetic evidence from a pleiotropic effect of the allele for achromatopsia, and also leaves unexplained the several achromatic individuals without appreciable refractive error.

The Pingelap Islanders are not an exceptional genetic isolate; many have been reported from remote areas and no doubt several more with other ocular problems will be

discovered. The combination of swift transportation and portable diagnostic equipment afford the ophthalmologist a unique opportunity to study in detail great numbers of patients afflicted with rare disorders. It is now possible to obtain, in a short period of time, enough information to completely define mode of transmission, expressivity, and penetrance of a specific genetic abnormality.

## Summary

A high percentage of a genetically isolated population from the island of Pingelap was found to have symptoms of poor visual acuity, loss of color vision, nystagmus, and photophobia. History indicated a high degree of ancestral consanguinity, and study of family groups showed the disorder to be transmitted as an autosomal recessive trait. Ocular examination, including psychophysical testing as well as electroretinography, was performed on affected patients and known carriers and revealed the disease to be congenital achromatopsia. This condition, relatively rare in the general population, was present in 6% of these islanders. In addition, about 80% of the affected individuals had associated myopia, the majority in the pathologic range.

### Acknowledgments

We thank Dr. Irene E. Hussels, who performed the original visual screening of the Pingelap population, and Jane Hurd and Beth Rye, Peace Corps volunteers, for their service as translators and their invaluable assistance. We also thank Dr. E. Pretrick, of Kolonia Hospital, who provided space for the study and arranged for transportation of the patients and ourselves on the island of Ponape.

# PERIODIC ALTERNATING NYSTAGMUS

## A Report of Eight Cases

Dale G. Davis, M.D., and J. Lawton Smith, M.D.
*Miami, Florida*

Periodic alternating nystagmus is infrequently recognized in this country. Towle[1] counted only 40 cases in the world literature, and of these, but three were in English. Only one case has appeared in the American ophthalmic literature.[2] The following is a report of eight cases of periodic alternating nystagmus, a description of its characteristic nature, and an etiologic differential diagnosis.

### Case reports

*Case* 1—This 38-year-old black woman was hospitalized because of leiomyomata of the uterus. Neuro-ophthalmic consultation was requested because of abnormal eye movements. On ocular examination the corrected visual acuity was 20/25 in both eyes. The pupils reacted 2+ to light, and there was a 4+ reaction to near. The slit lamp, fundus, and visual field findings were normal.

Motility examination revealed classic periodic alternating nystagmus. This was manifested by a horizontal, jerk-type nystagmus whose amplitude gradually increased to a maximum, and then similarly abated. This phase lasted 110 seconds and was followed by a 20-second quiet interlude during which there was no nystagmus. A similar sequence then followed with the rapid phase in the opposite direction. The amplitude of the oscillations increased when she looked into the direction of the rapid phase, and decreased when she looked into the direction of the slow phase. This cycle repeated itself over and over again. Of interest was the fact that the horizontal nystagmic movements were also present in vertical gaze. During the height of the oscillations the patient's visual acuity decreased and she experienced oscillopsia.

The past history revealed that at the age of 16 years she had delivered a stillborn fetus and several months later a serological test for syphilis was reactive. She was treated for this with penicillin at age 16 and again at age 20. At the age of 30 years a progressive neurologic disease began which was unremitting. In 1961 she began to note aching pains in her legs and began having difficulty seeing. An optician told her she had "jumping eyes." There was an insidious onset of difficulty in walking and paresthesia in the extremities. Hearing loss began on the left. She was hospitalized in 1963 and thought to have multiple sclerosis. By 1967 she required a walker, and began having difficulty with bladder and bowel control. One year prior to admission she obtained a wheelchair.

Neurologic examination revealed motor weakness in the lower extremities, and a mild dystaxia of the upper extremities. Skull x-ray examination and a cervical myelogram were normal. Blood tests for syphilis revealed a weakly reactive VDRL and a 2+ reactive FTA-ABS test.

### Comment

This 39-year-old woman had a stillborn fetus at the age of 16 years, and shortly thereafter was found to have a reactive serological test for syphilis. She was treated for this with penicillin at the ages of 16 and 20 years. In the past 10 years she developed progressive spastic paraplegia and periodic alternating nystagmus. She also had lightning pains in the right upper extremity, involvement of sphincters, and a hearing loss in the left ear. The impression was neurosyphilis with myelitis and periodic alternating nystagmus. A three-month course of ampicillin and probenecid (Benemid) was advised.

*Case* 2—A 49-year-old white man was referred with a chief complaint of "attacks of blurred vision." At the age of 44 years he noted the onset of episodes of blurred vision and oscillopsia which would last for five to 30 seconds. These increased in frequency to approximately 100 a day. The patient also noted clumsiness in walking and slurring of his speech for the past 18 months. Three years previously neurologic examination, lumbar puncture, bilateral carotid and right vertebral arteriograms were normal. A trial of corticosteroids was of no help.

On examination the visual acuity in the right eye was 20/25 and in the left eye 20/30. The visual fields and ocular fundi were normal. Electronystagmography demonstrated periodic alternating nystagmus with rapid phase to the right followed by a nystagmus with the rapid phase to the left. When

TABLE 1

ELECTRONYSTAGMOGRAPHIC DATA FROM CASE 2

| | Rapid Phase to the Right | | | Rapid Phase to the Left | | |
|---|---|---|---|---|---|---|
| | Right Gaze | Primary Gaze | Left Gaze | Right Gaze | Primary Gaze | Left Gaze |
| Duration (seconds) | 134 | 111 | 81 | 91 | 108 | 113 |
| Frequency/second | 3 | 3 | 1.8 | 1.8 | 2.2 | 4 |

the rapid phase was to the right, in right gaze the duration of the nystagmus lasted 134 seconds with an oscillation of three beats per second, in primary gaze the nystagmus persisted at 111 seconds at three beats per second, and in left gaze persisted for 81 seconds, at a rate of 1.8 beats per second. When the fast phase of the nystagmus was to the left, in right gaze the direction of each episode of nystagmus was 91 seconds with a frequency of 1.8 per second, and in primary gaze the duration was 108 seconds with a frequency of 2.2 per second, and in left gaze the duration was 113 seconds with a frequency of 4 per second (Table 1).

Optokinetic responses had no effect on the nystagmus in any direction. However, cold caloric responses had a definite effect in that irrigation of the ear with ice water abolished the nystagmus and reversed its direction.

Neurologic examination revealed mild dysarthria, vertical ocular dysmetria, modest abnormality in heel-to-shin testing, some imbalance in walking heel-to-toe, and some dyssynergy on foot patting and pivoting.

Skull x-ray films, electroencephalogram, serum FTA-ABS test, and spinal fluid examination were normal.

A trial of meclizine HCl (Antivert), isoxsuprine HCl (Vasodilan), and carbamazepine (Tegretol) showed no improvement. Diphenylhydantoin sodium (Dilantin) decreased the duration of the cycle by 30 seconds with a slight slowing of oscillations in the rapid phase to the left and a shorter period of crescendo in the rapid phase to the right. A repeat examination two years later revealed no change.

The clinical impression was periodic alternating nystagmus probably due to demyelinizing disease.

*Case 3*—A 21-year-old black woman was hospitalized with the chief complaint of headaches, nausea, and vomiting of 10 days' duration. Three days prior to admission she noted blurred vision and horizontal diplopia. Two days before admission severe vertigo and a staggering gait developed. This patient had sickle cell anemia since the age of three years requiring numerous transfusions, and had suffered bouts of abdominal and joint pain.

On admission she was lethargic and markedly ataxic. Spinal fluid examination revealed a normal opening pressure but a pleocytosis of 330 leukocytes/ml$^3$, 15% polymorphonuclear leukocytes, 85% mononuclear leukocytes, and a protein of 77 mg%. The impression was viral encephalitis and sickle cell anemia.

On neuro-ophthalmic examination the visual acuity was 20/60 in both eyes. There was a left blepharoptosis, a slight left hypertropia, and anisocoria, with the left pupil slightly larger than the right. Both pupils reacted well to light but there was a slight Marcus Gunn pupil phenomenon on the left. The optokinetic responses were right 1+, left 1+, up 3+, and down nil. The fundi showed slight optic nerve pallor on the left.

The most striking eye finding was periodic alternating nystagmus. An electronystagmogram showed disorganized, short, rapid saccades rather than a well-organized nystagmus. The periodic alternating nystagmus appeared as follows: left-beating nystagmus was 75 seconds per cycle at 28 to 35 beats per 10 seconds. There was a 10 to 15 second rest period, followed by a right-beating nystagmus of 110 seconds per cycle with 35 to 40 beats every 10 seconds. The left-beating nystagmus could be virtually eliminated by extreme right gaze, and the right-beating nystagmus could be reduced, though not eliminated, by extreme left gaze. The nystagmus could be increased by stimulating the visual attention, and diminished by having the patient stare at a blank wall. The nystagmus continued with the eyes closed. The nystagmus could be modified by the optokinetic drum, although not eliminated or reversed. The direction of the rapid phase could be reversed by irrigation of the left ear with cold water (30°C) during the left-beating nystagmus, and during right-beating nystagmus the rapid phase could be reversed to left-beating nystagmus by a similar irrigation into the right ear.

The patient was treated with whole blood for the hematologic problem, and the spinal fluid cleared in the succeeding three weeks. There was a gradual improvement in the patient's severe truncal ataxia. A 10-day course of corticosteroids gave no improvement.

The impression was postinfectious or viral meningoencephalitis with periodic alternating nystagmus and sickle cell disease with aplastic crisis.

*Case 4*—A 70-year-old white man complained of "a hemorrhage in the back of my left eye." Seven years previously the patient suffered a vitreous hemorrhage in the right eye with a permanent loss of vision. Tow months previously he noted a loss of vision in the left eye. A general medical examina-

TABLE 3

CLINICAL IMPRESSION IN EIGHT CASES OF PERIODIC ALTERNATING NYSTAGMUS

1. Syphilitic myelitis
2. Demyelinizing disease with cerebellar involvement
3. Encephalitis with cerebellar involvement
4. Total amaurosis secondary to vitreous hemorrhage
5. Total amaurosis secondary to syphilitic optic atrophy
6. Congenital
7. Encephalomyelitis
8. Congenital, associated with albinism

amaurosis. Case 5 had bilateral syphilitic optic atrophy, whereas Case 4 developed periodic alternating nystagmus two to three weeks following a vitreous hemorrhage. Cases 1 and 5 both had syphilis. Cases 6 and 8 should be considered congenital.

Case 8 was remarkable since the patient was a universal albino, but without the usual searching nystagmus seen characteristically in such individuals. There is no previous record in the literature of periodic alternating nystagmus associated with albinism.

The pathophysiology of periodic alternating nystagmus has not been firmly established. Duke-Elder[3] stated that the phenomenon was most probably a central vestibular disturbance but that the mechanism was not clear. Kestenbaum[9] also indicated a central vestibular mechanism as the cause of this form of nystagmus. Kornhuber[19] proposed a central vestibular disturbance following a lesion in the tegmentum. He stated that the nystagmus was caused by a bilateral lesion of parts of the rostral paramedian reticular formation of the pontomesencephalic tegmentum.

Towle[1] reported the first case of periodic alternating nystagmus studied neuropathologically and found an arachnoid cyst caudal to the cerebellum, displacing the cerebellum upward, with medullary compression. His second case[24] studied neuropathologically was found to hae a midline posterior fossa (Arnold-Chiari variant) lesion. These two cases have strengthened the hypothesis that a central vestibular disturbance is present in periodic alternating nystagmus. The fact that periodic alternating nystagmus may occur on a congenital basis as well as following blindness due to ocular disease does not necessarily rule out the presence of a concomitant central vestibular lesion.

It is our feeling that periodic alternating nystagmus is not as rare as it has been previously reported. Because of its characteristic nature it can be easily recognized merely by studying all cases of nystagmus over a more prolonged period of time than is usual, and comparing right and left lateral gaze on repeated occasions. Three of our eight cases have been recognized in the past six months.

It is important to recognize this peculiar form of nystagmus because of its known etiologic factors. These include demyelinizing disease, neurosyphilis, encephalitis, blindness, congenital anomaly, and albinism. Their recognition may often obviate the necessity for extensive neurologic studies.

A careful history should be taken, inquiring as to onset, exacerbations, and remissions. A complete ophthalmic and neurologic examination, including examination of the serum FTA-ABS test and spinal fluid are suggested as the initial workup in these cases.

## SUMMARY

Periodic alternating nystagmus is a characteristic neuro-ophthalmic motility disturbance. Horizontal nystagmus with the rapid phase to the right is followed periodically by left-beating nystagmus. This pattern recurs at regular intervals. This entity is present in vertical gaze, and is an exception to the general rule that horizontal nystagmus on upgaze or downgaze points to congenital nystagmus. Periodic alternating nystagmus is associated with certain clinical conditions; it is important to recognize this peculiar form of nystagmus because known etiologic factors include demyelinizing disease, neurosyphilis, encephalitis, blindness, congenital anomaly,

and albinism. Diphenylhydantoin sodium (Dilantin) therapy merits further trials in reducing oscillopsia in this disorder.

ACKNOWLEDGMENTS

We thank Dr. Noble J. David for Case 4 and Dr. J. Donald M. Gass for Case 8.

grees of dysfunction of intraocular postganglionic innervation.

Abnormalities on pupillography were typical of defective oculosympathetic innervation with anisocoria, absent psychosensory response, and characteristic alterations of the pupillary reactivity (Fig. 1). The initial anisocoria average approximately 10.06 mm, and there was no significant difference in anisocoria between darkness and dim background light (Table 1). Seven patients had anisocoria of less then 0.25 mm, whereas three had anisocoria of greater than 1.0 mm. The degree of anisocoria was exaggerated by repetitive light stimulation or by psychosensory stimuli. The psychosensory response was absent on the affected side in all but three patients, and in these three, it was markedly reduced in comparison to the normal side. At the termination of the series of light stimuli, the affected pupil had a delayed recovery toward its initial size, contributing to an exaggeration of the anisocoria.

Pharmacologic testing in 19 of the 21 patients with abnormal findings on pupillograms allowed separation into two groups: those with complete postganglionic sympathetic denervation and those with incomplete denervation (Table 2). Complete sympathetic denervation was found in five patients who had no mydriatic response to cocaine on the involved side but a good response to dilute epinephrine, indicating denervation with supersensitivity. Only one patient in this group was tested on separate occasions with cocaine and with hydroxyamphetamine, and this patient had no mydriatic response to either drug.

TABLE 1

EXTENT OF ANISOCORIA IN 21 PATIENTS WITH IMPAIRED INTRAOCULAR SYMPATHETIC INNERVATION

| Anisocoria | Dark | | Background Light | |
|---|---|---|---|---|
| | Mean (in mm) | SE | Mean (in mm) | SE |
| Initial | 0.57 | 0.08 | 0.61 | 0.08 |
| After three light stimuli | 0.95 | 0.11 | 0.91 | 0.10 |
| Increase with light stimulation | 0.37 | 0.06 | 0.31 | 0.05 |

In 14 patients, incomplete postganglionic sympathetic denervation was indicated by pupillographic abnormality and reduced mydriatic response to either cocaine or hydroxyamphetamine. Either drug produced an average mydriatic response that was less than half of the response of the normal pupil. There was no significant difference between the average response to cocaine and the average response to hydroxyamphetamine for the groups that received these drugs alone or for the five patients who received each drug on separate occasions.

Intraocular pressures, recorded for 16 of the patients, were lower by 2 to 6 mm Hg on the side with oculosympathetic paresis in

TABLE 2

MYDRIATIC RESPONSE OF PUPILS TO PHARMACOLOGIC TESTING

| Drug | Ocuolosympathetic Paresis | | | | Normal Pupil | |
|---|---|---|---|---|---|---|
| | Complete | | Incomplete | | | |
| | Mean (mm) | SE | Mean (mm) | SE | Mean (mm) | SE |
| Cocaine (4%) | −0.10 (n=5) | 0.03 | +0.50 (n=14) | 0.11 | +1.62 (n=19) | 0.20 |
| Epinephrine (0.1%) | +1.78 (n=5) | 0.41 | — | — | — | — |
| Hydroxyamphetamine (1%) | −0.32 (n=1) | — | +0.63 (n=6) | 0.09 | +1.45 (n=7) | 0.16 |

three patients, all of whom had incomplete sympathetic denervation. In the remaining 13 patients tested, intraocular pressures were equal in both eyes.

## Comment

Cluster headaches are considered a variant of migraine or vasodilating headaches in which the transient vasodilatory phenomena responsible for the syndrome are limited to the distribution of the carotid artery.[3] Experimental studies have demonstrated that, in some patients, dilatation of the branches of the external carotid reproduces pain in the typical region involved by the headaches and that, clinically, dilatation and tenderness of the temporal artery may occur, as well as flushing of the skin on the affected side. In other patients, however, the pain is reproduced by dilatation of the internal carotid artery and its branches.

In evaluating ocular signs associated with cluster headaches, Kunkle and Anderson[8] observed transient miosis during attacks in seven patients, while eight of their patients had permanent signs of oculosympathetic paresis with blepharoptosis and miosis. Two patients observed by these authors during an attack,[10] as well as one observed by Cogan,[11] each had a dilated pupil that later returned to normal size, thus suggesting a transient irritative sympathetic lesion. In attempting to explain the transient and permanent changes in pupillary size, these authors postulated a combination of sympathetic paresis, which probably occurs in the region of the carotid siphon where dilatation of the artery within the bony canal would injure the internal carotid plexus, and of parasympathetic discharge, which would contribute to the transient miosis, lacrimation, and rhinorrhea.[10] Nieman and Hurwitz,[5] however, stated that the miosis noted during attacks appeared to be solely the result of sympathetic dysfunction and that there was little evidence that parasympathetic discharge was responsible for this change.

All of our patients had permanent oculosympathetic paresis at the time of their evaluation; each of them had been aware of blepharoptosis on the involved side. Some patients remarked that this had been a transient phenomenon initially, occurring only with headaches for a varying time before becoming permanent; the majority were aware of the permanent narrowing of the palpebral fissure after their first episode of headaches. A few patients had permanent narrowing of the fissure only after many years of the attacks. The degree of narrowing of the palpebral fissure is consistent with the narrowing observed in Horner's syndrome due to a postganglionic sympathetic lesion or induced by blockade of the postganglionic oculosympathetic fibers.[9] The narrowing is due to involvement of the sympathetic innervation of both the upper and lower eyelids.

Dissociation of eyelid and pupillary involvement was found in three of our patients with typical narrowing of the palpebral fissure but normal pupillary and pharmacologic responses. This has been mentioned by other authors,[5,8] who have observed blepharoptosis or miosis alone, or blepharoptosis associated with miosis. The dissociation suggests that there may be a separation within the internal carotid plexus of the fibers innervating eyelids and pupil and that selective injury results in this dissociation.

Most of our patients were found by pupillography to have dysfunction of pupillary sympathetic innervation. On the basis of responses to topical pharmacologic testing, we have interpreted this as complete or incomplete postganglionic sympathetic denervation. Cocaine and hydroxyamphetamine are both indirect-acting sympathomimetic agents, and a mydriatic response to these drugs is predicated on the presence within the iris of intact sympathetic neurons that contain stores of norepinephrine. The mechanism of action of the two drugs, however, is different. Cocaine blocks the uptake mechanism of the presynaptic neuronal membrane, which is primarily responsible for terminating the action of norepinephrine (which has been released ei-

ther spontaneously or by nerve stimulation); cocaine does not by itself cause a release of norepinephrine from the neuron or its storage vesicles. Hydroxyamphetamine, however, acts by a competitive displacement of norepinephrine from presynaptic storage vesicles; its sympathomimetic activity depends only on intact sympathetic neurons and has no relationship to the rate of liberation of norepinephrine from the neurons. The usefulness of hydroxyamphetamine and similar indirect-acting agents such as tyramine as pharmacologic indicators for evaluating oculosympathetic innervation recently has been emphasized by Thompson and Menscher.[12] Although cocaine has commonly been utilized for such evaluation, the results may be difficult to interpret because a response depends not only on intact sympathetic neurons but also on the rate at which transmitter is released. With hydroxyamphetamine, any variability due to the rate of release of transmitter is eliminated. For this reason, we have utilized hydroxyamphetamine with increasing frequency in evaluating oculosympathetic paresis.

When complete sympathetic denervation occurs, there is no response to indirect-acting sympathetic drugs, and a supersensitivity to direct-acting sympathomimetic agents such as epinephrine and phenylephrine develops. Five of our patients had findings consistent with complete postganglionic sympathetic denervation and supersensitivity, for there was no reaction to cocaine or hydroxyamphetamine but a prompt mydriatic response to dilute epinephrine. Fourteen patients had a subnormal response to cocaine or hydroxyamphetamine, which we interpret as evidence of incomplete postganglionic sympathetic denervation. In support of this interpretation is the observation that two of the patients had segmental mydriasis only, limited to less than 30% of the circumference of the iris.

The observations regarding oculosympathetic paresis in these 24 patients and the variations in the extent of sympathetic dysfunction seem consistent with the supposition that injury to the internal carotid plexus occurs during the episodic dilatation of the artery that produces the headache. Anatomically, the most likely site for this injury is along the intraosseous portion of the internal carotid,[5,8] with variation in the extent of sympathetic involvement that may be related to the distribution of the fibers constituting the internal carotid plexus. Alternatively, one would have to postulate focal lesions occurring at different levels of the internal carotid plexus to explain the variation in sympathetic involvement. Data from our group of patients indicate that patients more likely will develop incomplete sympathetic denervation involving the eyelids and pupil, or the eyelids alone, rather than complete oculosympathetic denervation.

The incidence of permanent oculosympathetic paresis in patients with cluster headache evaluated at the Mayo Clinic is approximately 5%, which is comparable to the group reported by Kunkle and Anderson[8] (about 8%) but considerably less than that recorded by Nieman and Hurwitz[5] (22%), who commented on the selective bias which accounted for their high incidence. In the past seven years, more than 245 patients have been evaluated in the Pupillography Laboratory for Horner's syndrome or oculosympathetic paresis. Cluster headaches and associated oculosympathetic paresis account for approximately 10% of this group, and constitute one of the largest categories in which a specific etiologic diagnosis can be assigned to Horner's syndrome. For comparison, in patients evaluated in the Pupillography Laboratory, Horner's syndrome due to a malignancy represents less than 3% of the entire series (unpublished observation). This incidence is strongly biased by the selection and referral of patients for pupillography.

## Summary

Twenty-four patients with oculosympathetic paresis associated with cluster head-

aches were studied by infrared electronic pupillography and pharmacologic testing. Sympathetic dysfunction varied from paresis of the sympathetic innervation of the eyelids alone to complete postganglionic denervation of the eyelids and iris with denervation supersensitivity; most of the patients had incomplete postganglionic sympathetic denervation. These findings are consistent with the supposition that injury of the internal carotid plexus during the headaches results from dilatation of the intraosseous portion of the internal carotid artery.

# GUARDED THERMAL SCLEROSTOMY

ROBERT N. SHAFFER, M.D., JOHN HETHERINGTON, JR., M.D.,
AND H. DUNBAR HOSKINS, JR., M.D.
*San Francisco, California*

An overfunctioning sclerocorneal fistula is the most frequent cause of complications following filtration surgery. These complications include hyposecretion with resultant risk of failure of filtration, choroidal detachment, macular edema, cataractogenesis, synechia formation, and corneal endothelial damage causing stromal edema. By the suture technique to be described, the surgeon is able to control aqueous flow through the surgically produced stoma during the early postoperative period, thus diminishing the problem of a flat anterior chamber.

The established surgical method of correcting the problem of an overfunctioning sclerocorneal fistula is usually quite effective and involves the injection of air into the anterior chamber, accompanied, when necessary, by posterior sclerotomy and drainage of subchoroidal fluid. However, it is desirable to have a method of avoiding the flat anterior chamber in order to obviate the attendant trauma to both the patient and the surgeon resulting from a second trip to the operating room so soon after a primary procedure.

More recently, the microsurgical techniques of trabeculectomy, trabeculotomy, and sinusotomy have been introduced. One of the major advantages of these techniques is to obtain a surgically produced pressure-lowering effect without causing a flat chamber. These techniques, however, are more difficult to perform than routine filtration procedures and require an intimate knowledge of the minute structure of the limbal area as well as familiarity with microsurgical techniques.

Various nonoperative techniques which usually involve tamponade of the bleb area have been suggested. Gehring[1] devised a bandage which exerted pressure over the bleb by its position on the upper eyelid. Chandler and Simmons[2] have tried several scleral contact shells and conjunctival suture techniques in an effort to flatten the bleb and thus prevent unimpeded drainage of aqueous from the chamber.

These methods, though frequently effective, have the disadvantages of being cumbersome, uncomfortable, or too inflexible to meet varying postoperative conditions. They are, however, useful in other types of filtration surgery while the procedure to be described here can effectively close only the slit-like opening of a thermal sclerostomy. We believe the guard suture avoids the above-mentioned disadvantages while remaining simple, effective, and relatively free of complications.

The evolution of this procedure began 15 years ago as an extension of a technique advocated by Dr. William Ferguson of San Francisco. In those narrow-angle eyes suspected of having associated trabecular damage, he suggested performing a peripheral iridectomy in the routine manner. On the third postoperative day, if the pressure remained elevated, he removed the suture closing the sclerocorneal incision in hopes of obtaining filtration. In 1960, Dr. Thomas Pettit expanded this idea and performed a procedure similar to the one to be described here on a small series of patients. It was also per-

formed by Becker and Shaffer[3] in the early 1960s, but it is only within the past few years that it has been used with any frequency.

## Technique

Thermal sclerostomy is a procedure familiar to most ophthalmic surgeons and will be described only briefly:

A large limbus-based conjunctival flap is fashioned in the upper nasal quadrant. The usual 3-4 mm incision is made through the outer two-thirds of the surgical limbus and cautery is applied to the wound edges. A 7-0 black silk suture double-armed with 3/8 circle reverse cutting needles (Ethicon G-6, Davis & Geck CE 20) is then passed into clear cornea at a point 2 mm anterior to the conjunctival flap. It is guided posteriorly at a depth of one-half the corneal thickness, passing beneath the limbal insertion of the conjunctiva to emerge in the incision at the junction of its middle and medial thirds. It is continued through the posterior lip of the wound to emerge from the sclera 1.5 mm behind the incision (Fig. 1-B). The return passage of the suture reverses the route, passing through the sclera, crossing the incision at the junction of its middle and lateral thirds to emerge from the cornea 2 mm anterior to the conjunctival insertion (Fig. 1-A). Thus, a firm mattress guard suture has been placed across the limbal incision with its free ends emerging from the cornea anterior to the conjunctival flap. At no time is the flap perforated. The transincision portions of the suture are then withdrawn from the wound and used for traction while the operation proceeds (Fig. 1-C).

The incision is deepened by sharp dissection interspersed with applications of cautery. After entering the anterior chamber, an iridectomy is performed. A surgeon's knot is then fashioned in the guard suture, and,

while the operator fills the anterior chamber with balanced salt solution, the assistant tightens the knot to approximate the wound edges and form the chamber. The surgeon's knot is secured with a single bowknot (Fig. 1-D). The conjunctival flap may be closed with continuous or interrupted 7-0 black silk sutures and the eye is patched. To facilitate manipulation of the suture during the postoperative period, the ends should be left 2 cm long. Subsequent adjustments of the suture can then be easily performed in the office under topical anesthesia.

At the first postoperative dressing, the eyes will have a formed chamber and 50% will have a bleb present. This is the ideal situation, and the suture should remain undisturbed until the fifth postoperative day, when both the bow and surgeon's knot are loosened. If the chamber remains formed for two days, the suture may be removed. If, however, the chamber should flatten, the suture should be re-tied to be loosened again in while the operator fills the anterior chamber two days.

In those eyes with a formed chamber but no evidence of bleb formation by the second postoperative day, both knots are loosened and a bleb usually forms spontaneously. If the bleb does not form with the suture loosened, gentle pressure on the cornea has rarely failed to form one. The suture should then be left in place, untied, until the fifth postoperative day so that it may be tightened again should the chamber collapse. If this occurs, the suture is secured for two more days. This process may be repeated as necessary. These sutures have been left in place for as long as 14 days without adverse affects.

## Discussion

It is generally accepted that flow of aqueous through the corneoscleral stoma is necessary to maintain patency of the fistula by collagenolysis. Teng and associates[4,5] found degeneration of collagen around filtration wounds where collagen fibers were in direct contact with aqueous. However, they also found portions of fistulas with an endothelial lining which prevented the lysis of collagen. They suggested that this lining arose from the iris endothelium which gained access to the fistula when the chamber was flat postoperatively.

Bellows and Chinn,[6] and later Bietti,[7] demonstrated in experimental animals that free drainage of aqueous from the anterior chamber, rather than resulting in an increased flow, actually caused decreased production of aqueous by the ciliary body after the first hour, resulting in a marked diminution of flow from the anterior chamber.

Thus a freely draining fistula can result in diminished aqueous flow, cause a flat chamber, and increase the risk of ultimate failure of filtration.

Although these studies seem to indicate a theoretical advantage could be gained by utilizing the guard suture in open-angle glaucoma, in practice the results have not varied significantly from those achieved by standard filtration procedures.

In the eye with narrow-angle configuration, however, there is a definite indication for the use of this technique. In such a globe, there is always risk of precipitating malignant glaucoma. Deepening the anterior chamber at the end of the procedure prevents anterior displacement of the lens–iris diaphragm and allows good cycloplegia and mydriasis. These factors encourage the normal anterior flow of aqueous and diminish the likelihood of malignant glaucoma. It also decreases the probability of lens incarceration in these eyes. In those narrow-angle eyes with combined-mechanism glaucoma in which it is impossible to preoperatively differentiate outflow obstruction that is due to iris apposition from obstruction that is due to trabecular damage, this technique may be used with a lighter application of cautery. If, postoperatively, no significant opening of the angle can be seen by gonioscopy, or marked elevation of intraocular pressure occurs, the suture can be loosened to obtain filtration.

Similarly, in aphakic glaucoma there are distinct advantages of this technique. By pushing the hyaloid back, incarceration of vitreous in the fresh wound is avoided. Immediate reformation of the chamber also prevents vitreocorneal adhesions and, by allowing mobility of the iris, averts iridovitreal adhesions. The latter can result in aphakic pupillary-block glaucoma resistant to treatment.

## Summary

A technique utilizing a mattress guard suture to obtain a formed anterior chamber immediately following thermal sclerostomy has several advantages, both theoretical and practical. The postoperative adjustment of the suture in the office can be carried out without difficulty. In order to prevent malignant glaucoma and postoperative problems with the vitreous body, this technique should be used in eyes with narrow-angle configurations and in aphakic glaucoma. The results, although based on a small series of cases, are encouraging, and this technique appears to have a useful place in the arsenal of anti-glaucoma surgery.

Propranolol (Inderal), an adrenergic beta-receptor blocking agent, is reported to reduce intraocular pressure in patients with chronic simple glaucoma.[1,2] The mode of action of propranolol was not elucidated, but it was suggested that the effect resulted from the action of propranolol on an adrenergic mechanism responsible for either the rate of formation of aqueous humor or on the facility for outflow. On the other hand, it was also demonstrated that topical application of isoprenaline and adrenaline will reduce intraocular pressure in man.[3-6] Consequently, propranolol may affect intraocular pressure by actions not directly related to an effect on adrenergic receptors in the eye. In man, the systemic administration of propranolol reduces heart rate and cardiac output and increases total peripheral resistance[7]; as a consequence the rate of formation of aqueous humor may be reduced.

To eliminate the actions of propranolol on the systemic circulation, we have studied the effect of the drug on intraocular pressure by applying it directly to the eye. In addition to its adrenergic blocking properties, propranolol, is a potent local anesthetic.[8] As this property may also affect intraocular pressure, we have compared the effects of propranolol with those of lignocaine, MJ 1999 and INPEA. The latter two drugs block adrenergic beta receptors,[9] but which have no local anesthetic action.

## METHODS

Observations were made in 62 hospitalized patients, 31 men and 31 women, all between the ages of 30 and 80 years. The patients were divided into three groups, according to diagnostic criteria:

*Group* 1. *Normal subjects*—These were 43 patients—(25 men and 18 women) admitted to the ophthalmic service for conditions not affecting intraocular pressure (e.g., conjunctivitis, dacryocystitis, central retinitis, strabismus, and cataract). These patients had not previously been given any drugs which might alter intraocular pressure.

*Group* 2. *Patients with chronic simple glaucoma*—The 12 patients belonging to this group (six men, six women) had monocular or binocular open-angle glaucoma as judged by field loss, tonometry, gonioscopy, visual acuity, and fundus observation. Prior to their present hospitalization, all had routinely used drugs commonly prescribed for the treatment of glaucoma, and after admission, treatment with these drugs was continued until the danger of an acute rise of intraocular pressure had passed. A period of at least five days elapsed after drug therapy ceased before the administration of propranolol began. Consequently, the intraocular pressures in these patients were not unduly high at the time observations were made (Table 1). In all patients in this group, the effects of the instillation of 0.9% saline was

studied on one day (as a control) and the effects of propranolol on the following day. The treatments were given in random order.

The patients in Groups 1 and 2 were randomly picked from the whole population of the ophthalmic service.

*Group 3. Patients with acute glaucoma*—Observations were made in seven women patients admitted to hospital with idiopathic or secondary acute glaucoma.

All patients remained in the supine position throughout periods of examination. Intraocular pressure was measured by a Schiøtz tonometer and expressed in mm Hg. With the exception of the experiments in which the effects of lignocaine and propranolol were compared in both eyes of the same patients, local anesthesia of the cornea was produced by the instillation of 3 drops of lignocaine 10 seconds before making the first control observations. Anesthesia was maintained throughout the period of observation by the administration of lignocaine every 30 minutes. In all patients except those seven who had a different drug applied to each eye at the same time, an electrocardiogram was made and heart rate determined by measurement of at least 10 R–R intervals (R–R = interval between two subsequent R waves of the electrocardiogram). Arterial pressure was measured by auscultation using a sphygmomanometer applied to the left arm. Mean arterial pressure (mm Hg) was taken as diastolic pressure plus one-third of pulse pressure. Local anesthetic activity was measured on the human cornea by using the Aesthesiometer (Cochet and Bonnet, Ltd.) and expressed in conventional units. The comparison between the activities of the four compounds was made by using the Friedman rank test. Intraocular pressure, heart rate, and arterial pressure were measured every 30 minutes, and when steady values were obtained, one of the following solutions was administered: (1) three drops of propranolol HCl (2% solution), (2) three drops of MJ 1999 HCl (2% solution), (3) six drops of INPEA HCl (2% solution), or (4) three drops of sodium chloride (0.9% solution). Each solution was administered to the conjunctival sac. In order to control the influence of sex, eye laterality, and experimental times on the changes in intraocular pressure, heart rate, and arterial pressure induced by any

treatment, an analysis of variance was carried out on the data exhibited at 0, 30 and 60 minutes before treatment and 30, 60, 90, 120 and 150 minutes after treatment.

## Results

*Intraocular pressure*—The averaged results from the three groups of patients are shown in Figure 1 and Tables 1 and 2.

*Control observations*—The instillation of saline into the conjunctival sac did not cause any change in intraocular pressure in patients with chronic simple glaucoma.

*Normal subjects*—In 18 patients (nine men, nine women) with normal intraocular pressure, propranolol eye drops produced a progressive reduction in intraocular pressure. This was maximal 120 minutes after administration of propranolol and was highly significant ($p < 0.01$) when men and women patients were taken as one group. No difference in the response to propranolol instillation was observed between the right and left eyes, while a marked and highly significant difference was recorded between the two sexes ($p < 0.01$): the decreases in intraocular pressure was 39% for men and 19% for women (Table 1).

*Patients with chronic simple glaucoma*—Propranolol produced a marked and significant reduction in intraocular pressure ($0.01 < p < 0.05$) in this group which was maximal 120 minutes after treatment. The response was similar in both sexes and in right and left eyes (Table 1, Fig. 1).

*Patients with acute glaucoma*—In patients with monolateral acute glaucoma, the administration of propranolol had no effect on the intraocular pressure of the diseased eye (Tables 1 and 2, Figs. 1 and 2) whilst it decreased the intraocular pressure in the contralateral, normotensive eye to 73.5% of control.

*Heart rate and arterial pressure*—The mean heart rates (beats per minute) during the control period were 8 in normal subjects, 78 in patients with chronic simple glaucoma, and 82 in those with acute glaucoma. After the administration of saline to patients with chronic simple glaucoma and of propranolol to the others, heart rate fell (Fig. 1). The decrease was maximal at 90 minutes and was highly significant ($p<0.01$) in all groups; this response was similar in men and women. The mean value for arterial pressure was 109 mm Hg and did not alter significantly in any of the groups of patients following the administration of either saline or propranolol.

*Effect of experimental drug in normal subjects*—Observations were made in 14 patients (seven men, seven women) in whom three drops of MJ 1999 were applied to both eyes after a one-hour control period. The averaged results in these patients are given in Table 3. In both sexes the introcular pressure fell during the control period, but no further change occurred.

*Effect of INPEA in normal subjects*—Observations were made in 14 patients (seven men, seven women) and the averaged results are given in Table 3. The administra-

| | | SE | ±0.4 | ±0.4 | ±0.4 | ±0.4 | ±0.4 | ±0.4 | ±0.8 | P>0.05 |

* Three drops of a 2% solution.
† Six drops of a 2% solution.

tion of six drops of INPEA had no effect on intraocular pressure in either sex.

*Local anesthetic effect on the cornea*—The effects of the four drugs, propranolol, lignocaine, MJ 1999, and INPEA, were compared in both eyes of 15 patients. Lignocaine was applied to one eye of all patients (either left or right at random) and either propranolol, MJ 1999, or INPEA was applied to the other eye. The averaged results are given in Figure 3. In the concentrations used, MJ 1999 and INPEA had no anesthetic effect. Propranolol and lignocaine were equally active and had a similar duration of action ($p>0.05$).

*Comparison of intraocular pressure effects*—Observations were made in seven patients with normal intraocular pressures. Propranolol and lignocaine were applied randomly to either eye of all patients. The drugs were applied every 30 minutes for 240 minutes and intraocular pressure was measured 15 seconds after each administration. The averaged results are given in Table 4 and Figure 4 and show that both the drugs lowered intraocular pressure; the effect was maximal at 120 minutes and was followed by a rise in pressure. There was no significant difference between the effect of the two drugs (Table 5).

## DISCUSSION

The present observations show that the topical administration of propranolol to the eye reduces intraocular pressure in patients with normotensive eyes and in those with chronic simple glaucoma. This result cannot be ascribed to propranolol-induced changes in systemic hemodynamics, as arterial pressure was unaltered after topical application of the drug to the eyes and heart rate decreased to some extent both in control and in propranolol-treated patients. The effect is apparently not due to blockade of adrenergic beta receptors, as MJ 1999 and INPEA administration had no effect on intraocular pressure. In patients with normotensive eyes both lignocaine and propranolol reduced intraocular pressure to the same extent.

In all patients with normotensive eyes and in those with chronic simple glaucoma, intraocular pressure fell during the control period during which lignocaine had been applied to the eye to enable the measurement to be made. Thus lignocaine would appear to reduce intraocular pressure in these patients

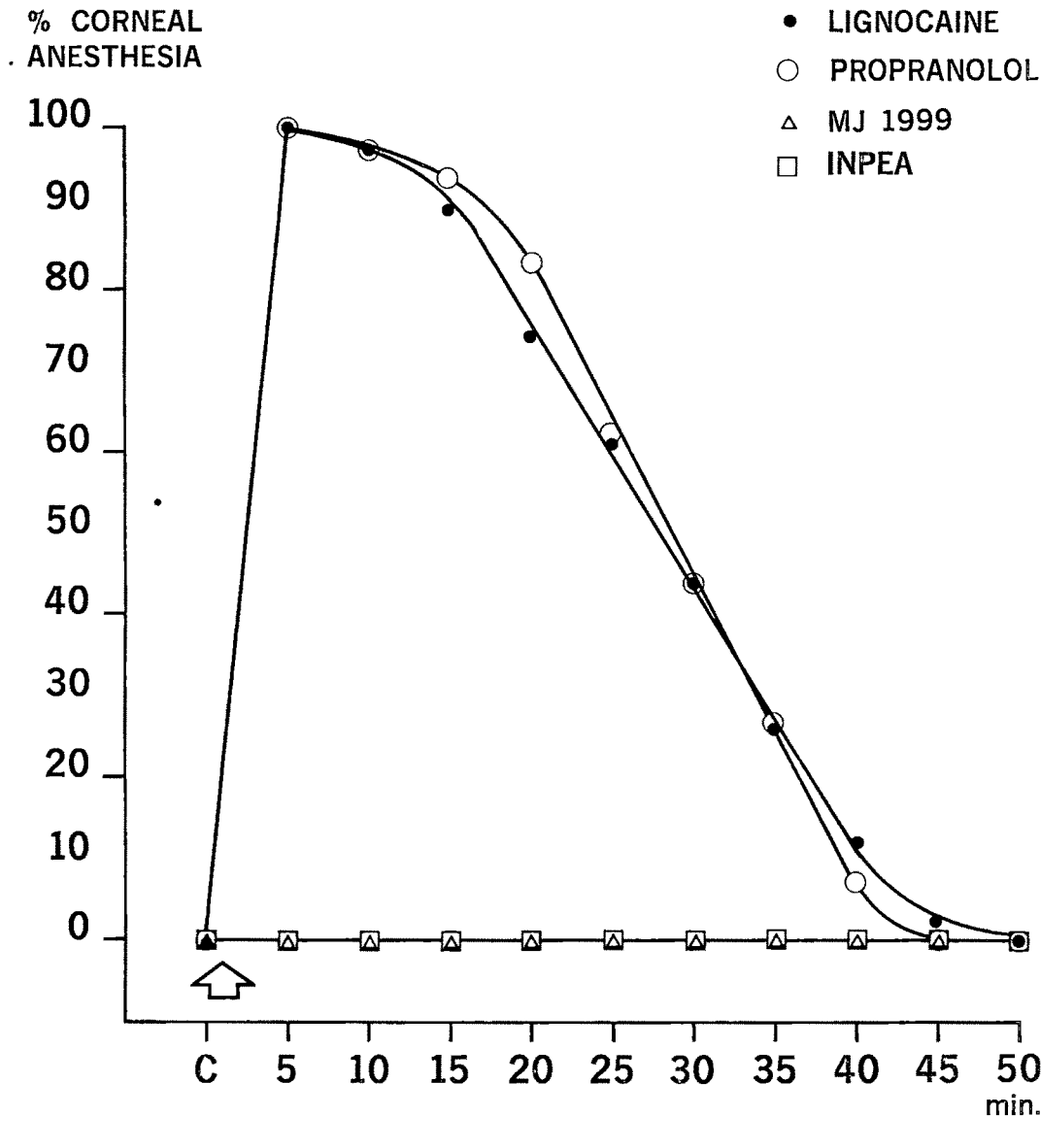

Fig. 3 (Musini and associates). Curves representing the intensity and duration of the local anesthetic activity of lignocaine (-O-), propranolol (-●-), MJ 199 (-□-), and INPEA (△). Each point is the mean value expressed as percent of the highest level of recorded from 15 healthy male subjects.

through its local anesthetic action. The present experiments have also shown that propranolol is as effective as lignocaine as a local anesthetic agent on the human cornea. These results all suggest that reduction in intraocular pressure produced by propranolol on topical application to the eye is due to its local anesthetic action. The present experiments do not explain the observations of Phillips and associates,[1] who reported a decrease in intraocular pressure after intravenous and oral administration of propranolol, as the local anesthetic action of propranolol on parenteral administration has not yet been determined in man.

There is also evidence from our results

TABLE 4

COMPARISON OF EFFECTS OF PROPRANOLOL AND LIGNOCAINE WHEN APPLIED CONTEMPORANEOUSLY TO FELLOW EYES

| Treatments | No. Eyes | | Time (in minutes) After Treatment | | | | | | Controls |
|---|---|---|---|---|---|---|---|---|---|
| | | | 30 | 60 | 90 | 120 | 180 | 240 | |
| Propranolol | 7 | $\bar{x}$ mm Hg | 15.6 | 15.1 | 14.5 | 14.0 | 14.2 | 15.1 | 16.9 |
| | | SE | ±0.46 | ±0.66 | ±0.80 | ±0.67 | ±0.77 | ±0.54 | ±0.57 |

that, when topically applied, both propranolol and lignocaine lower intraocular pressure when the iridocorneal angle is open, but not when the angle is closed, as in acute glaucoma. This conclusion is further supported by the evidence that propranolol and lignocaine decrease the intraocular pressure of the normotensive eye of patients whose contralateral eye is glaucomatous.

These findings suggest that the site of action of these drugs is in the chamber angle and that it involves a mechanism which can modify the resistance to outflow of the aqueous humor. The effect of these drugs may result from a reduction of the myogenic tone of the smooth muscle in the canal of Schlemm and in the other drainage channels, as the intra-arterial administration of propranolol and lignocaine reduce vascular smooth muscle tone.[11] Propranolol and ligno-

caine have also been observed to depress the myogenic activity of the isolated rabbit ileum.[11]

## SUMMARY

When the mechanism underlying the hypotensive action of propranolol on intraocular pressure was investigated in three groups of ophthalmic patients, propranolol, applied topically, decreased intraocular pressure in the normotensive eyes and in those with open-angle glaucoma, but not in eyes with acute glaucoma. Two beta-adrenoceptor blocking drugs which have no anesthetic activity, MJ 1999 and INPEA, did not alter intraocular pressure. When propranolol was applied to one eye and lignocaine to the other contemporaneously in normotensive patients, the two drugs were found to be equally potent in decreasing intraocular pressure. The present results suggest that the reduction in intraocular pressure consistently observed after topical application of propranolol to the eyes is due to the strong local anesthetic action of this drug.

## ACKNOWLEDGMENTS

The propranolol used in these experiments was supplied as Inderal (Imperial Chemical Industries, Ltd.) eye drops by Vister, Ltd., MJ 1999 (Sotalol) is a product of Mead Johnson, and the INPEA was supplied as eye drops by Selvi and Co., Ltd.

# ACQUIRED AUTOSENSITIVITY TO DEGENERATING DESCEMET'S MEMBRANE IN A CASE WITH ANTERIOR UVEITIS IN THE OTHER EYE

J. Reimer Wolter, M.D., Frank D. Johnson, M.D., Roger F. Meyer, M.D., and John A. Watters, M.D.

*Ann Arbor, Michigan*

Acquired hypersensitivity to degenerative products of certain ocular tissues is an important factor in several serious eye diseases. Such diseases include phakoanaphylactic uveitis, sympathetic ophthalmitis, scleritis (necroscleritis nodosa, scleromalacia perforans, or massive scleritis), and giant cell arteritis (temporal arteritis). Hypersensitivity to degenerating Descemet's membrane may also develop, and this possibility, being apparently less well known, seems worthy of emphasis.

Hogan, Kimura and Thygeson[1] first reported the presence of foreign-body giant cells next to Descemet's membrane in cases of herpes simplex keratitis with stromal involvement. In 1964 and in 1967 reports by Zimmerman,[2] and Green and Zimmerman,[3] described similar observations in cases of longstanding ulcerative keratitis and suggested that the granulomatous reaction around Descemet's membrane might be indicative of an aquired autosensitivity to this structure. Green and Zimmerman[3] emphasized that Descemet's membrane is a remarkably permanent structure that resists the usual proteolytic enzymes released in corneal inflammations. They concluded that the granulomatous reaction around Descemet's membrane could be related either to a change in the physiochemical nature of Descemet's membrane or to the development of different proteolytic enzymes capable of its dissolution.

This paper presents a case in which there was a granulomatous inflammatory reaction to Descemet's membrane fragments which definitely showed evidence of dissolution. Clinical evidence of granulomatous uveitis in the other eye of this patient was of special interest.

## Case report

This 84-year-old white man was first seen in the Veterans Administration Hospital Eye Clinic in December, 1969, with a six-month history of corneal ulcer of the right eye. Initially, the eye was scratched by the branch of a fruit tree. Treatment with topical antibiotic eye drops proved unsuccessful. Examination revealed hand motion vision only in the right eye and normal vision in the left. The right eye was irritated and red, and a deep corneal ulcer extended over most of the lower half of the cornea. This was surrounded by corneal edema and neovascularization. Descemet's membrane was bulging and formed a broad descemetocele.

The patient was admitted. Cultures revealed coagulase-positive Staphylococcus aureus. Treatment with systemic and topical antibiotics plus calcium disodium EDTA was started. The cultures soon became negative, but the ulcer persisted. In January, 1970, a conjunctival flap procedure was performed over the lower half of the right cornea. This temporarily improved the condition and the patient was discharged. Over the next several months he remained comfortable, but the cornea continued to bulge and form a large corneal staphyloma with a paper-thin, opaque corneal layer (Fig. 1). There was definite evidence of slowly increasing chronic irritation and deep pain.

In May, 1970, a one-plus flare reaction was found in the anterior chamber of the previously normal left eye. This eye also exhibited multiple mutton-fat keratic precipitates (KPs). Topical corticosteroid and mydriatic therapy was started in the left eye and removal of the blind and irritated right eye was advised. The patient absolutely refused enucleation, but he finally permitted the blind eye to be eviscerated after being told that with this procedure the outer shell of the eye would be left in place. Evisceration of the right eye was accomplished without difficulties. Postoperatively recovery was uneventful. The left anterior uveitis quickly cleared and has not recurred.

### Histopathologic study

The ocular contents of the right eye were composed of cornea, lens, and the collapsed uvea, retina, and vitreous. The thin cornea with its conjunctival covering was cut in cross sections. Histologically, it exhibited extreme thinning and neovascularization of the stroma. Fragmentation of Descemet's membrane was seen and this had caused many defects in this layer. Extensive granulomatous inflammatory reaction with giant cells, epithelioid cells, and a broad zone of mononuclear cells was seen in the region of the fragmented Descemet's membrane. Giant cells were found, especially next to and around the margins of the fragments of Descemet's membrane (Fig. 2). In many areas, the margins exhibited splitting of Descemet's glass membrane into two layers, and the most extensive granulomatous reaction was found in areas with this autolytic splitting (Fig. 3). More advanced destruction of Descemet's membrane also seemed to have caused a severe granulomatous inflammatory reaction (Figs. 4 and 5).

The iris was attached to the bulging cornea causing a total adherent leukoma. The lens exhibited cortical cataractous changes only and the lens capsule was intact. The retina exhibited diffuse atrophy and perivascular lymphocytic infiltration. It is important to emphasize that all of the uvea showed only a diffuse non-granulomatous inflammatory response, exhibiting dense lymphocytic infiltration (Fig. 6).

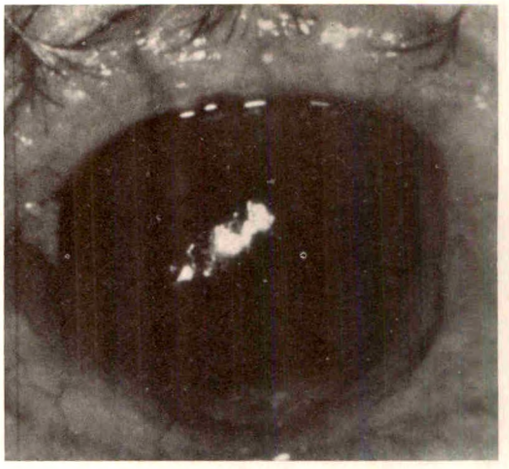

Fig. 1 (Wolter, Johnson, Meyer, and Watters). Right eye, showing staphyloma and adherent leukoma shortly before evisceration.

### Discussion

A rare combination of interesting findings is seen in the present case: fragmentation

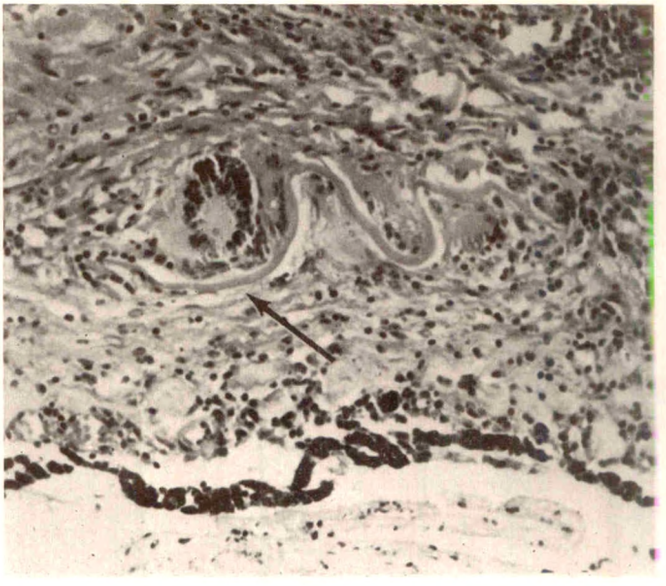

Fig. 2 (Wolter, Johnson, Meyer, and Watters). A fragment of Descemet's membrane (arrow) with a large giant cell near its deteriorating end. The iris is atrophic and firmly attached to the posterior corneal surface (paraffin section, hematoxylin and eosin, ×250).

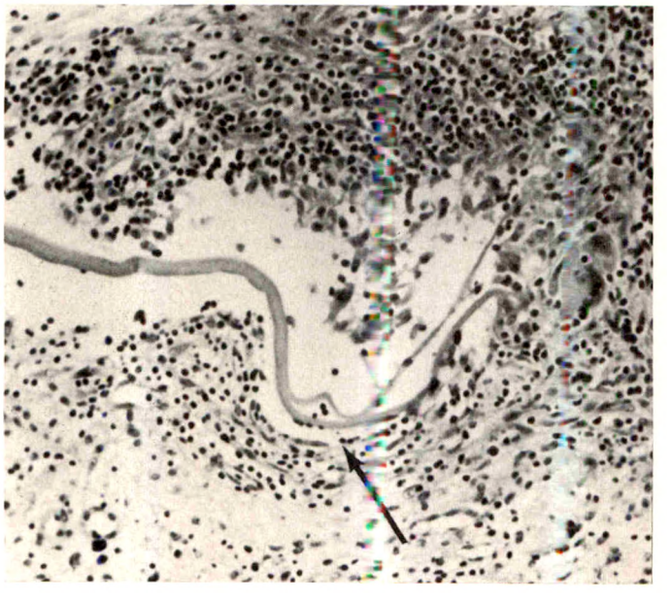

Fig. 3 (Wolter, Johnson, Meyer, and Watters). Autolytic lamellar splitting of Descemet's membrane (arrow) with granulomatous inflammation around it deep in the cornea (paraffin section, hematoxylin and eosin, ×250).

and autolytic splitting of Descemet's membrane, granulomatous inflammatory reaction centering on Descemet's membrane fragments, and clinical evidence of granulomatous anterior uveitis in the other eye.

Autolytic lamellar splitting of Descemet's membrane was observed long ago by anatomists in maceration studies.[4] Similar splitting has been described more recently as a late consequence of corneal trauma and degeneration.[5] Typical autolytic splitting of Descemet's membrane was observed in a case of a longstanding corneal ulcer in a 64-year-old patient (Fig. 7). The ulcer in this case was treated conservatively for several weeks and then covered with a conjunctival flap. Enucleation was finally necessary. Lamellar splitting of Descemet's membrane

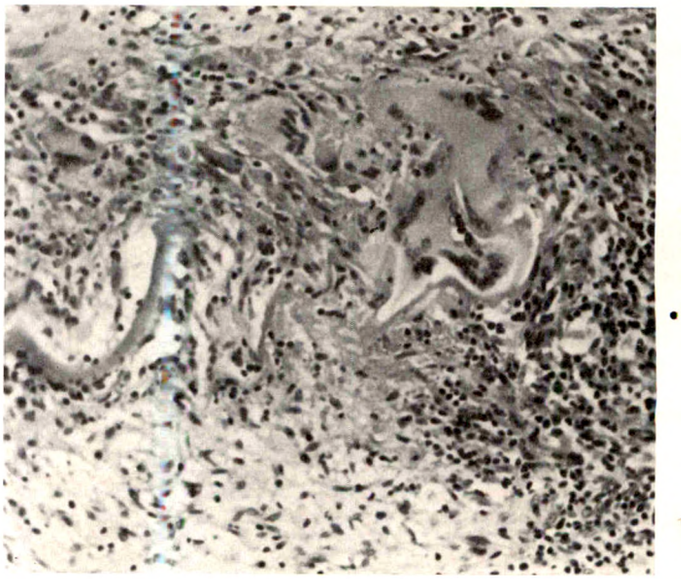

Fig. 4 (Wolter, Johnson, Meyer, and Watters). Large giant cells, epithelioid cells and lymphocytes around the degenerating edges of a fragment of Descemet's membrane deep in the cornea (paraffin section, hematoxylin and eosin, ×250).

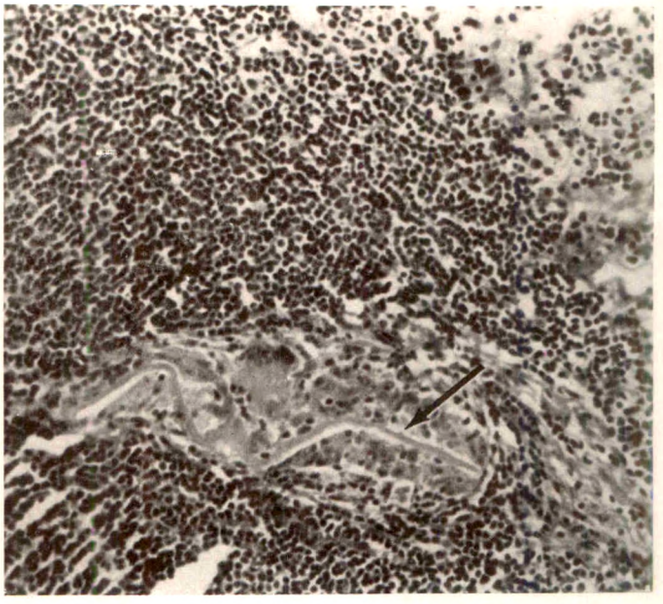

Fig. 5 (Wolter, Johnson, Meyer, and Watters). Low-power view of the localized granulomatous response around a fragment of Descemet's membrane (arrow) deep in the cornea (paraffin section, hematoxylin and eosin, ×100).

was found around the ruptured corneal ulcer.

The autolytic lamellar splitting in the present case indicates an advanced stage of deterioration of Descemet's membrane. This can be assumed to accompany the occurrence of protein breakdown products—much like those known to occur in the lens, for example, in situations that lead to a phakoanaphylactic uveitis.

The cases of Zimmerman and Green[2,3] showed little evidence of proteolytic changes in Descemet's membrane; whereas in contrast the present case shows advanced changes of this kind. This may indicate that the granulomatous reaction around Descem-

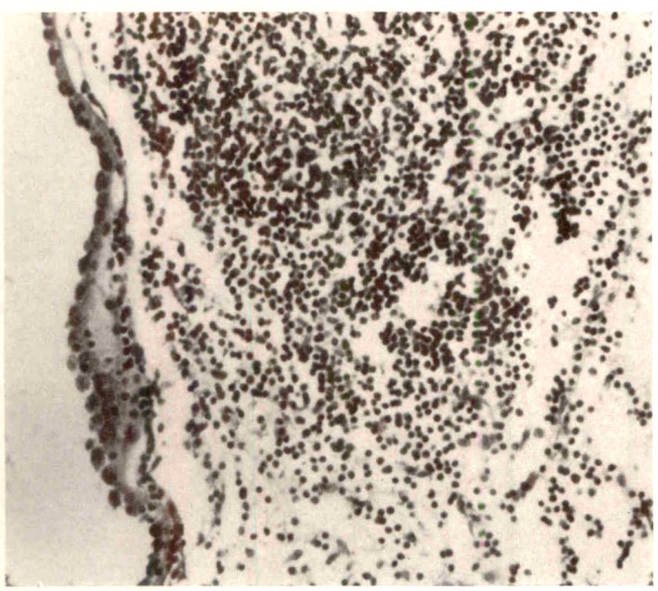

Fig. 6 (Wolter, Johnson, Meyer, and Watters). A portion of choroid and pigment epithelium exhibiting non-granulomatous chronic inflammation only (paraffin section, hematoxylin and eosin, ×250).

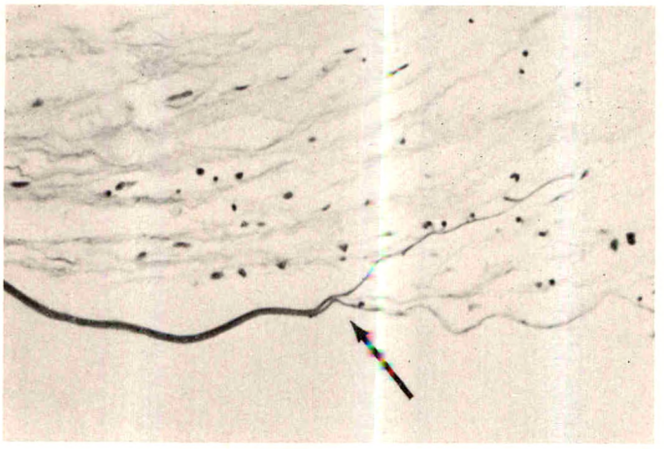

Fig. 7 (Wolter, Johnson, Meyer, and Watters). Typical autolytic lamellar splitting of Descemet's membrane (arrow) as seen in a second case with longstanding corneal ulcer (paraffin section, hematoxylin and eosin, ×250).

et's membrane fragments was not simply a foreign-body reaction, but that true hypersensitivity to breakdown products of this glass membrane had developed. Support for this theory is gained by a consideration of the factors surrounding the development of anterior uveitis with mutton-fat KP's in the other eye. In this connection it should be emphasized that the uvea of the primarily involved eye showed only non-granulomatous inflammation and that the granulomatous reaction was limited entirely to the deep cornea and seen next to Descemet's membrane fragments. The granulomatous reaction in the other eye might, thus, have been due to a generalized hypersensitivity to degenerated Descemet's membrane. This mechanism might resemble that of sympathetic ophthalmitis with its hypersensitivity to uveal pigment or that of phakoanaphylactic uveitis with hypersensitivity to degenerated lens. It is of great interest that ocular evisceration with complete removal of the cornea was apparently successful in eliminating the anterior uveitis in the other eye. It can be argued that specific generalized hypersensitivity can develop to degenerating Descemet's membrane and that this can cause a granulomatous reaction—possibly even involving both eyes.

## Summary

Fragmentation and autolytic lamellar splitting of Descemet's membrane in a blind eye with anterior staphyloma after longstanding corneal ulcer was found to have caused a localized granulomatous inflammatory response. Anterior granulomatous uveitis eventually developed in the other eye, but it cleared quickly upon evisceration of the staphylomatous eye and has not recurred. Both clinical and histologic evidence in this case suggest that a specific generalized hypersensitivity had developed to degenerating Descemet's membrane, thus causing the granulomatous inflammation in both eyes, an effect similar to that seen, for example, in sympathetic or phakoanaphylactic uveitis.

# THE PATHOGENESIS OF CONGENITAL HEREDITARY ENDOTHELIAL DYSTROPHY OF THE CORNEA

KENNETH R. KENYON, M.D., AND BART ANTINE, M.D.
*Baltimore, Maryland*

In a recent investigation of congenital hereditary corneal dystrophy occurring in a neonate,[1] histopathologic study disclosed a complete absence of endothelial cells except at the corneal periphery and a uniform thinning of Descemet's membrane. The present study describes the ultrastructural changes evident in the ocular tissues of this same infant.

## MATERIALS AND METHODS

The child died of respiratory insufficiency at the age of 36 hours. His eyes were enucleated about 13 hours postmortem, were fixed in formalin, and were embedded in paraffin. This material was subsequently prepared for electron microscopy by dissolution of the affin with chloroform, rehydration in veronal acetate buffer, dissection into suitably sized specimens, fixation in veronal-acetate buffered 2% osmium tetroxide, and embedding in Araldite. (This method, while unfortunately sacrificing much ultrastructural detail of the cellular components, does sufficiently preserve extracellular material for accurate electron microscopic study.[2]) Thin sections were cut on a Porter-Blum MT-2 microtome, doubly stained with uranyl acetate and lead citrate, and examined with a JEM 100-B electron microscope at 60 kv.

## RESULTS

*Corneal epithelium and Bowman's membrane*—In the anterior corneal layers, only the effects of chronic corneal edema are apparent (Fig. 1). These nonspecific changes include: (1) thinning of the corneal epithelium to three or four cell layers and probable hydropic change of the basal cells, (2) distension of the intercellular spaces by edema fluid, (3) occasional subepithelial microbullae in association with discontinuities of the epithelial basement membrane, and (4) surface irregularities of Bowman's membrane. Bowman's membrane is otherwise unaffected and appears as a layer ($\sim$ 15 $\mu$ thick) of randomly oriented collagen fibrils which display the usual cross-sectional diameter ($\sim$ 26 nm) and longitudinal periodicity (55-60 nm) of corneal collagen.

*Corneal stroma*—Stromal edema accounts for the marked swelling of the cornea to about three times normal thickness. Ultrastructurally, the deep stroma is most severely disorganized, as edema fluid has formed pools which grossly distort the lamellae. In the anterior stroma, although the lamellar pattern is generally maintained, the collagen fibrils are variably separated and displaced from their usual lattice-like orientation (Fig. 2). The individual collagen fibrils, however, seem entirely normal as they consistently measure 26-30 nm in diameter with $\sim$ 60 nm longitudinal periodicity. Swollen collagen fibrils of $>$ 30 nm diameter are nowhere evident. The stromal keratocytes are also unremarkable in appearance.

*Corneal endothelium and Descemet's membrane*—At the corneal periphery the cuboidal endothelial cells appear essentially normal, having formed a single continuous layer in close apposition to the posterior surface of Descemet's membrane (Fig. 4). In the mid-periphery of the cornea, however, the endothelial cells become attenuated and then abruptly disappear (Fig. 5). Beneath the central cornea, neither isolated endo-

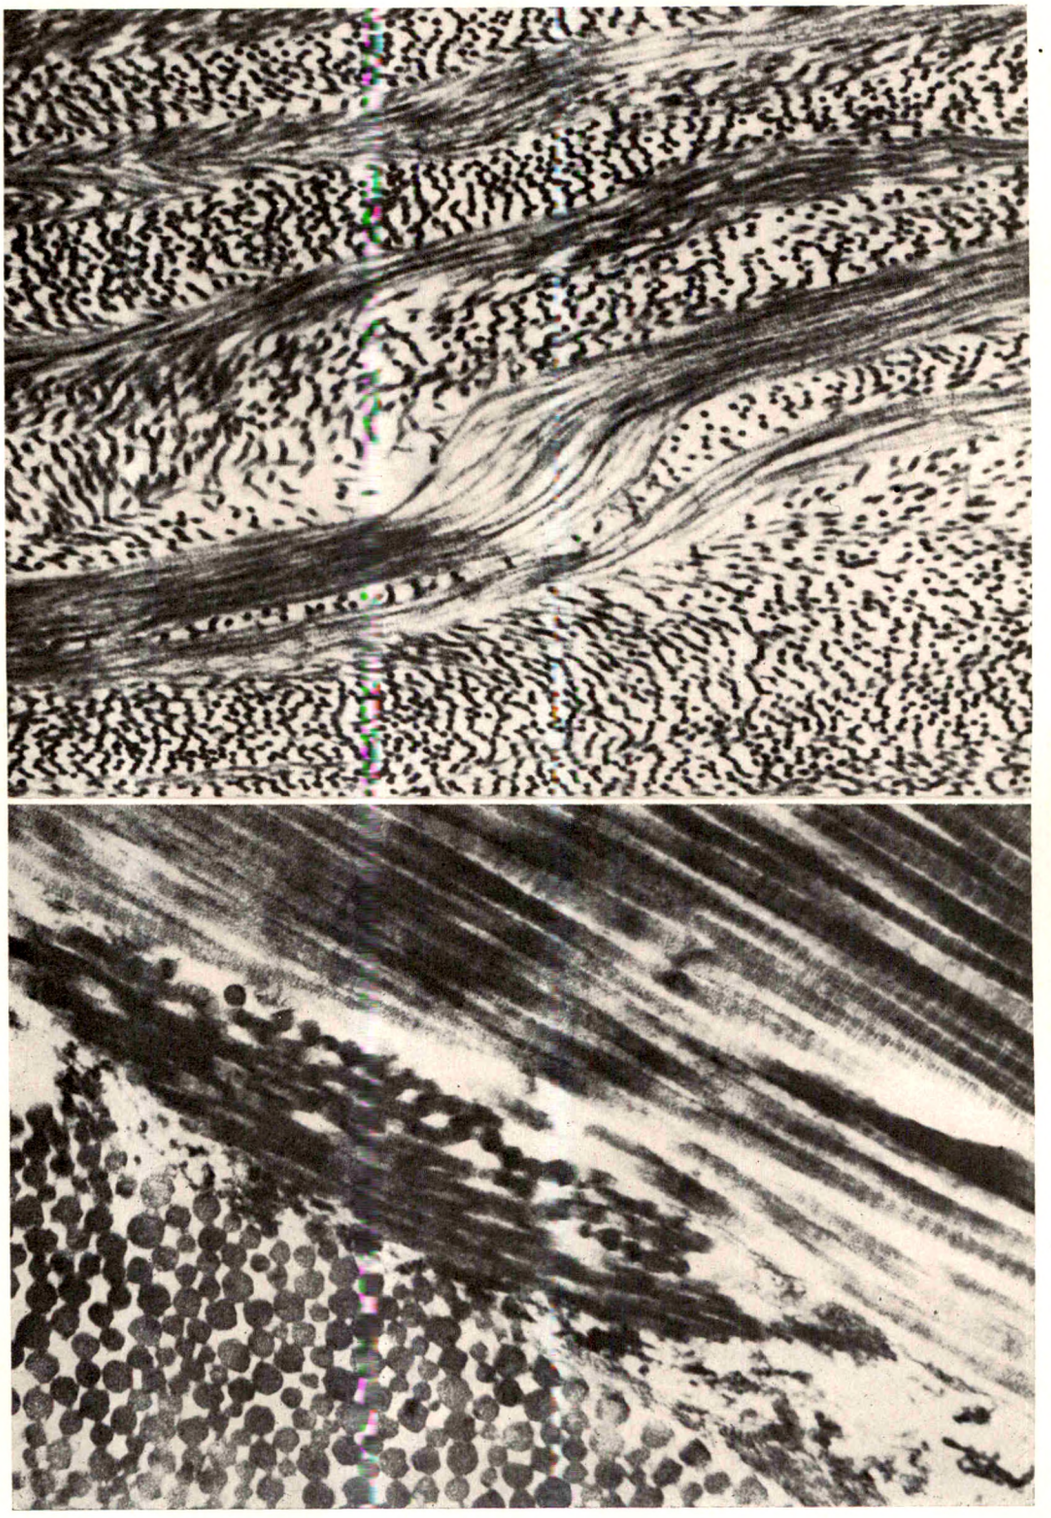
thelial cells nor cellular remnants are present (Fig. 6). Descemet's membrane, though appearing by light microscopy as a uniformly thinned layer (~3 μ thick—normal thickness in newborn humans = 4-6μ), actually displays significant ultrastructural variability which is seemingly dependent upon the condition of the endothelium. In particular, Descemet's membrane at the corneal periphery consists entirely of multiple layers of fine filamentous basement membrane-like material (each layer ~40-60 nm thick) interspersed with small diameter (~15 nm) collagen fibrils (Fig. 4). More centrally, at the point of endothelial termination, a thin layer of randomly oriented collagenous fibrils initially appears, covering the posterior surface of the multilayered Descemet's membrane (Fig. 5). Progressing toward the central cornea, this collagenous zone assumes greater prominence as it maximally constitutes about 80% of the overall thickness of Descemet's membrane, whereas the multilayered zone diminishes to a thin strip immediately subjacent to the stroma (Fig. 6). Despite the variable contributions of these two components, the overall thickness of Descemet's membrane remains remarkably constant.



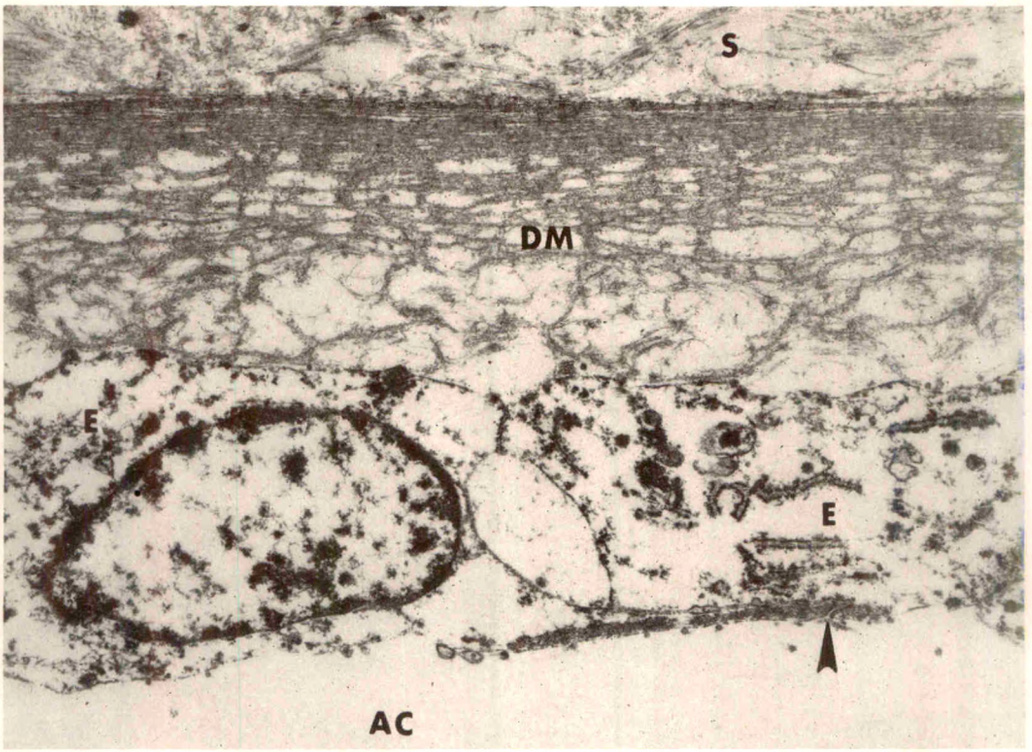
*Other ocular tissues*—In the sclera, the large collagen fibrils of ~75-120 nm diameter and ~60 nm longitudinal periodicity are entirely within normal limits (Fig. 3). The iris, ciliary body, and choroid also exhibit no significant ultrastructural abnormalities. Retinal tissue could not be evaluated by electron microscopy.

## Discussion

The pathogenesis of congenital disease is often best studied in the newborn, since in the neonatal period primary pathologic alterations are least obscured by secondary chronic sequelae. Among the above-mentioned ultrastructural observations of congenital hereditary corneal dystrophy in a neonate, the evidences of endothelial degeneration and the effects of stromal edema are most prominent. Accordingly, discussion will be limited to consideration of these key alterations as they relate to the pathogenesis of this corneal dystrophy.

*Endothelial degeneration*—In 1960, Maumenee[3] studied the histopathology of congenital hereditary corneal dystrophy in four patients (ages six to 22 years) and suggested the possibility that an endothelial defect might constitute the primary etiologic factor. The initial electron microscopy of this dystrophy[4] supported this hypothesis with the findings of a thin Descemet's membrane and an absent endothelium in the keratoplasty. More recently, Pearce and associates[5] were able to demonstrate by light and electron microscopy either an absence or a marked reduction of the endothelial cells in keratoplasty specimens from six patients (ages 37 to 71 years). In each of these reports, the possibilities of surgical damage, or aging changes of the endothelium, or both, could not be altogether excluded. Finally, however, the finding of a complete absence of the central corneal endothelium in the enucleated eye of a newborn[1] provided good histopathologic evidence that this dystrophy represents

Fig. 1 (Kenyon and Antine). The anterior layers of the cornea exhibit the changes of chronic corneal edema. The epithelium is thinned to three or four cell layers. Bridging dilated intercellular space, cytoplasmic processes of adjacent epithelial cells are joined by desmosomal attachments (circled). (The large cleft beneath the nucleus (N) of the basal cell is artifactitious.) Discontinuities (arrows) of the epithelial basement membrane (BM) are associated with surface irregularities of Bowman's membrane (Bow M). The randomly oriented collagen fibrils of Bowman's membrane are distinct from the organized collagenous lamellae of the stroma (S) (×7700).



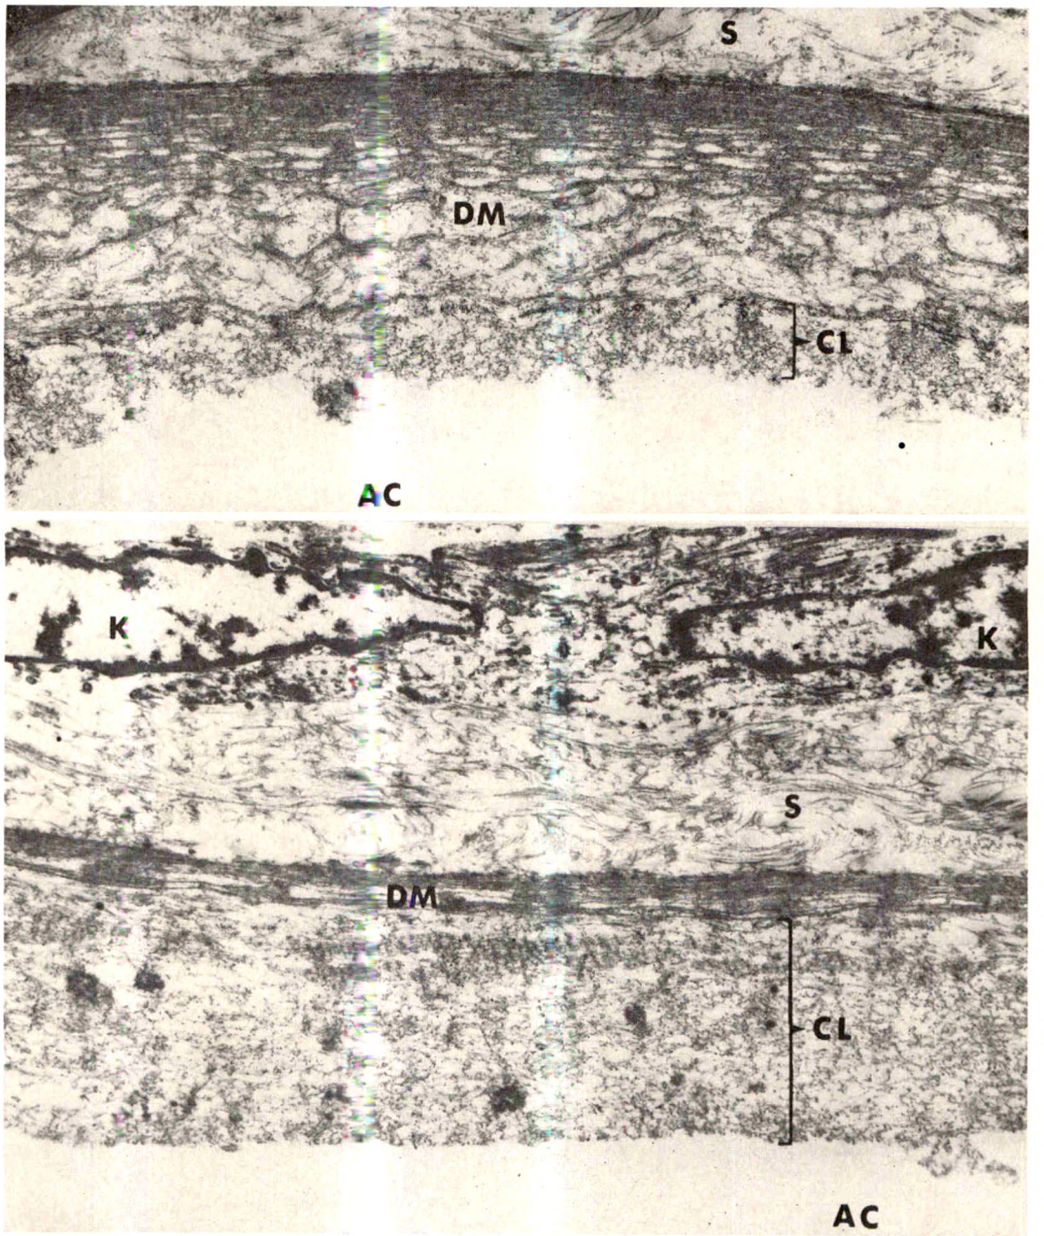


Fig. 4 (Kenyon and Antine). At the corneal periphery, the cuboidal endothelial cells (E) are joined by junctional complexes (arrow) to form a continuous layer in close apposition to Descemet's membrane (DM), which displays a multi-layered ultrastructure of basement membrane-like material throughout its entire thickness (S = stroma, AC = anterior chamber) (×12,000).

the clinical manifestation of an intrauterine degeneration of the corneal endothelium. The findings of the present electron microscopic study of ocular tissues from this same infant are in complete accord with this conclusion.

Comparison of the normal developmental appearance of Descemet's membrane with the abnormal ultrastructure of that membrane in this dystrophy provides additional insight into the progressive course of the endothelial degeneration. It is generally held that Descemet's membrane respresents the hyperplastic basement membrane of the endothelial cells. In the human embryo, Wulle and Lerche[6] have found that between the eighth and 14th weeks of gestation, Descemet's membrane initially appears as short, discontinuous segments of basement membrane-like

←

Figs. 2 and 3 (Kenyon and Antine). In Figure 2 (top), edema in the anterior corneal stroma has produced some distortion of the lamellae and irregular separations among the collagen fibrils. The individual collagen fibrils are of normal diameter (26-30 nm) and longitudinal periodicity (~ 60 nm) (×40,000). In Figure 3 (bottom), the large collagen fibrils of the sclera show much greater variability of cross-sectional diameter (~75-100 nm) than in the cornea (see also Fig. 2 at same magnification). The longitudinal periodicity of about 60 nm is clearly visible (×40,000).

Figs. 5 and 6 (Kenyon and Antine). In Figure 5 (top), in the mid-periphery of the cornea, central to the termination of the endothelial cell layer, the posterior surface of Descemet's membrane (DM) is covered by a layer of collagenous fibrils (CL) (S = stroma, AC = anterior chamber) (×12,000). In Figure 6 (bottom), in the central cornea, no endothelial cells are evident. The multilayered zone of Descemet's membrane (DM) is markedly thinned, whereas the collagenous layer (CL) has become considerably thickened (see also Figs. 4 and 5 at same magnification) (×12,000).

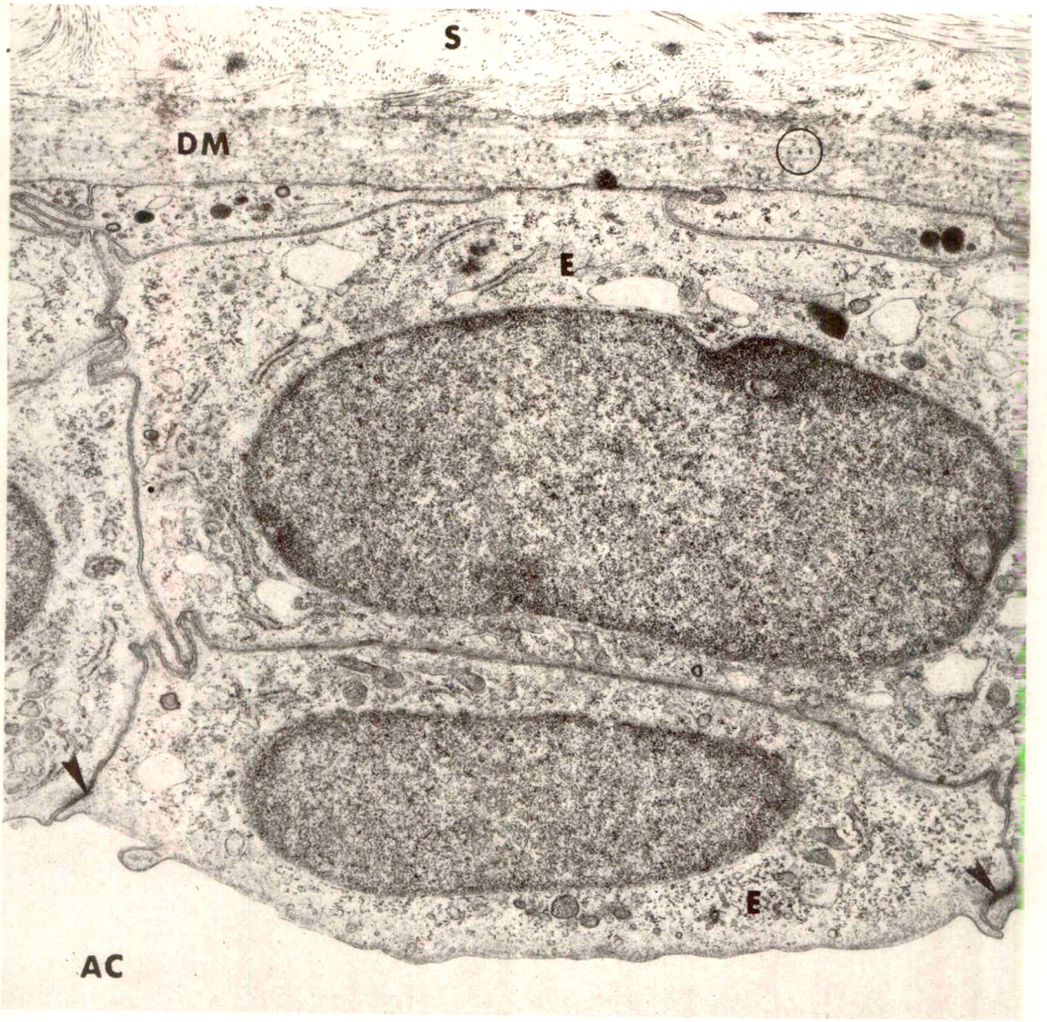

Fig. 7 (Kenyon and Antine). In the normal human fetus of 24 weeks' gestational age, the endothelial cells (E) assume a pseudo-stratified configuration, and well developed junctional complexes (arrows) have formed to seal the intercellular space from the anterior chamber (AC). Descemet's membrane (DM) is composed of several layers of basement membrane-like material, interspersed with fine collagen fibrils. Banding of 90-120 nm periodicity (circled) is evident (S = stroma) (×12,000).

material which coalesce to form a continuous lamina (measuring ~40-60 nm in thickness) lying immediately subjacent to the basal cell membrane of the endothelial cells. Subsequent development is depicted in Figure 7, which shows that in a human fetus of 24 weeks' gestation Descemet's membrane has progressed to about 1 μ in thickness and is composed of several layers of basement membrane (~50-70 nm thick) with fine collagen fibrils interspersed between the layers. The hexagonal organization pattern, which eventually confers a banded appearance upon the anterior portion of Descemet's membrane, is also evident here as electron-dense nodes which display 90-120 nm internodal periodicity. The later growth of Descemet's membrane presumably involves the deposition of additional basement membrane material, thereby increasing the thickness of this layer to 4-6 μ in the normal newborn infant and as much as 20 μ in the normal adult.

Prior to this report, keratoplasty specimens from three patients with congenital hereditary corneal dystrophy had been studied by electron microscopy. In all three specimens, an anterior banded zone of Descemet's membrane, measuring about 3-4 μ in thickness, was covered posteriorly by a non-banded collagenous layer of variable thickness, measuring $< 1$ μ in a 10-year-old boy,[4] about 14 μ in a 37-year-old woman, and about 30 μ in a 63-year-old woman.[5] If interpreted within the framework of normal corneal development, these alterations of Descemet's membrane in the preceding cases and in the present case seem consistent with the following conclusions:

1. The presence of a continuous Descemet's membrane over the entire posterior surface of the dystrophic cornea indicates that the endothelium is functionally intact through at least the third month of intrauterine development.

2. As demonstrated by the present case, the endothelial degeneration commences centrally and progresses peripherally, perhaps beginning after the fifth gestational month (as can be inferred by the comparable thicknesses of the multilayered Descemet's membrane in the central corneas of both the infant reported here and the normal 24-week fetus). In the other reported cases, the remarkably similar thicknesses of the banded zone of Descemet's membrane further localizes the onset of endothelial dysfunction to a relatively constant period in developmental time.

3. In areas where the endothelium is absent, a retrocorneal membrane of fine collagenous fibrils is formed which blankets the exposed multilayered or banded zone of normal Descemet's membrane and which apparently thickens with advancing age (to produce the misleading clinical and histologic impression of a thickened Descemet's membrane).

*Stromal edema*—In five patients with congenital hereditary corneal dystrophy, Kenyon and Maumenee[2,4] found that, in addition to the anticipated ultrastructural effects of chronic stromal edema, there was also a consistent swelling of the stromal collagen fibrils to almost twice normal diameter (measuring 41-49 nm as compared to a normal diameter of 24–26 nm). Sears has told us that he observed similar changes in the cornea of another patient with this dystrophy. Since stromal edema usually effects a swelling of the interfibrillar ground substance to produce nonuniform increases in spacing among collagen fibrils of normal dimensions, the stromal edema in congenital hereditary corneal dystrophy seemed, therefore, to constitute a distinct pathologic alteration.

Subsequently, however, Pearce and associates[5] were able to locate only a few corneal collagen fibrils of increased diameter in the corneas of two patients with congenital endothelial dystrophy which they studied by electron microscopy. In the present case as well, we have observed only collagen fibrils of the usual 26-30 nm diameter and these are accompanied by the usual changes of chronic stromal edema.

Unfortunately, the uncertainty over the pathologic significance of swollen stromal collagen is additionally confused by conflicting electron microscopic findings in several other diseases affecting the cornea. In particular, whereas various investigators have reported the occurrence of large-diameter collagen fibrils in the chronically edematous corneas of patients with metaherpetic keratitis and Fuchs' dystrophy (Offret and associates[7]), congenital glaucoma (Pouliquen and Saraux[8]) and Hurler's mucopolysaccharidosis (Pouliquen and associates[9]), others have not confirmed these observations. In our own study of stromal swelling,[2] we were unable to find enlarged collagen fibrils in corneas affected by congenital and secondary glaucomas, Fuchs' dystrophy, or systemic mucopolysaccharidosis (Hunter and Maroteaux-Lamy variants). The definitive resolution of these conflicting observations must await further careful study.

Finally, however, it is of speculative interest that the corneal endothelium itself might be a determinant of the size of the stromal collagen fibrils. Zinn,[10] who recently studied the effects of early lens removal in the chick embryo, found that following lentectomy a retrocorneal membrane formed which consisted of collagen fibrils with a diameter of about 50-60 nm. While that investigator attributed these changes as a specific response to lens removal, the failure of endothelial development in these embryonic corneas also suggests that the endothelium might influence stromal fibrillogenesis, an influence which could hold obvious implications for the endothelial dysfunction of congenital hereditary corneal dystrophy.

In conclusion, it is apparent that the weight of recent evidence now clearly favors the likelihood that congenital hereditary corneal dystrophy is a true primary dystrophy of the corneal endothelium which secondarily produces stromal and epithelial edema with concomitant corneal clouding. Therefore, in the interest of improving the etiologic classification of diseases, it would seem advisable to redesignate this disease entity as congenital hereditary endothelial dystrophy of the cornea.

## Summary

In an electron microscopic study of the ocular ultrastructure of a newborn infant with congenital hereditary endothelial dystrophy of the cornea, the pathologic alterations were found to include chronic epithelial and stromal edema, abnormalities of Descemet's membrane, and absence of the central endothelium. On the basis of these findings, the pathogenesis of this dystrophy is interpreted as follows: (1) There is a primary degeneration of the corneal endothelium which initially affects the central endothelium after the fifth month of gestation and subsequently progresses peripherally. (2) A secondary development is the diffuse stromal and epithelial edema which produces the clinically apparent clouding of the affected cornea.

# MALIGNANT MELANOMA OF THE CORNEA IN AN AFRICAN PATIENT

N. H. WELSH, F.R.C.S. (ENG.), AND Y. JHAVERY, D.O.
*Durban, South Africa*

Malignant melanoma of the cornea is a rare disease. Reports by Clune,[1] Stallard,[2] Lamers,[3] and Notter[4] among others, describe isolated cases. The case presented here involved the cornea first and later, the conjunctiva in a young African patient. Certain features are unusual, and it is thought that the melanoma could have arisen independently from cornea and limbal conjunctiva. While it is recognized that malignant melanomata of the uveal tract occur rarely in the pigmented races compared to Caucasians, malignant melanomata of the conjunctiva and the limbus do not show this difference. Malignant melanoma of the cornea has not been reported previously as occurring in the African, despite the increased pigmentation occurring naturally in the conjunctiva, limbus, and cornea.

Malignant melanoma occurred in the conjunctiva of the orbit in this patient 17 months after enucleation and the patient delayed in seeking further treatment for six additional months. By this time, enlarged pre-auricular and submandibular glands were present. The orbital contents were eviscerated and 18 months later, although he still has palpable and enlarged submandibular glands, there is no recurrence in the orbit and the patient remains alive and well. The other eye shows interesting changes with extensive pigmentation involving the basal cells of the corneal epithelium.

## CASE REPORT

A 23-year-old African, a Zulu man, reported to the outpatient department on August 1, 1967, because of a black mass on the right cornea which he said had been present for approximately three months. The mass protruded forward for about 5 mm. The conjunctiva appeared normal. It was noted that the cornea of the left eye was pigmented. The right eye was enucleated and the histologic report was that of a malignant melanoma of the cornea.

On June 10, 1969, the patient returned, presenting with a large black mass occupying the right orbit (Fig. 1) that he said had been present for six months. There were enlarged pre-auricular and submandibular glands. The left cornea now showed an irregular, pigmented surface (Fig. 2), with areas of thinning of superficial opacification. The left conjunctiva was normal. On June 16, 1969, the contents of the right orbit were exenterated. A biopsy was taken from a lymph node from the pre-auricular group of glands which, in conjunction with the submandibular group, looked black and tarry. Histopathology revealed the presence of metastatic malignant melanoma.

The state of the left cornea was now causing concern, as vision was deteriorating to the level of counting fingers. Biomicroscopy, showed irregularity of the superficial cornea with pigmentation. The cornea was thin with maximum pigmentation cen-

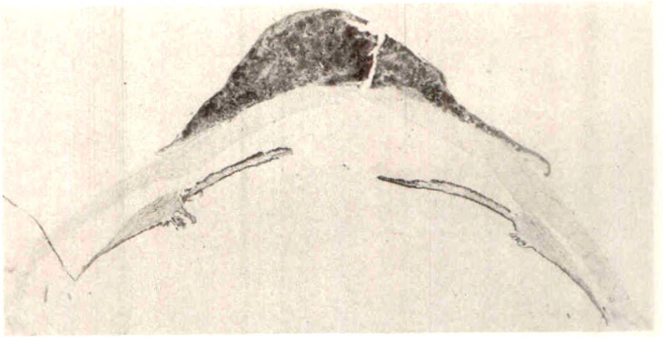

Fig. 3 (Welsh and Jhavery). Malignant melanoma of cornea (hematoxylin-eosin, ×6).

trally. The conjunctiva showed scattered areas of pigmentation in the exposed palpebral portion, but this was not considered to be abnormal. On February 3, 1970, a 7 mm penetrating corneal graft was performed.

Laboratory tests showed hemoglobin 13.4 g/100 ml, packed cell volume 42%, mean corpuscular hemoglobin concentration 32 g/100 ml, white blood cell count 7000, erythrocyte sedimentation rate 5 mm/hour. X-ray films of skull and chest were normal.

Systemic cytostatic drugs and radiotherapy were thought to be ineffective and to date (January 12, 1971), the patient is alive and well.

### Pathologic findings

*Right cornea*—The bulk of the tumor was found to be lying anterior to the corneal stroma. In parts it had penetrated through Bowman's membrane to involve corneal stroma (Fig. 3). Tumor cells containing melanin occurred in a predominately alveolar pattern. Superficial vascularization was present (Fig. 4). The tumor appeared to have arisen from the corneal epithelium.

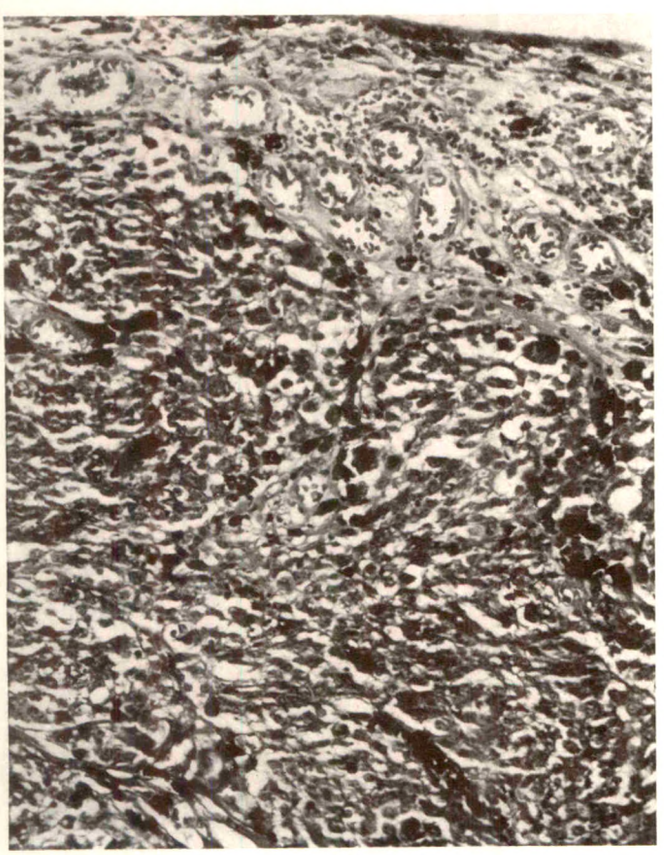

Fig. 4 (Welsh and Jhavery). Malignant melanoma of cornea. Pigmented cells arranged in alveolar pattern. Superficial vascularization of epithelial surface (hematoxylin-eosin, ×300).

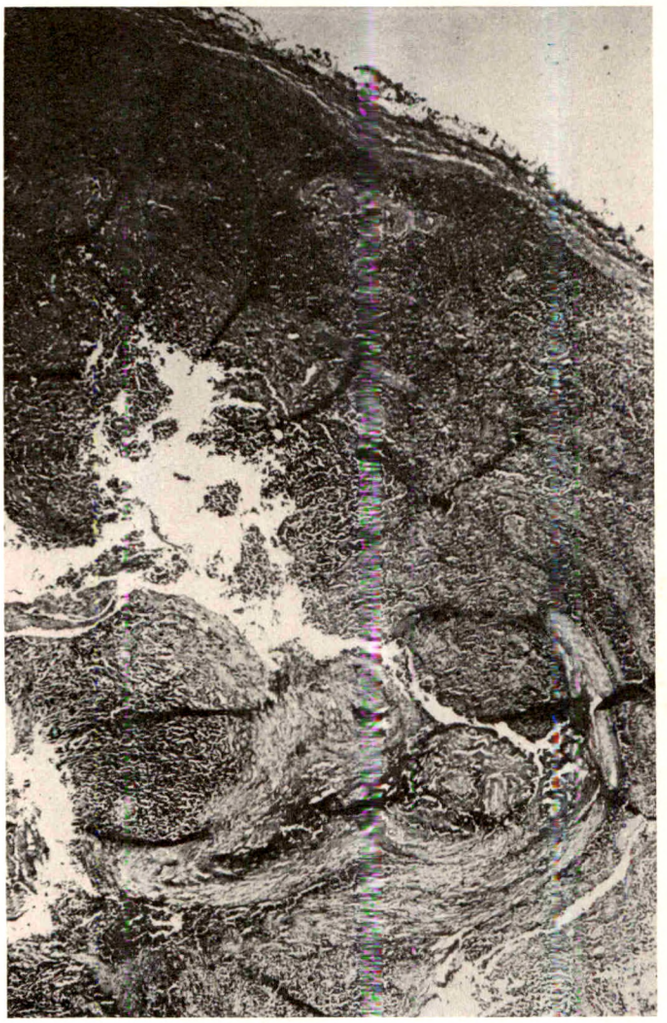

Fig. 5 (Welsh and Jhavery). Pre-auricular lymph node showing secondary malignant melanoma (hematoxylin-eosin, ×25).

*Pre-auricular lymph node*—The section of the pre-auricular lymph node shows pigmented secondary tumor cells (Figs. 5 and 6).

*Left cornea*—The cornea of the left eye that had been removed by corneal transplant showed marked hyperpigmentation of the basal cells and to a lesser extent in the prickle cells. There was no indication of junctional nevus or melanoma in the sections (Fig. 7).

## Discussion

In the case presented here, a malignant melanoma involving the cornea was thought to have arisen primarily from the cornea, but extension from a small limbal melanoma could not be excluded since serial sections were not taken. Clinically, the melanoma appeared to be corneal. Reese[5] reports on 10 cases described by von Hippel and says that some of these cases may have been malignant melanomata extending from the limbus. Hogan and Zimmerman[6] state that primary malignant melanomata of the limbus and of the cornea are very similar. In African patients, there is normally increased limbal pigmentation, and superficial pigmentation can extend onto the surface of the cornea. Occasionally, small areas of superficial pigmentation occur in areas of superficial keratitis or trauma. Michaelson[7] has produced pigment-cell proliferation from the limbus to the cornea experimentally in the rabbit. One

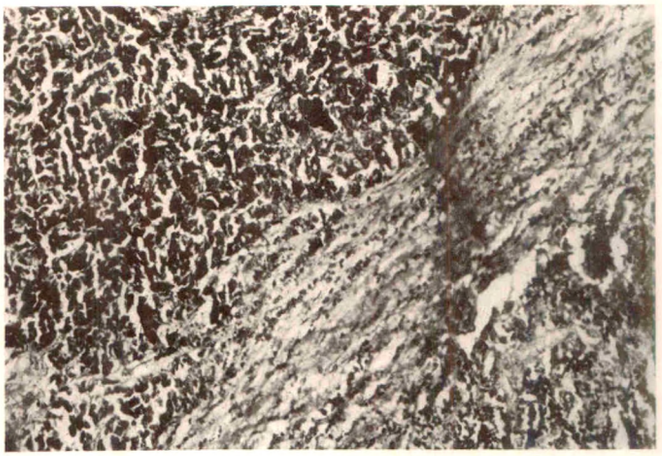

Fig. 6 (Welsh and Jhavery). Secondary malignant melanoma cells from pre-auricular lymph node (hematoxylin-eosin, ×150).

would have supposed that there would be an increased tendency for pigmented races to develop melanomata of the limbus and cornea, but this is not so in our experience. The appearance of the cornea of the left eye was abnormal and unusual. Pigmentation of the basal cells appeared to be the primary lesion and although no junctional activity was present, it is tempting to suggest that this could arise in the future and that originally the right eye presented a similar appearance.

The appearances of the tumor fit with previous descriptions and superficial vascularization is a prominent feature. It invaded Bowman's membrane, which is not characteristic.[6] Stallard's case[2] also destroyed most of Bowman's membrane, corneal epithelium, and bulbar conjunctiva, and had infiltrated the substantia propria of the cornea. He mentions one case report by François, Gildemyn, and Rabaey in which the authors considered the neoplasm to be slowly penetrating and a partial keratectomy was performed.

The subsequent metastasis of the tumor also invites comment. Following the enucleation, since the conjunctiva looked normal and the pathologic report was that of a malignant melanoma of the cornea, exenteration was not contemplated.

When the patient returned on June 10, 1969, there was extensive involvement of the conjunctiva with secondary extension to the parotid and submaxillary lymph nodes. Last[8] says that the cornea has no lymphatic drainage, and that the conjunctiva has a lymphatic drainage that drains to the parotid glands from the lateral side and to the submandibular glands from the medial side. The secondary deposits are thus derived from the con-

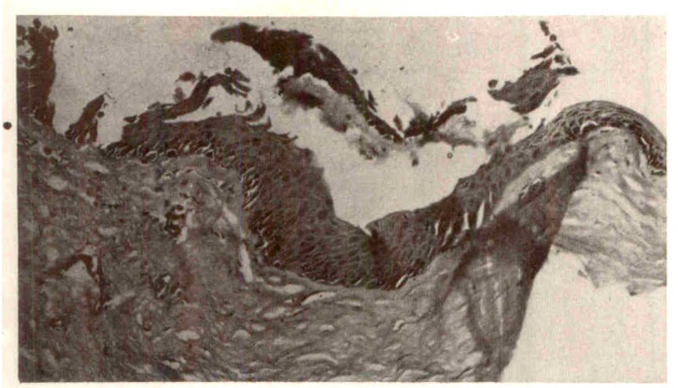

Fig. 7 (Welsh and Jhavery). Hyperpigmentation of basal cells and prickle cells of left cornea (hematoxylin-eosin, ×300).

Fig. 8 (Welsh and Jhavery). Photograph showing present appearance of right orbit 18 months after exenteration. Tissue at apex is skin graft. Left eye shows corneal graft.

junctiva and not from the cornea. The orbital contents were exenterated and microscopic examination revealed no extension of melanoma deep to the conjunctiva. It is interesting to note that conjunctival involvement from the cornea took at least 18 months to develop. By January 12, 1971, there had been no orbital recurrence (Fig. 8), with no further evident lymphatic extension, indicating the slow rate of general systemic involvement.

## Summary

A malignant melanoma of the cornea arose in a 23-year-old African Zulu man. The eye was enucleated, but 18 months later there was recurrence in the orbit, conjunctiva, and in the pre-auricular and submandibular glands. The fellow cornea showed irregularity of the superficial layers with pigmentation and thinning. The tumor was thought to have arisen primarily from the cornea, but extension from a small cornea sclerolimbal melanoma could not be excluded histologically.

## Acknowledgments

I thank Professor L. Baker Head, Department of Surgery, and Dr. H. Wannenburg, Superintendent of King Edward VIII Hospital, for permission to publish this case. I also thank Professor J. Wainwright, of the Department of Pathology, and Mr. Stuart for the preparation of the photographs.

# THE HISTOPATHOLOGY AND ULTRASTRUCTURE OF CONGENITAL, CENTRAL CORNEAL OPACITY

## (PETERS' ANOMALY)

ISAO NAKANISHI, M.D., AND STUART I. BROWN, M.D.
*New York, New York*

Peters' anomaly is a congenital, central corneal stromal opacity usually associated with a defect in the posterior stroma and Descemet's membrane and anterior synechiae which extend from the pupillary zone of the iris to the periphery of the corneal opacification.[1-3] Glaucoma is commonly associated with this condition. Less frequent associations are anterior polar cataracts or other forms of congenital cataracts, and it is not infrequently associated with microphthalmus and sclerocornea.[3] Eighty percent of the reported cases of Peters' anomaly are bilateral. Because it may coexist with other developmental anomalies of the anterior segment, i.e., mesodermal dysgenesis of the iris and posterior embryotoxin, it has been suggested by Reese and Ellsworth[4] that these anomalies be classified into a single group and called the anterior chamber cleavage syndrome.

Peters' anomaly was first considered to be caused by an intrauterine infection.[5] At present, it is generally believed to be a developmental anomaly that is caused by either a delayed separation of the lens vesicle,[6] or a primary disorder in the development of the endothelium of the anterior chamber,[7] or a combination of both of these.

Recently, one of us (S.I.B.) reported the successful transplantation of one cornea of a ten-month-old infant with Peters' anomaly.[8] The eye that received the corneal graft had adhesions of the central iris to the cornea, in addition to an anterior polar cataract that was also adherent to the back of the cornea. At surgery, it was apparent that the anterior layer of the iris was underdeveloped, indicating that in addition to Peters' anomaly, there was an additional component of mesodermal dysgenesis of the iris. Preliminary histologic examination of the excised host cornea indicated that in the zone of the opacification, the endothelium, Descemet's membrane, and Bowman's membrane were absent.[8] The second cornea of this patient was grafted and the histologic description and ultrastructure of both specimens are presented in this report.

### MATERIALS AND METHODS

The second corneal specimen was a corneal disk 7 mm in diameter removed during corneal transplantation of the right eye of a 20-month-old baby girl. During surgery, iris adhesions to the peripheral temporal portion of the opacification were removed with sharp dissection, leaving the iris grossly intact with the pupil responsive to mydriatics. The donor cornea was sutured to the host cornea as reported with the left eye. The sutures were removed after four months and the graft has remained transparent to the present time. Visual psychological testing performed at the New York Lighthouse for the Blind indicated that the child could perform visual tasks equal to those of children in her age group with normal vision.

The corneal specimens were fixed in 3% glutaraldehyde in 0.2M sodium cacodylate buffer (pH 7.4) and post-fixed with 2% osmium tetroxide in 0.2M sodium cacodylate and embedded in Epon. Thick sections of the epoxy-embedded tissue were stained with basic fuschin and alkalinized methylene blue and examined with the light microscope. Thin sections were cut with a LKB-3 micro-

tome with a diamond knife, mounted on uncoated copper grids, stained with uranyl acetate and lead citrate, and examined with an AEI EM-6B at 60 kv.

## Histology

The epithelium of both specimens was of normal thickness. The basal layer appeared edematous and contained a few darkly staining cells. Bowman's membrane appeared to be of normal thickness in the periphery of both specimens (Fig. 1), thinned in the midperiphery (Fig. 2) in the first cornea, and was absent in the central 3-4 mm of both specimens (Figs. 3 and 4). The left cornea contained many blood vessels throughout the stroma. The right cornea was avascular. The architecture and cells of the peripheral stroma of both specimens appeared normal. However, in the more central area, there was an increased number of stromal cells in the subepithelial zone where Bowman's membrane was absent. The endothelium and Descemet's membrane were present in the pe-

riphery of both specimens (Fig. 5). Descemet's membrane thinned in the midperiphery and disappeared behind a retrocorneal membrane of loose connective tissue (Fig. 6). The central endothelium appeared to be absent in the first and present in the second specimen.

### Electron microscopy

The anterior epithelial cell layers appeared normal except for fewer tonofilaments. The nuclei of the basal cells were usually in the anterior half of the cells. The basal portion of the basal cells projected deeply and irregularly into the stroma (Fig. 7). The basement membrane of the epithelium was well developed and generally intact throughout both specimens.

The peripheral portions of the Bowman's membrane appeared to have a normal thickness and configuration, except that it was absent immediately posterior to the basement membrane. Instead, there were fine, closely-packed fibrils that were particularly promi-

nent within the unfoldings of the basement membrane and basal epithelium cells (Figs. 7 and 8). An occasional dendritic type of cell was observed in the basal layer of the epithelium (Fig. 9).

In the midperiphery, the anterior portion of Bowman's membrane thinned (Fig. 10), tapered, and finally disappeared. In the central portions of both specimens, Bowman's membrane was absent (Fig. 11).

In the central anterior stroma, cytoplasmic processes of keratocytes were frequently observed to contact the basal epithelial cells through defects in the basement membrane. In the posterior central stroma, the collagen lamellae were disorganized (Fig. 12). In this area, the cytoplasm of the stromal cells were surrounded by an electron-dense amorphous material (Fig. 13).

Endothelial cells lined the posterior surface of the second specimen but were absent behind the central portion of the first specimen. In these cells, the endoplasmic reticulum though well developed were never observed to be close to the anterior cell membrane. This suggests reduced secretory activity. In the peripheral portions of the specimen, Descemet's membrane appeared to consist of a thin layer of amorphous material contiguous with the endothelial cell membrane (Fig. 14). In addition, there were strands of a similar material anterior to this

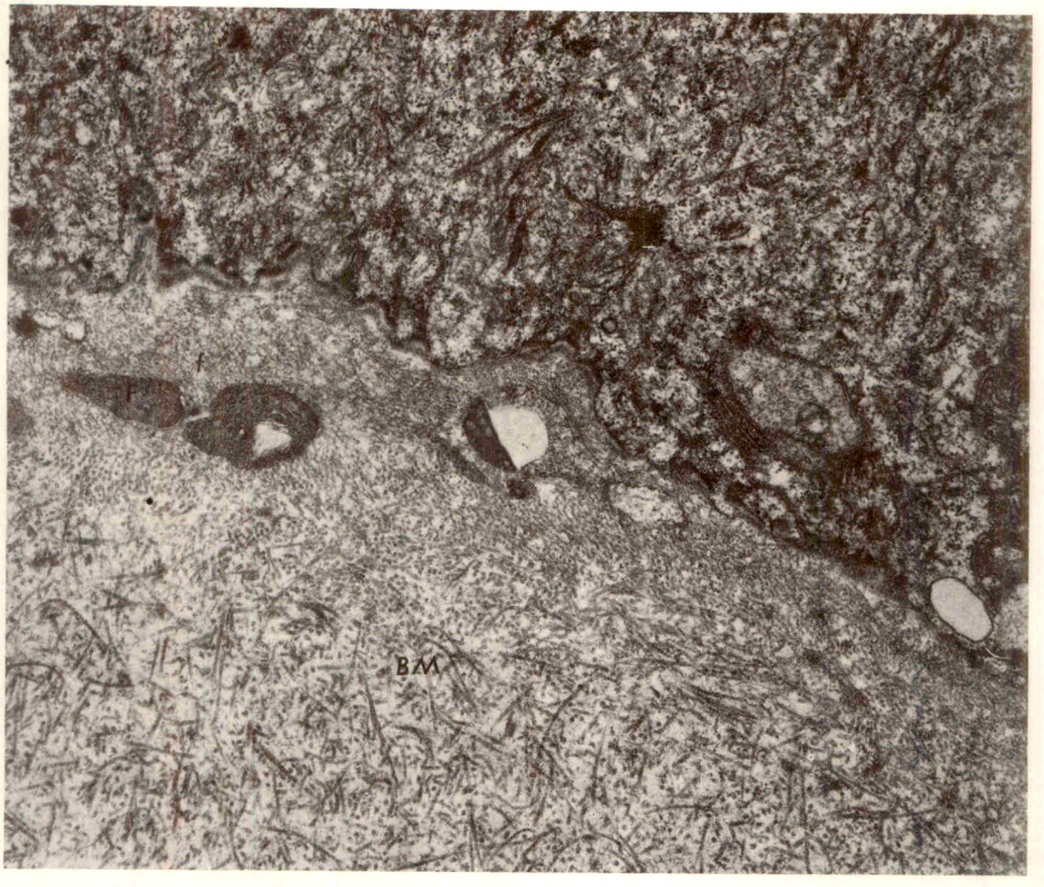

Fig. 10 (Nakanishi and Brown). Electron micrograph of the epithelial-stromal junction of the midperipheral portion of the specimen. Portions of stromal cells (F) are in this layer (×30,000).

layer. Centrally, the amorphous layer was much thinner and appeared similar to the material surrounding the keratocytes in the posterior stroma (Fig. 15).

## Comment

Histologic examination of the two specimens from corneas with Peters' anomaly indicated that both Bowman's membrane and Descemet's membrane were intact and had apparently normal thicknesses in the periphery of the specimens. In the midperiphery, these layers gradually thinned and were absent in the most central portions of both specimens. The central stroma was unusual in that anteriorly there were many keratocytes and posteriorly there was a retrocorneal connective tissue membrane. This retrocorneal membrane was localized and filled the area where a defect in the stroma is usually found in Peters' anomaly.

Electron microscopy showed that the peripheral portions of both Bowman's membrane and Descemet's membrane were abnormal. Bowman's membrane was absent immediately beneath the epithelial basement membrane.

The appearance of Descemet's membrane in the periphery of the specimens was similar to the Descemet's membrane secreted by

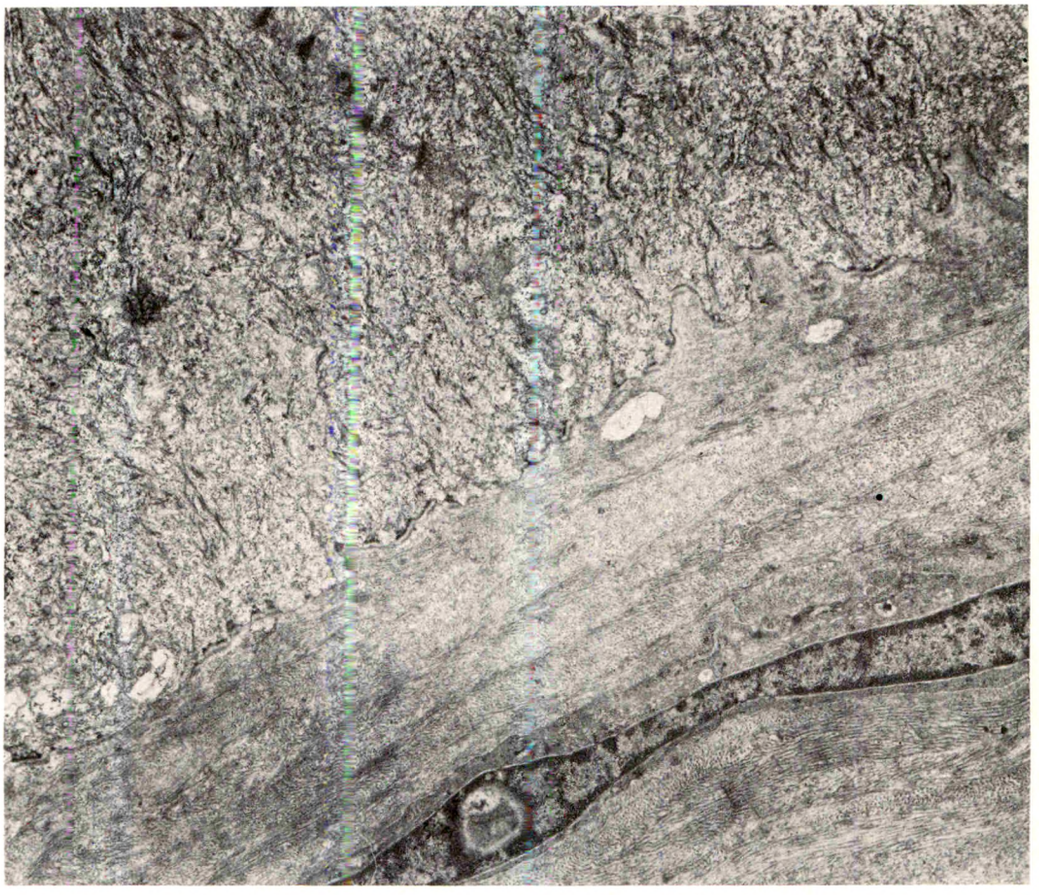

Fig. 11 (Nakanishi and Brown). Electron micrograph of the epithelial-stromal junction of the central portion of the excised cornea showing complete absence of Bowman's membrane (×15,500).

endothelial cells that have spread behind a two- to three-week-old wound.[8] The electron dense amorphous material contiguous with the cell membrane of the endothelial cells in the midperiphery was similar to newly secreted Descemet's membrane in a three-day old wound.[9] This immaturity of Descemet's membrane is difficult to explain because the specimens were from one- and two-year-old infants.

Amorphous electron dense material which resembled the presumed immature Descemet's membrane surrounded cells in the posterior central stroma. These cells probably represent aberrant endothelial cells. Similar cells were observed in studies of the wounds of grafted corneas.[9]

These studies of Peters' anomaly show that in addition to the usual defect in the central portion of Descemet's membrane, there was also an absence of Bowman's membrane in the central portion of both specimens. Recent studies by Hay and Ravel[10] indicate that the epithelium is responsible for the embryogenesis of Bowman's membrane. If this is true, Peters' anomaly is an ectodermal alteration in addition to the generally recognized mesodermal dysgenesis. We contend that the grouping by Reese and Elsworth[4] of many of the developmental anomalies of the struc-

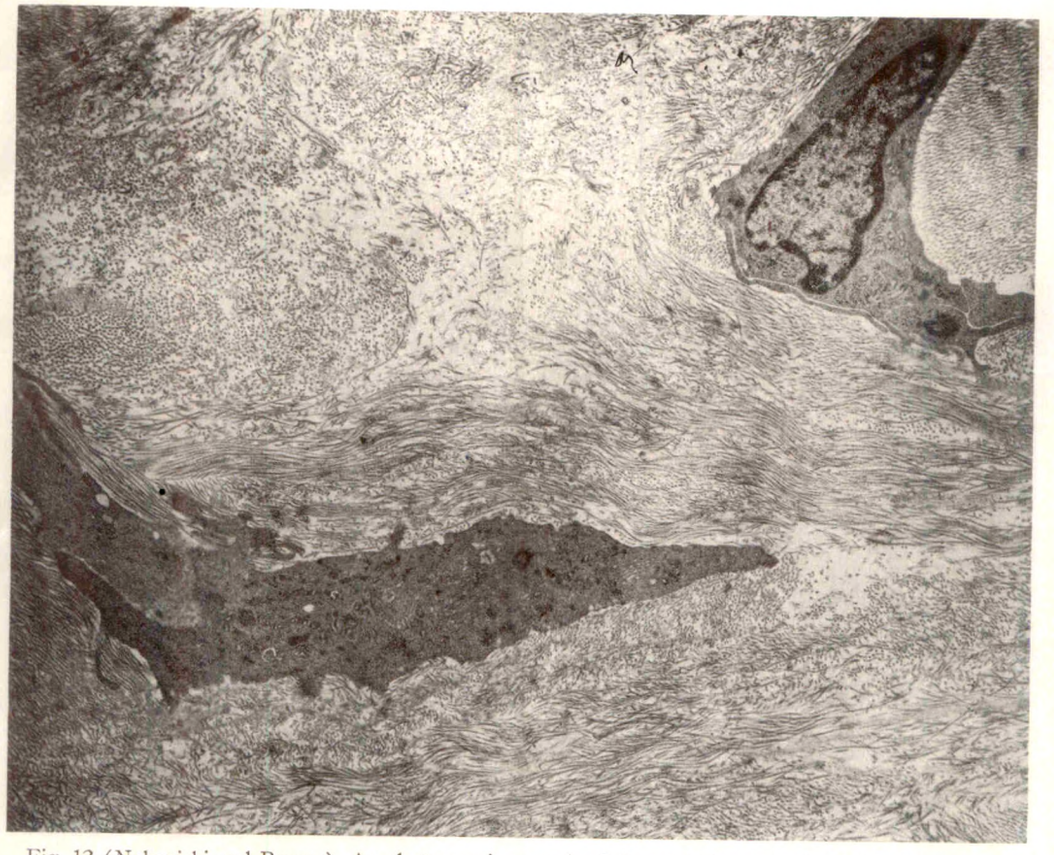

Fig. 12 (Nakanishi and Brown). An electron micrograph of the posterior central stroma showing a cell surrounded by a thin, amorphous, electron-dense layer (×25,000).

tures bordering the anterior chamber under one classification is a useful contribution. However, the absence of Bowman's membrane in the cornea of Peters' anomaly indicates that, as Alkemade[3] recently suggested, the name anterior chamber cleavage syndrome is embryologically incorrect, i.e., the portions of cornea that are altered in Peters' anomaly do not normally develop during the formation of the anterior chamber.

## Summary

Histologic examination of two corneas with Peters' anomaly showed that in addition to the usual absence of a central portion of Descemet's membrane, Bowman's membrane was also absent in the central portion of both specimens. The peripheral portions of both Bowman's and Descemet's membrane appeared to be of normal thickness. Electron microscopy showed that the peripheral portions were separated from the epithelium by a thin layer of fibrous tissue and that the peripheral portions of Descemet's membrane were separated into lamellae.

# REPORT OF A CASE OF NOCARDIA ASTEROIDES KERATITIS

EMANUEL NEWMARK, M.D., FRANK M. POLACK, M.D.,
AND ARTHUR C. ELLISON, M.S.
*Gainesville, Florida*

Ocular infection caused by Nocardia asteroides is rare. External infections have been reported infrequently,[1-4] but more recent reports deal with intraocular endogenous infection.[5-6]

This organism is a Gram-positive, filamentous bacterium classified in the order Actinomycetales and sensitive to antibacterial treatment. However, frequently it is described as a fungus.[3,4,7,8] It is important to recognize the characteristics of Nocardia keratitis so that adequate treatment can be initiated. Ths case report describes a Nocardia corneal ulcer in a patient treated with antiviral agents and corticosteroids. The effect of topical corticosteroids upon experimentally induced infection was studied.

## CASE REPORT

A six-year-old boy was struck in the right eye with a "dirt ball." Particles of dirt were removed from the eye by irrigation, and within 24 hours it showed no signs of irritation. Three weeks later, however, the eye became inflamed and oxytetracycline (Terramycin) ophthalmic ointment was then applied for several days without improvement. The patient was referred to an ophthalmologist who found a corneal lesion and prescribed chloramphenicol ointment and topical corticosteroids, but the infection became progressively worse. Another ophthalmologist treated the boy with sulfacetamide and 5-iodo-2-deoxyuridine for several days without improvement. The patient was referred to the University Eye Clinic. The child's visual acuity in the affected eye was counting fingers. His left eye was normal and he was otherwise healthy. There was right corneal edema and infiltration about 5 mm in diameter which extended from the temporal limbus to the pupillary margin. The epithelium was absent centrally and thickened at the margin of the lesion. There were multiple infiltrates, some of them expanding in a branched fashion. Peripheral deep neovascularization extended 4 mm into the cornea

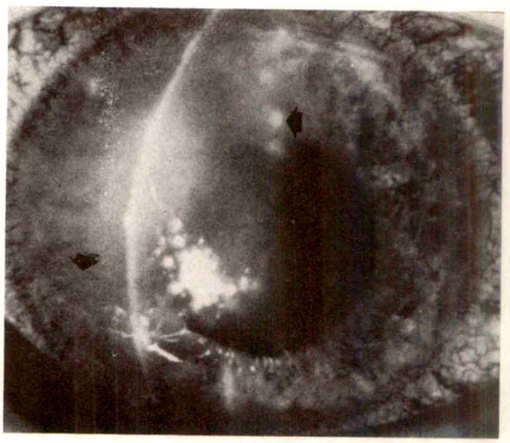

Fig. 1 (Newmark, Polack, and Ellison). Nocardia asteroides keratitis. Arrows indicate multiple infiltrates at the advancing edge of the corneal lesion and mid-stromal corneal vascularization.

(Fig. 1). The anterior chamber showed a mild inflammatory reaction.

Gram and Giemsa stains of corneal scrapings for fungus, and a potassium hydroxide wet preparation, did not reveal bacteria or fungi. Three days after plating cultures, minute mealy white colonies appeared along the culture streak on the blood-agar plate. The organism was a Gram-positive and acid-fast filamentous bacterium identified as Nocardia asteroides (Fig. 2), sensitive to sulfonamides, tetracycline, and penicillin. The patient was treated with sulfadiazine systemically, sulfacetamide 30% every two hours, and tetracycline in oil, 1%, every two hours topically, alternating with sulfacetamide. Similar white mealy colonies grew also on the Sabouraud's medium five days after inoculation. Systemic therapy was discontinued after approximately three weeks of treatment. At this time, the corneal lesion was healed (Fig. 3), and the patient's right vision was 20/25 without correction.

## EXPERIMENTAL STUDY

The possibility that Nocardia infection of the cornea could be aggravated by corticosteroid treatment was investigated in rabbit eyes. The corneas of 12 pigmented rabbits were inoculated intralamellarly with a diluted suspension of Nocardia asteroides filaments (isolated from the patient described). Corneal infiltrates were noted within three days. Six rabbits were treated with normal saline

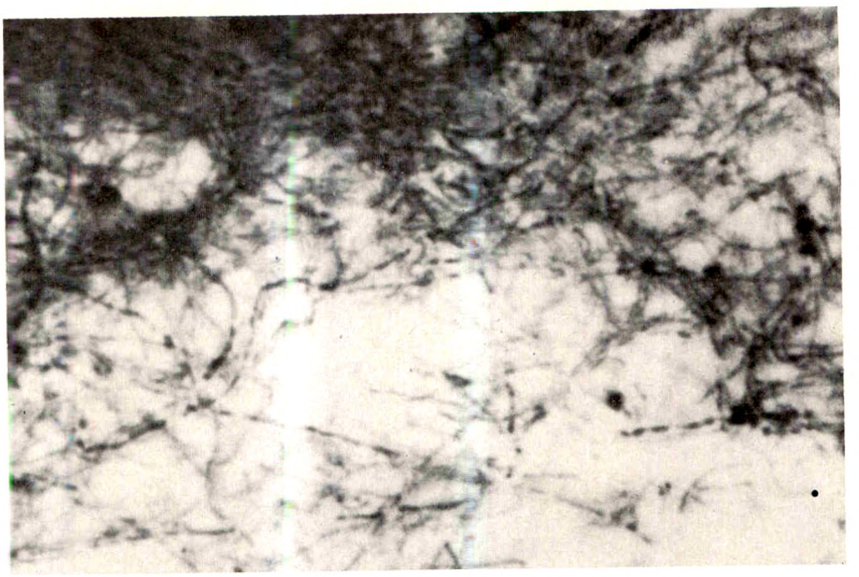

Fig. 2 (Newmark, Polack, and Ellison). Nocardia asteroides from blood-agar culture. Note the filaments with fragmentations into bacteria-like particles (Gram stain, ×1000).

solution drops four times daily, and six rabbits were treated with instillations of dexamethasone ophthalmic solution 0.1% four times daily for a three-week period.

Rabbit corneas treated with the corticosteroid developed large granulomatous lesions (Fig. 4) with extension into the anterior chamber in two animals. The saline-treated eyes showed small lesions which eventually healed by vascularization. Even though the corticosteroid-treated group showed large corneal granulomas, the eyes showed minimal intraocular reaction, except in the two cases of anterior chamber extension.

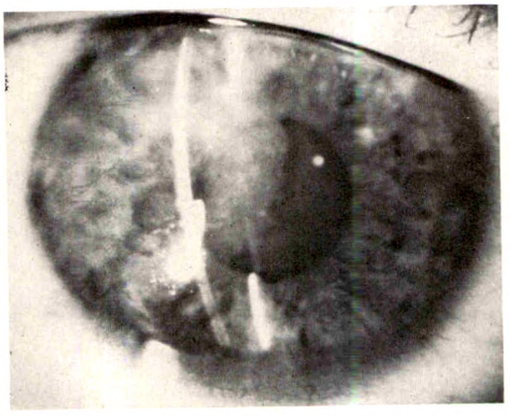

Fig. 3 (Newmark, Polack, and Ellison). Appearance of the cornea four weeks after sulfacetamide and tetracycline treatment.

## Discussion

The Actinomycetales are filamentous bacteria related to the Mycobacteria, while superficially resembling fungi. In tissue culture, they grow in branched fashion with fragmentations into bacteria-like particles. The genus Nocardia is aerobic and has narrow, Gram-negative, acid-fast bacillary or coccal forms. These forms grow best in blood-agar, but also on simpler media, producing white colonies with a dry and crumbly appearance. Nocardia is usually sensitive to sulfadiazine and frequently to tetracycline and penicillin; however, in vitro tests are warranted to determine the sensitivity of each new strain.

The corneal lesion seen in this patient was not unlike that caused by atypical Mycobacteria[9-10] or mycotic infections. The history and the aggravation caused by topical corticosteroids suggested a mycotic lesion; however, it is unusual for a fungal ulcer to show minimal or absent ocular inflammation. The corneal scrapings were not stained for acid-fast organisms, but with this type of corneal lesion, particularly when no bacteria or fungus was found, this should have been done. It is interesting that this patient was initially treated with appropriate medications, but not frequently enough.

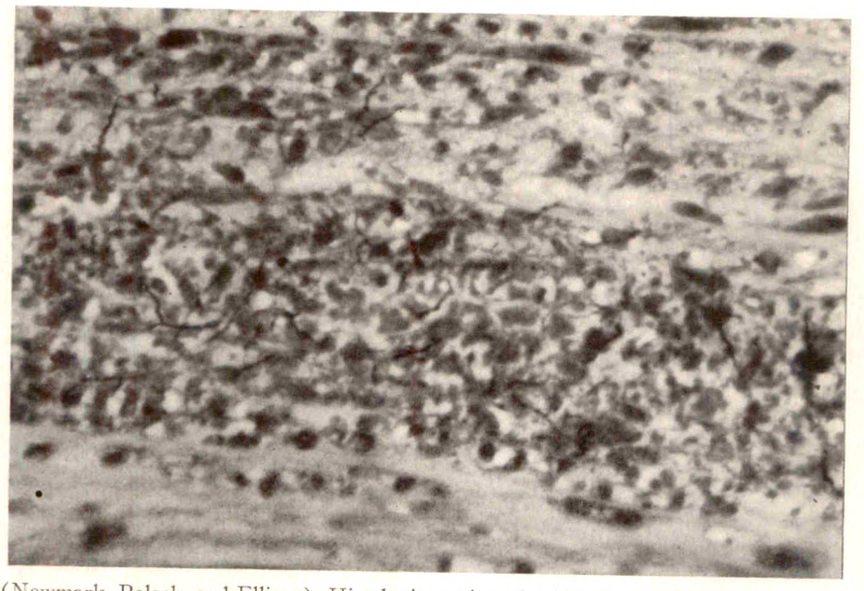

Fig. 4 (Newmark, Polack, and Ellison). Histologic section of rabbit cornea showing Nocardia asteroides (arrows) within the granulomatous lesion (Ziehl-Neelsen, ×400).

It is well known that corticosteroids aggravate bacterial and fungal infections, and this also is true for this type of infection, as substantiated by the rabbit experiment reported. Experimental corneal infection by Nocardia, as reported by others[1,11] and confirmed by us, causes corneal granulomata with ocular inflammation and heals by vascularization. When corticosteroids are used, the corneal infection is much more severe, and bacterial extension into the anterior chamber may occur.

## Summary

Corneal infection due to Nocardia asteroides developed in a six-year old boy who was initially treated with antibiotics, corticosteroids, and antiviral agents. Once the organism was identified, the keratitis responded to therapy with topical and systemic sulfonamides and topical tetracycline. Experimental infections in rabbit eyes showed that granulomatous nocardial corneal lesions regress spontaneously by vascularization with almost no intraocular inflammation, but instillation of topical corticosteroids aggravates the infection.

# TESTING FOR CONGENITAL SYPHILIS IN INTERSTITIAL KERATITIS

J. Lawton Smith, M.D.
*Miami, Florida*

The presence of viable and virulent Treponema pallidum in the human eye in congenital syphilis despite massive doses of penicillin has recently been proven by Hardy and associates.[1] Furthermore, the incidence of congenital syphilis in children under 10 years of age in the United States rose by 168% in the past decade.[2] Since it is known that 90% of cases of interstitial keratitis are due to congenital syphilis,[3] this review of interstitial keratitis with emphasis on the serum FTA-ABS test is presented.

## Materials and Methods

Cases of interstitial keratitis personally examined at the Bascom Palmer Eye Institute between 1963-70 were reviewed. Only those showing typical biomicroscope signs of syphilitic interstitial keratitis were accepted. These signs were: the presence of deep stromal opacifications, often patchy or feathery in outline, usually seen with a silvery sheen reflex just in front of Descemet's membrane, and accompanied by the presence of ghost vessels seen by direct or retroillumination in both eyes. Unilateral cases and those not confirmed by external ocular photographs were excluded to preclude inclusion of other forms of corneal disease in the study group. Twenty patients fulfilled these criteria, and their records were reviewed for the following data: age, sex, history of ocular inflammation in childhood, family history suggestive of syphilis, right eye vision, left eye vision, pupillary findings (with emphasis on the presence of light-near dissociation), presence of glaucoma, visual field defects, ophthalmoscopic appearance of the optic nerve, presence or absence of chorioretinitis, deafness, stigmata, findings of aqueous humor paracentesis, serum VDRL, and serum FTA-ABS findings. The data are summarized in Table 1.

*Findings*—There were five males and 15 females in this series. This 3:1 ratio of higher incidence of interstitial keratitis in females has been noted in previous studies.[4] The age range was nine to 70 years, with a median age of 49 and a mean age of 53 years. This finding was consistent with the fact that the patients were for the most part adults referred for neuro-ophthalmologic consultation. There were only two patients with acute attacks of interstitial keratitis in the group, and these were the two youngest in the series (females aged nine and 22 years). The patients in this study were thus typical of cases of late interstitial keratitis when the diagnosis is made at routine slit-lamp examination of eye clinic patients. A history of ocular inflammation in childhood, usually lasting for many months, was easily elicited in 15 of the 20 patients, or 75%. While some elderly patients may not recall this history, it is usually present and is helpful in the differential diagnosis. Three patients stated that the attacks were considered to be scarlet fever, recurrent streptococcal sore throats, or rheumatic fever in childhood. The visual acuity was 20/50 or better in one eye in 15 cases, or 75%. The visual acuity was 20/200 or worse in one eye in 12 cases, or 60%. The visual acuity was markedly asymmetric in the two eyes in eight patients, or 40%. Two patients had surgical anophthalmos as a consequence of the disease, and only one patient had legal blindness in both eyes. It is known that 70% of patients with interstitial keratitis will recover at least 20/60 vision during the natural course of the disease.[3] This group therefore

† Case 3 only patient with active optic neuritis; WR†=history of weak reaction.
‡ Light-near dissociation.
§ This patient was reactive for Treponema pallidum.

reflects the fact that those referred had more severe involvement of visual acuity.

The family history was of great interest. This was positive for syphilis or very suspicious in nine cases. Data was incomplete in eight cases, and family history was negative in three patients. In addition to asking about the serologic reactions, it is important to inquire about fetal wastage early in the second trimester or a history of stillborn infants in the mother of a patient with interstitial keratitis. Cassewitz law (the severity of congenital syphilis is inversely proportional to the duration of maternal syphilis) is helpful in this regard. It was seen that when a meticulous family history was taken for syphilis, this was positive in nine of 12 patients with interstitial keratitis, or 75%.

Another intersting observation made in this review was the fact that the pupillary light reactions were crisply intact in patients with late syphilitic interstitial keratitis. Anisocoria was noted in two patients. Light-near dissociation was looked for carefully in these cases, but was found in only three patients. Glaucoma was present in five cases, or 25% of the series. Criteria for this diagnosis were a history of elevated intraocular pressures on several occasions, as well as a history of miotic therapy combined with at least some ophthalmoscopic evidence of cupping of the optic disks. The visual fields were normal in seven cases, abnormal in seven others, and not adequately examined in six patients. There was thus a visual field defect in one-half of the patients studied by quantitative perimetry. Of the seven cases of interstitial keratitis with field defects, central scotomas were found in three; peripheral wedge-shaped optic nerve-type field defects were present in three others, and a ring scotoma was noted in one case. Ophthalmoscopic examination revealed definite chorioretinitis morphologically consistent with a luetic basis in eight of the 20 patients, or 40% of the series. Other fundus findings were noted, and in nine cases the fundus examination was within normal limits. Some degree of deafness apparent at a conversational level was found in four cases, or 20% of this series.

Stigmata of congenital syphilis were evident on inspection in eight patients, or 40% of the series. Frontal bossing, saddle nose, rhagades scars, mulberry molars, marked dental caries, high-arched palate, and short little fingers were assessed in these patients. One can palpate a notched scapula through the patient's clothing, and this finding was helpful at times.

The optic nerve was not remarkable on ophthalmoscopic examination in 18 patients. One case did present with active optic neuritis as evidenced by small hemorrhages on the disk margins, however. Focal segmental pallor was found in some patients, but was a minimal finding that required careful scrutiny.

The serologic findings were of particular interest in this study. A serum VDRL test was obtained in 19 cases. This was nonreactive in 14 patients (73%), weakly reactive in two (11%), and reactive in three cases (16%). A serum FTA-ABS test was obtained in 17 cases. This was nonreactive in five patients (29%), borderline in four cases (24%), reactive in six cases (35%), and was conflicting (reactive on one occasion, nonreactive on another) in two cases (12%). A TPI test was obtained in only three patients. One of these was of interest in that the TPI test was reactive, but the FTA-ABS test was nonreactive. In another patient, the TPI was nonreactive, but the FTA-ABS test was borderline. In the third patient, the TPI test was nonreactive, but an FTA-ABS test was not recorded.

The aqueous humor was studied by dark field examination in 10 patients. This was definitely positive for motile treponemes in one case, suspicious in one other case, and negative in eight patients. The cerebrospinal fluid was studied in six patients. Dark field examination was strikingly positive in one of these cases, with seven treponemes seen in one microscopic field. The cerebrospinal fluid was borderline to slightly elevated in two patients (45 and 60 mg%). Three of the fluids were completely negative.

## Discussion

Since the time of Jonathan Hutchinson (1858-63), it has been known that over 90% of cases of diffuse interstitial keratitis occur in syphilitic patients. Interstitial keratitis is due to acquired syphilis in 4% of cases, and the other 6% of cases have been due to tuberculosis, sarcoid, trypanosomiasis, onchocerciasis and other rare infections. Therefore, a careful slit-lamp examination of a patient with typical interstitial keratitis, showing a deep silvery-sheen like opacity in the posterior corneal stroma, accompanied by the presence of ghost vessels, enables one to make a clinical diagnosis of prior syphilitic infection with greater than 90% accuracy. This is thus an important clinical prototype by which to evaluate laboratory tests. Syphilitic interstitial keratitis has been presumed to be an allergic reaction to the treponeme for the following reasons: (1) in the newborn or stillborn infant Treponema pallidum organisms often abound and yet the cornea is clear and the eye white and quiet; (2) in the eye with active or late interstitial keratitis, however, treponemes are found in the cornea only in small numbers and after careful search; (3) there is a characteristic delay between onset of infection until appearance of the clinical process, with 50% of cases recognized between five and 15 years of age, and 85% of the cases found by the age of 25 years; (4) the process does not respond to penicillin or heavy metal therapy; and (5) the process often shows prompt clinical improvement on topical corticosteroid therapy.

Spicer's[4] classic series of 700 cases of interstitial keratitis revealed a sex incidence of 38% males and 61% females in congenital syphilis. He found that the process was bilateral in congenital cases, with the second eye involved within 12 months in 75%. All cases in this report were bilateral. In 9% of cases there are recurrences, and these may be as late as 15-30 years after the primary attack. The occurrence of glaucoma years after interstitial keratitis, which may first appear in early adult life, has been known since the time of Hutchinson. In the natural course of the disease 70% retain 20/20 to 20/60 vision with no therapy, and only 10% have vision less than 20/200.

Today, most cases of interstitial keratitis are adult patients seen in eye clinics, diagnosed by careful biomicroscopic examinations. The acute attack, so prevalent in Spicer's day, is seldom noted. However, the clinician should be aware of the significance of the slit-lamp detection of interstitial keratitis. Emphasis is placed here upon clinical diagnosis. The disease is seen in females in a ratio of 3:1, often at about 40-50 years of age, and 75% give a history of significant ocular inflammation in childhood. A careful family history for reactive serologic tests, fetal wastage, Cassewitz law, previous treatment, and other manifestations of syphilis will be positive in 75% of the cases. The pupils are typically spared, and do not commonly show light-near dissociation which is so prevalent in late-acquired syphilis. Glaucoma is present in 25% of cases. Careful search for stigmata of frontal bossing, depressed nasal bridge, Hutchinson's teeth, marked dental caries, hearing loss, sparse outer brows, high-arched palate, and short little fingers will often be rewarding. Perivascular pigmentation, sheathing of vessels, and salt-and-pepper chorioretinitis changes are seen on ophthalmoscopy in at least 40% of these patients.

This study emphasizes, however, the frequency of seronegativity in patients with interstitial keratitis. The routine reagin (VDRL) test was definitely reactive in only 16% of cases. If weakly reactive tests are included—and it should be remembered that weakly reactive reagin tests may be reported as nonreactive or weakly reactive on repeat testing in 50% of laboratories—some reagin reactivity was found in 27% of cases. However, 75% of patients with typical syphilitic interstitial keratitis will be nonreactive on serum VDRL testing.

Furthermore, even specific (treponemal) tests are often nonreactive in interstitial keratitis. The serum FTA-ABS test was definitely reactive in only 35% of cases in this

series. If one includes borderline tests and conflicting data, some FTA-ABS reactivity was noted in 71% of the cases. However, 29% of the cases showed nonreactive serum FTA-ABS tests. It is important for the ophthalmologist to be aware of the frequency of complete seronegativity in patients with late congenital syphilitic interstitial keratitis.

If the patients have not been previously treated for syphilis, one of two courses of therapy has been advised: Erythromycin 250 mg four times daily and probenecid (Benemid) 500 mg orally twice daily for 30 days has recently been proposed. Ampicillin 1g and oral probenecid 0.5 g three times daily for 30 days may also be given. The patient should be seen one month after treatment and the decision should then be made as to whether or not therapy should be continued. If the patient is worse, therapy should be discontinued. If the patient is the same, clinical discretion is in order. If the patient is better, the therapy should be continued until maximum improvement is obtained. This may often require a total course of three months. A trial with high myopic cylindric corrections is in order in these patients. It is suggested that the ophthalmologist put a −9.00 sphere with a +5.00 cylinder in the trial frame and allow the patient to turn the cylinder axis at will. This will on occasion produce surprising improvement in patients with a difficult retinoscopy, and who are unable to use a pin-hole aperture well. Some patients develop secondary band keratopathy superimposed on interstitial keratitis, and one man was treated with EDTA therapy with improvement from 20/200 to 20/25 corrected vision. Medical therapy for one month before and until one month after intraocular surgery appears in order in these patients because of recent evidence of the persistence of treponemes in such cases. One patient in this series was so treated and had a penetrating keratoplasty and later a lens extraction with improvement of vision from 5/200 to 20/20 in the involved eye. In a study[5] of aqueous humor and cerebrospinal fluid made in a series of patients with late treponemal disease, treponemes were found in 26 of 101 cases studied with the fluorescent antibody stain.

In summary, although serum VDRL and FTA-ABS tests should definitely be obtained on patients with late interstitial keratitis, it should be stressed that this disease requires a clinical diagnosis. An adult woman with a history of ocular inflammation in childhood, sparse outer brows, Hutchinsonian teeth or full dentures, prominent frontal regions, moderate hearing loss, whose mother lost two pregnancies during the late first or early second trimester or who had a stillborn fetus before the birth of the patient, and who shows typical biomicroscopic signs of interstitial keratitis, should be diagnosed as congenital syphilis on clinical criteria with no reservation. In late interstitial keratitis deriving from congenital syphilis, seronegativity is a common finding.

## Summary

A review of 20 cases of late syphilitic interstitial keratitis revealed the frequent finding of seronegativity in such patients. The VDRL test was nonreactive in 74%, weakly reactive in 11%, and reactive in 16% of these cases. The serum FTA-ABS test was nonreactive in 29%, borderline in 24%, reactive in 35%, and conflicting in 12% of the cases. Emphasis is placed upon clinical criteria for diagnosis.

# LONG-TERM TOPICAL POLY I:C IN EXPERIMENTAL CHRONIC OCULAR HERPES SIMPLEX INFECTION

ANTHONY B. NESBURN, M.D., AND PAUL J. ZINITI, B.S.
*Los Angeles, California*

Topical synthetic double-stranded polyinosinic polycytidylic acid (Poly I:C) is moderately active against acute experimental herpes simplex (HS) keratitis in rabbits,[1,2] although its antiviral effect is not nearly as potent as that of idoxuridine.[3,4] If the same Poly I:C treatment regimen was continued beyond the period of acute infection, few recurrences were noted initially; however, after six to eight weeks recurrent keratitis, as measured clinically, occurred with equal frequency in treated and control groups.[3]

The present study was undertaken to investigate the effect of Poly I:C on a different facet of the problem. We attempted to discover whether long-term, low-dosage topical Poly I:C therapy could suppress or eradicate the disease in established chronic ocular HS infection. A previously described rabbit model[5] which mimics human recurrent ocular HS infection was employed. In contrast to other studies basing recurrence rate on clinical observation, this investigation was conducted using the virus culture method. Recovery of the agent from the tear film has been shown to be a more sensitive indicator of recurrent virus release.[5,6]

## MATERIAL AND METHODS

*Infection*—The unscarified eyes of male New Zealand albino rabbits weighing approximately 2 kg were infected by instilling two drops of high-titer herpes simplex virus (HSV) into the conjunctival cul-de-sac. The eyelids were closed and gently massaged against the globe for 10 seconds. The infecting suspension was from the 12th passage of McKrae strain HSV in primary rabbit kidney cell cultures and in this tissue had $ID_{50}$ of $10^{7.3}$ per 0.1 ml.

During the three-week period of acute infection daily slit-lamp biomicroscopic evaluation of the eyes, using 0.25% fluorescein, was carried out. Based upon these observations, rabbits were divided into groups containing equal numbers of mildly, moderately, and severely affected animals. These groups were then randomly assigned to receive drug or placebo therapy.

*Experimental design*—Beginning 30 days after virus inoculation, when clinical evidence of acute infection had subsided, culturing and treatment of eyes was initiated. Each morning (six days a week) conjunctival swab cultures were taken. Immediately afterwards, both eyes of each animal received either two drops of Poly I:C (1 mg/ml) or placebo, as outlined below.

Cross-over design was selected for these experiments, since it is both an efficient way to demonstrate drug effect and an acceptable means to obtain information about the effect of therapy after treatment is stopped. Experiment 1 was a non-blind complete cross-over study. All animals treated with Poly I:C in the first half of the experiment were treated with placebo in the second half and vice versa (Table 1).

Experiment 2 was carried out in a blind fashion and was of the half-group cross-over type. After 15 weeks of therapy, all treatment was discontinued for three weeks. When therapy was reinstated, half of the placebo group then received Poly I:C and half continued to receive placebo medication. Half of the previously Poly I:C treated group continued to receive Poly I:C while the other half of that group then received placebo therapy (Table 2).

TABLE 1

EXPERIMENT 1—NON-BLIND COMPLETE CROSS-OVER DESIGN

| | First Treatment (12 Weeks) | Second Treatment (17 Weeks) |
|---|---|---|
| Group 1 | Poly I:C | Placebo |
| Group 2 | Placebo | Poly I:C |

*Poly I:C*—Poly I:C was obtained from two commercial sources (Biopolymers Laboratory and PL Biochemical Company). With minor variations, each lot of double-stranded polymer was handled and stored according to the manufacturer's recommendation. In the second half of Experiment 2, the Poly I:C (PL Biochemical Company) was reconstituted in phosphate-buffered saline at pH 7.6 rather than at pH 6.8. At the conclusion of the study, an aliquot of each batch of Poly I:C used was tested by us and by Dr. Samuel Baron for in vitro interferon-inducing activity, employing methods outlined elsewhere.[7] Except for the instance cited below, the activity of the Poly I:C employed in this study was equal to and usually greater than NIAID Poly I:C standard.

*Virus cultures*—Conjunctival swab cultures were taken as previously described.[8] Swabs were immediately inoculated onto primary rabbit kidney cell monolayers grown in two-dram rectangular perfume bottles containing 1 ml of medium (Eagle's minimal essential medium supplemented with 10% fetal calf serum, 10% NCTC 135, glutamine, penicillin, streptomycin, and amphotericin B). Cultures were incubated at 35°C in 5% $CO_2$ atmosphere and read daily. After 10 days all normal appearing cultures were recorded as negative and discarded. All positive, suspicious, and degenerating cultures were frozen at −70°C for passage. Only those cultures showing typical HS cytopathic changes in the second passage were accepted as positive HSV isolations. To verify the reliability of cytopathic diagnosis, 50 randomly selected, second passage positives were subjected to standard microneutralization testing. All were definitely identified as HSV.

*Statistical analysis*—On the assumption that the drug had no effect on recurrence rate (null hypothesis), the number of HSV isolations should be approximately equal between groups (i.e., a "50-50 split" would be expected). The probability (p) of the observed splits (weighted when necessary for comparison) was obtained from a binomial probability table.

## RESULTS

In chronically infected rabbit eyes, Poly I:C, as administered, suppressed the number of HSV isolates obtained during the first 10 to 12 weeks of treatment. After this period of time, the number of positive cultures was approximately equal to that of placebo-treated controls despite continued therapy. Except as otherwise indicated, results reported in Tables 3 through 6 are those obtained during the consecutive weeks in which Poly I:C was considered effective.

*Experiment* 1—The results of this experiment are shown in Table 3. In Part 1 of this experiment there were 40 positive cultures in 14 placebo treated eyes for an average of 2.9 positive cultures per eye. In the same 10-week period the Poly I:C treated group yielded two HSV isolates from eight eyes, an average of 0.25 positives per eye. During the last two weeks of Part 1, Poly I:C appeared to lose its effectiveness (the number of positive cultures was similar in the

TABLE 2

EXPERIMENT 2—BLIND HALF-GROUP CROSS-OVER DESIGN

| | First Treatment Period (15 Weeks) | No Treatment Period (3 Weeks) | Second Treatment Period (18 Weeks) |
|---|---|---|---|
| Group A | Placebo | | Poly I:C |
| Group B | Placebo | | Placebo |
| Group C | Poly I:C | | Placebo |
| Group D | Poly I:C | | Poly I:C |

two groups, Poly I:C = 13, placebo = 16).

Therapy was switched in the second section of the experiment. The eyes in which Poly I:C was discontinued did not yield more positive cultures (20 isolates from eight eyes) than would be expected for placebo treated eyes (i.e., there was no rebound phenomenon). However, the previously placebo-treated eyes which had a large number of HSV isolates (40) in Part 1 now showed only six positive cultures in 12 weeks of testing. Again, the effectiveness of Poly I:C appeared to be limited, lasting 12 weeks in this trial despite continued therapy. For the last five weeks of the experiment, the number of positives in both groups (result not shown in Table) was the same (placebo = 6, Poly I:C = 7). The difference in the number of positive cultures obtained from Poly I:C-treated animals and the controls during the consecutive weeks in which the drug appeared to be effective was highly statistically significant ($p = < 0.00001$).

*Experiment* 2—This was performed on a blind basis and confirmed the previous findings. Tables 4 and 5 show data accumulated during the period in which Poly I:C was effective. Not included are the results from eight weeks of therapy inadvertently carried out with an inactive batch of Poly I:C (16 positive cultures in control eyes and 14 in Poly I:C treated eyes). During the seven weeks when active Poly I:C was employed, there were nine HSV isolates in 14 Poly I:C-treated eyes and 36 isolates in 16 placebo-treated eyes. When therapy was stopped for three weeks, the number of HSV isolates was essentially the same in all groups (Group A = 10, Group B = 11, Group C = 14, Group D = eight). In the last section of Experiment 2, half of each treatment group was switched to the opposite therapy. During the 12 weeks in which Poly I:C was effective, there were five positive cultures in 16 eyes as compared with 40 positive cultures in 14 eyes of placebo-treated animals.

Further analysis of this half-group crossover experiment yields some very interesting information (Table 5). Group A (placebo–Poly I:C) showed a marked decrease in the number of positive cultures when placed on Poly I:C. Group B (placebo–placebo) yielded about the same number of isolates in both parts of the trial. Group C (Poly I:C–placebo) showed few positive cultures while on Poly I:C and a normal number when changed to placebo therapy.

TABLE 3

RESULTS OF EXPERIMENT 1

| | Placebo | Poly I:C | Probability |
|---|---|---|---|

| | Placebo | Poly I:C | Probability |
|---|---|---|---|
| First treatment (7 weeks*)† | | | |
| No positive cultures | 36 | 9 | <0.001 |
| No treatment (3 weeks) | | | |
| No. positive cultures | 21 | 22 | >0.5 |
| Second treatment (12 weeks*)‡ | | | |
| No. positive cultures | 40 | 5 | 0.00001 |
| Both treatment periods (19 weeks*) | 76 | 14 | <0.00001 |

* Consecutive weeks during which treatment was considered effective.

† In first treatment period groups A and B (16 eyes) received placebo and groups C and D (14 eyes) received Poly I:C.

‡ In second treatment period groups B and C (14 eyes) received placebo and groups A and D (16 eyes) received Poly I:C.

TABLE 5

RESULTS OF EXPERIMENT 2 BY GROUP

| | No. Positive Cultures First Treatment Period | No. Treatment Period | No. Positive Cultures Second Treatment Period | Probability |
|---|---|---|---|---|
| Group A (Placebo—Poly I:C) | 21 | | 5 | 0.001 |
| Group B (Placebo—Placebo) | 15 | | 18 | >0.3 |
| Group C (Poly I:C—Placebo) | 5 | | 22 | 0.001 |
| Group D (Poly I:C—Poly I:C) | 4 | | 0 | <0.05 |

As in Experiment 1, no rebound phenomenon was encountered. Group D eyes (Poly I:C–Poly I:C) yielded few positives in either test period, demonstrating that Poly I:C had re-established its effectiveness after a three-week lapse in treatment.

Table 6 shows the combined results of both experiments. During the 41 weeks in which Poly I:C was considered to be effective, placebo-treated eyes yielded 136 positive cultures for an average of 2.6 positive cultures per eye, while the Poly I:C-treated eyes showed 22 positives for an average of 0.42 per eye. The difference in the number of HSV isolations between Poly I:C and placebo-treated eyes in all individual trials, and for the study as a whole, was highly statistically significant. During the 20 weeks in which Poly I:C was not effective, there were 68 HSV isolates from placebo-treated eyes and 71 isolates from Poly I:C-treated eyes.

*Distribution of HSV isolations*—One extraordinary finding of these experiments is that every eye yielded at least one HSV isolation, indicating that all eyes were chronically infected. This may be a chance happening or may be in part related to the improved culture techniques discussed below.

There was a total of 360 HSV isolations from the 11,880 cultures taken during the study, an incidence of 3%. On the basis of number of isolations, some eyes would be considered high responders and others low responders. The distribution of high and low responders was evenly spread among the experimental groups and therefore introduced no bias to the results reported. The highest number of positive cultures for any eye was 22 and the lowest was one. Of eyes yielding more than one positive culture, 90% did so in more than one episode. The average number of separate episodes of virus shedding was three, and these were usually separated by a considerable time span.

## DISCUSSION

In human ocular herpes simplex infections, fairly adequate methods exist to treat acute epithelial disease. Vision is usually compromised by repeated bouts of the disease with accompanying stromal or endothelial damage and iritis. While better agents to treat epithelial herpes would be desirable, therapeutic means to protect against initial ocular infection, to prevent deep herpetic disease, or to eliminate recurrent infection are needed. It is with the latter goal in mind

TABLE 6

SUMMARY OF RESULTS OF EXPERIMENTS 1 AND 2

|---|---|---|---|
| Experiments 1 and 2* | | | |
| No. positive cultures | 136 | 22 | 0.00001 |

* During consecutive weeks in which Poly I:C was effective.

that this study of experimental treatment of chronic HSV infection in rabbits was undertaken.

Unfortunately, chronic ocular HSV infection in rabbits was not eradicated by long-term, low-dosage Poly I:C therapy. When therapy was stopped or became ineffective, the number of positive cultures from treated eyes was the same as that from controls. However, during the first 10 to 12 weeks of treatment, Poly I:C significantly decreased the number of HSV isolations obtained from chronically infected eyes. With cessation of therapy for three weeks, another 10- to 12-week period of responsiveness to Poly I:C was established. The mode of Poly I:C action is assumed to be the induction of local interferon production,[2,4] but no direct evidence for this hypothesis was obtained or sought in these studies. The regimen in which the Poly I:C is given is of importance. In a pilot experiment we found that Poly I:C given topically three times a day every three days had no effect on the number of HSV isolations obtained from chronically infected rabbits.

In spite of the fact that man is less responsive to the interferon-inducing activity of Poly I:C than rabbits,[4] the polymer might be useful in temporarily suppressing herpes recurrences in man. Such a study is presently underway elsewhere.

The true incidence of chronic ocular HSV infection in man or experimentally infected animals is difficult to determine. However, the fact that all 52 eyes in this experiment shed virus long after the acute infection indicates that the incidence in rabbits may be much higher than suspected previously.[5,6]

Analysis of many experiments using this model has allowed us to make three rather general observations: (1) As previously reported, there appears to be a clustering of HSV isolations in any group of animals.[5] This clustering is in periods lasting 30 to 40 days occurring every 60 to 120 days. (2) The severity of the initial infection is in no way related to the number of HSV recurrences. (3) There appear to be fewer positive cultures obtained as the time from acute infection increases. The reasons for the above phenomena are at present obscure.

Obtaining a higher than usual isolation rate is at least in part due to improved culturing techniques. Freshly obtained culture material was inoculated directly onto a very sensitive herpes virus indicator, primary rabbit kidney cell cultures. With present procedures, this tissue can be maintained for the full period of observation with few instances of contamination or degeneration. Only 318 cultures were contaminated with fungus or bacteria and had to be eliminated, a rate of less than 3%. Important also was the practice of retesting all suspicious or degenerating cultures. Of 446 such repassed specimens, which would have been discarded in our previous studies, 31 or approximately 7% proved to be harboring HSV.

In spite of an improved yield of positive cultures and improved experimental design, the rabbit recurrence model remains a difficult research tool, requiring extended periods of culturing to obtain statistically significant results. However, until a better test system is developed we will continue to use this model to investigate the effect of therapeutic agents on recurrent ocular herpes simplex infections.

## Summary

Daily topical Poly I:C therapy was tested for its effect upon chronic recurrent ocular herpes simplex infection in rabbits. Fifty-two chronically infected eyes were cultured six days a week for seven to nine months. Topical Poly I:C repeatedly produced a marked, but temporary supression of positive herpes cultures—placebo-treated eyes yielded six times as many isolations (136) as the drug-treated eyes (22) during the first 10 to 12 weeks of therapy. After that period, continued therapy had no effect. However, if Poly I:C were witheld for three weeks, responsiveness to the drug was again established. No rebound in the number of virus

isolations was found when treatment was discontinued or became ineffective. The highest incidence of chronic herpes infection ever reported was encountered in these experiments. All 52 eyes (or 100%) shed culturable herpes virus.

## Ophthalmic miniature

As he sat on the grass and looked across the river, a dark hole in the bank opposite, just above the water's edge, caught his eye, and dreamily he fell to considering what a nice snug dwelling place it would make for an animal with few wants and fond of a bijou riverside residence above flood level and remote from noise and dust. As he gazed, something bright and small seemed to twinkle down in the heart of it, vanished, then twinkled once more like a tiny star. But it could hardly be a star in such an unlikely situation, and it was too glittering and small for a glow-worm. Then, as he looked, it winked at him, and so declared itself to be an eye; and a small face began gradually to grow up around it, like a frame 'round a picture.

# NOTES, CASES, INSTRUMENTS

## HETEROCHROMIA ASSOCIATED WITH COLOBOMA OF THE IRIS

ROBERT C. DREWS, M.D.
*Clayton, Missouri*

AND

GUILLERMO PICÓ, M.D.
*Santurce, Puerto Rico*

Each of us has seen a patient who had both heterochromia and a coloboma of the iris. We could find no prior description of this association.

### CASE REPORTS

*Case* 1—A six-year-old white girl was seen in November, 1966, at the University of Puerto Rico because of a defective left eye, present since birth. Her medical history was non-contributory. There were no other physical abnormalities.

The right iris was thinner at the six o'clock position than elsewhere. There was a complete coloboma of the left iris at the six o'clock position. The right iris was blue and the left was brown. The left cornea was smaller than the right, but the eye was not microphthalmic. Left esotropia measured 55 prism diopters for distance and near. A small coloboma was present inferiorly in the right choroid. A large coloboma of the left choroid extended from a point near the disk to involve a large area inferiorly. The optic disks were normal. Visual acuity was 20/25 in the right eye and light perception and projection in the left. Retinoscopy following atropine instillation indicated a correction of +2.50 sph ⊃ −0.75D cyl.ax.180° for the right eye. It was impossible to perform accurate retinoscopy on the left eye.

When this child was last seen in May, 1970, the findings were unchanged.

*Case* 2—A 57-year-old woman was first seen in May, 1955, for a mild conjunctivitis in both eyes. A coloboma had been present in the left iris since birth. Vision in this eye, always slightly less than in the right, had previously been corrected to 20/38. Corrected vision in the right eye was 20/15.

The right iris was blue and the left a yellowish blue. There was no microphthalmos. Early arteriolarsclerosis was present. There was no sign of a choroidal coloboma in either eye, but a partial coloboma was present in the left iris. The right eye showed no evidence of prior iritis. Astigmatism in the left eye measured 3.50 diopters. Visual acuity with best correction was 20/25 in the right eye and 20/60 in the left.

This patient has been followed at irregular intervals. In 1963, Goldmann perimetry showed normal visual fields. In 1968, a cortical cataract in the left eye was more advanced then one in the right eye.

In a rabbit colony bred by Jesberg[1] for coloboma of the uvea, a few of the animals were born with heterochromia rather than a coloboma. Following this experience, Jesberg saw a patient with both coloboma of the iris and heterochromia. In Jesberg's patient, the eye without the coloboma had hyperpigmentation of the conjunctiva as well as the iris. We submit that Jesberg's experience, together with the patients reported herein, tends to suggest the association of heterochromia and coloboma as a true syndrome.

From the Department of Ophthalmology and the Oscar Johnson Institute, Washington University School of Medicine, and the Department of Ophthalmology of the University of Puerto Rico.

Reprint requests to Robert C. Drews, M.D., 211 North Meramec, Clayton, Missouri 63105.

### SUMMARY

Coloboma of the iris was associated with heterochromia in two female patients. In both, the darker and amblyopic eye had the coloboma. Another investigator has described a similar patient, and in this case, too, the eye without a coloboma had hyperpigmentation. In a colony of rabbits bred for coloboma of the uvea, a few were born without coloboma, but with heterochromia instead.

## NEW SURGICAL INSTRUMENT CARRYING CASE

DAVID J. MCINTYRE, M.D.
*Bellevue, Washington*

Although this is an age of rapid advancement in instrumentation, we have seen little innovation in the area of surgical instrument storage and carrying. Existing cases are rather archaic combinations of little elastic straps, cardboard and loose boxes. The pri-

Reprint requests to David J. McIntyre, M.D., 1300 116th Avenue N.E., Bellevue, Washington 98004.

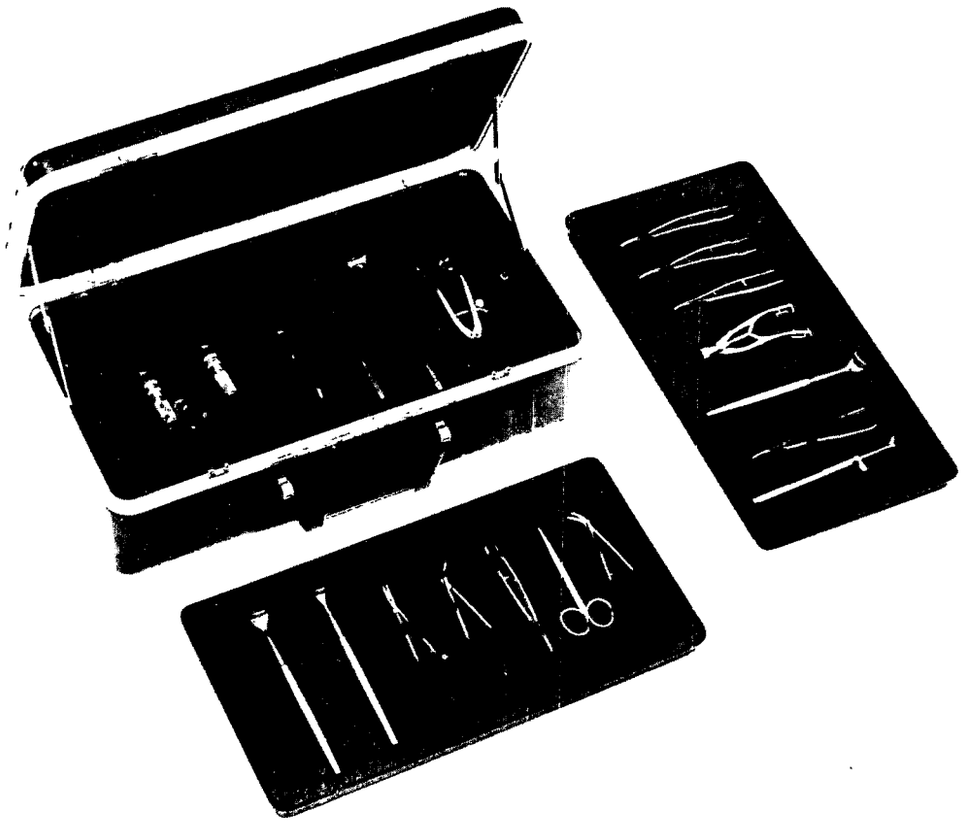

Fig. 1 (McIntyre). New surgical instrument carrying and storage case.

mary function of a case, of course, is to provide reliable protection for the vast assortment of small instruments the ophthalmic surgeon is prone to carry. Additional desirable features would be convenience, durability, compact size, and attractive appearance.

A case has been developed to meet these criteria, utilizing a new packaging concept.* Very simply stated, this case is full at all times. There is no room for instruments to move around. The case is filled with several layers of compressible plastic foam. These foam layers are molded into trays with a sufficiently rigid frame to facilitate handling. The instruments lying between the layers are held firmly in position by the compressed foam; in the absence of any instrument, foam fills the potential space. The lowest tray is equipped with a handle at each end allowing the stacked trays to be removed from, and returned to the case as a unit. When the trays are unstacked on a flat surface, each instrument is clearly visible for selection.

Immediately beneath the stacked trays, the case contains a thick foam pad which has been die-cut to hold bulky, less delicate instruments such as speculae, irrigator bulbs, cautery, and knives in their original boxes. The cores of these cutouts are held in place with narrow webs which can be easily divided for removal, but for those who must "do their own thing," an alternate pad can be cut to any desired pattern with only a sharp

* This instrument case is available from Surgical Products Division, Alcon Laboratories, Inc., Fort Worth, Texas 76101.

knife and the patience of an ophthalmic surgeon.

SUMMARY

A new surgical instrument carrying-storage case is designed on the basis of a new packaging concept. The case provides excellent instrument protection, combined with minimum weight and bulk, convenience, and durability.

---

OPHTHALMIC MINIATURE

North, South; Doctor, Patient—The Anglo-Saxon doctor, when dealing with a medical problem, may handle the physical aspects of the case with commendable dexterity, but in dealing with those aspects which are not encompassed by his clinical experience, notably the patient's histrionic manner, his distrust of the doctor's opinion, and his inadequate command of English, the doctor is likely to fall back on non-medical premises, usually culturally determined, but arising from a culture which differs from the Italian one. He may regard histrionic behavior as cowardly and asking for other opinions as ungrateful or as a challenge to his concept of himself as an authoritarian figure; his inclination is frequently to reject the patient, having excluded serious physical disease, to make a diagnosis of character defect, the implication often being that the patient—and sometimes, implicitly, the race—is inferior.

In contrast, a prevailing idea in Italian communities is that the sick person is the center of attention; he considers that it is his right that others forgo their normal activities in order to tend to his needs. The "stiff upper lip" of the British society does not exist. The patient expects this attention from his doctor and believes that he has a right to inconvenience the doctor. The Italian patient thinks that he knows his disease and has his own preconceived ideas about the etiology, prognosis, and implications. Above all, he lives to discuss his illness with the doctor, and puts himself on an equal plane when doing this. To the doctor unaware of these factors, the Italian patient appears to lack confidence and, worse, he is prepared to argue and put forward concepts of disease which have a totally different basis from the doctor's. It is evident that in this situation little mutual understanding can occur, unless the underlying premises are appreciated and allowed for by the doctor and, when relevent, the underlying concepts discussed.

# MEETINGS, CONFERENCES, SYMPOSIA

EDITED BY THOMAS CHALKLEY, M.D.

## FIFTH ANNUAL MEETING OF THE HORACIO FERRER EYE INSTITUTE INTERNATIONAL SYMPOSIUM ON OCULAR MOTILITY

Over 200 ophthalmologists from 15 countries met in Miami at the end of January, 1971, to discuss problems in strabismus at the fifth annual symposium on ocular motility sponsored by the Horatio Ferrer Eye Institute. The two and one-half day meeting was so well organized by Symposium Director Olga Ferrer, and by Program Chairman William Rubin, that it is possible only to mention the multiple nonscientific attractions of friendly cocktail gatherings, a banquet with a fabulous show, a barbecue outing with exiled Cuban guitarists. The Fontainbleau Hotel in Miami Beach housed the symposium. Arthur Linksz, the guest of honor, provided the opening paper on physiologic and anatomical factors pertinent to an understanding of squint, but in a characteristically erudite and yet modest way he also provided philosophical insight into the problems of absolute and subjective localization, amblyopia, and the crowding phenomenon. He provided an appreciation of the knowledge which accumulated many years before the advent of so-called pleoptic methods.

Hermann Burian, honorary president, dealt with the role of the AC/A ratio in the production of the two main forms of accommodative esotropia, and Harold Brown emphasized that a high AC/A ratio may be associated with an exodeviation almost as frequently as with an esodeviation. John Hermann discussed the rate of the movement of the convergence which occurs in response to an accommodative stimulus (the so-called "pace response") which can be measured by electro-oculography and which leads to a better understanding of the implications of the AC/A ratio in the management of an accommodative squint. Rethy considered that the term "partially accommodative," as applied to an esotropia, is usually a misnomer because it applies to a squint in which there is a failure to unmask the full extent of the underlying accommodative factor. Charles Windsor said that he thought that the gradient method is more reliable than the heterophoria method in determining the AC/A ratio because it introduces other factors such as the influence of proximal convergence. He pointed out, however, that the gradient method may be uncertain in the young child because its accuracy depends on an exact degree of accommodative change in response to different spherical lenses.

The nature of the A and V phenomena was discussed by Leonard Apt, Webb Chamberlain, Joseph Goldstein, and Joseph Lang. The necessity of using a target which excites a precise degree of accommodation during the measurements of the deviation in the different positions of gaze was stressed, and evidence was produced which casts doubt on the importance of anomalies of the horizontal recti in the genesis of the phenomena.

Detailed discussons on early convergent strabismus were led by Albert Ciancia, Joseph Lang, and Robert Reinecke. Late convergent strabismus was the topic of Bruno Bagolini, Pierre Vital Berard, and Glen Gibson, and divergent strabismus was discussed by Robison Harley, Emma Limon-Brown, Donelson Manley, Suzanne Veronneau-Troutman, and Charles Windsor. These discussions occupied the main part of the first afternoon. The association of congenital and latent nystagmus was mentioned, and attention was directed to the peculiar form of estropia of late onset which occurs in myopia. The difference between the true divergence excess form and the pseudodivergence (simulated divergence) excess form of exodevia-

tion were outlined. The importance of pre- and postoperative orthoptic treatment in the mangement of exodeviations was stressed.

In a discussion of vertical muscle imbalances by Webb Chamberlain, Jorge Ferrer, Hiram Hardesty, Robison Harley, Phillip Knapp, and Keith Lyle, the condition of alternating sursumduction was described in detail and also its distinction from a simple bilateral overaction of the inferior obliques.

In the opening paper of the second day, Keith Lyle (guest of honor) provided a comprehensive survey of the various forms of ocular palsy that follow trauma, including their surgical management. This was followed by a paper on the significance of nystagmus in early childhood presented by Kenneth Wybar, with emphasis on the importance of distinguishing between idiopathic congenital nystagmus, which is probably the result of a minor derangement of the centers in the brain stem, and the pendular type, which is probably the result of some syndrome or an ocular albinism which is only detected in the early stages by refined methods of investigation.

A discussion on various forms of supra and infranuclear paralytic strabismus was presented by Robert Jampel, Keith Lyle, Robert Reinecke, and Kenneth Wybar. They produced some interesting clinical and experimental observations which suggest that the condition of aberrant regeneration of the oculomotor nerve (the misdirection syndrome) is the result of a mass response of some or all of the nerve fibers in the distal part of the nerve, rather than the result of a misdirection of axons which pass into the distal part of the nerve from the proximal part. The finding of a co-contraction of the superior rectus and inferior rectus is part of the evidence for this concept. Discussion also centered on a peculiar form of dissociated vertical movement which may be the result of a "cross-wiring" of the supranuclear pathways of the centers of the brain stem.

The lesions of the orbit which lead to anomalies of ocular movement were dealt with by G. M. Bleeker, John Dyer, and Byron Smith. There is geometric evidence that the enophthalmos which occurs in a blow-out fracture accentuates the hypotropia and limitation of elevation of the affected eye.

The afternoon session of the second day opened with a discussion on contact lenses in sensory and motor anomalies presented by John Dyer, Olga Ferrer, Louis Girard, and John Hermann. The influence of contact lenses on the AC/A ratio was discussed; in myopia the AC/A ratio is higher with contact lenses than with spectacle lenses, so that contact lenses are less helpful in the management of an esodeviation than in an exodeviation. In hypermetropia it is lower with contact lenses than with spectacle lenses so that contact lenses are more helpful. The importance of contact lenses in the postoperative management of congenital cataracts was stressed, but a subsequent discussion emphasized the special problem of rubella cataracts because of the endophthalmitis which is prone to follow even faultless surgical technique. The occurrence of a stimulus deprivation amblyopia is also a possibility in any form of congenital cataract which is not susceptible to postoperative treatment with contact lenses. The use of soft contact lenses in aphakic children was evaluated by John Dyer. This panel was followed by another one on ocular muscle surgery. The tendon lengthening procedures of partial tenotomy and partial myotomy was discussed by Harold Brown, and the surgical treatment of congenital nystagmus was discussed by Keith Lyle and Leonard Apt, who provided interesting comments on the merits and demerit of plain catgut, chromic catgut, and collagen sutures in the surgery of the extrinsic muscles.

The concluding sessions were devoted to the sensory anomalies of squint, with discussions on amblyopia presented by Eugene Folk, John Flynn, Keith Lyle, and William Rubin. The therapeutic uses of prisms was discussed by Bruno Bagolini, Pierre Vital Berard, Hiram Hardesty, Arthur Linksz,

and William Rubin, and the role of orthoptics by John Dyer, Louis Girard, Emma Limon-Brown, and Suzanne Veronneau-Troutman. These disscusants gave particular attention to the application of prism therapy in esotropia with anomalous retinal correspondence, and also dealt with the different aspects of occlusion in the management of squint. An interesting contribution by John Flynn showed that Mach's bands, which are revealed by viewing a luminance gradient, are increased in width in the amblyopic eye. This is further indication of the complex changes in visual function which occur in amblyopia.

The meeting concluded with a discussion on the many different charts which are available for the recording of visual acuity. That there is a need to achieve a standardization of the composition and spacing of the letters in order to be able to obtain recordings which are readily comparable was pointed out by Jane Romanio and Marion Sterner.

Kenneth C. Wybar

---

## SOCIETY OF EYE SURGEONS MEETING

As its parent organization, the International Eye Foundation, celebrated the 10th anniversary of its founding, the first congress of the Society of Eye Surgeons (SES) was held in Washington, D.C., on May 27 and 28, 1971. There were 233 members in attendance among a total group of 320, including guests and residents. In all, 14 foreign countries were represented. The response of the membership exceeded all expectations and emphasized the need for and the value of a congregation of ophthalmologists interested in surgery.

The opening ceremonies were impressive and included the display of our national colors by honor guards from all branches of the United States military services. John Harry King, Jr., Executive Director of the SES, and Medical Director of the International Eye Foundation, read a congratulatory letter from President Nixon, which stated in part ". . . those who have supported this great humanitarian undertaking deserve the admiration and respect of all Americans." Congratulatory cablegrams were then read from members of many countries who were unable to attend the congress.

Prof. Hans Goldman was chosen the Honorary President of this first congress and Derrick Bail presented him with a large inscribed silver tray as a memento of the occasion.

Eight of the program participants were from foreign countries, with Canada, Latin America, Europe, Asia, the Middle East, Africa and Australia particularly well represented. The papers were grouped in panels on injuries, cornea grafting, extraocular muscles, glaucoma, plastic surgery, retinal detachment, and cataract. All presentations were given in English much to the credit of our Fellows from abroad. There was no language problem so that an easy exchange of views in the discussion was possible and was most profitable. The board representation enabled us to hear details of the most current techniques in all phases of eye surgery, and we were again impressed with the unique and valuable contributions from every part of the globe. Since such studies are often slow in appearing in our literature, the Congress provided us with the opportunity to evaluate and apply the new techniques which are constantly improving operative results.

Prior to his discussion on parasitic disease of the orbit, Lorenz E. Zimmerman was made an honorary fellow of the society. R. Townley Paton, one of the guests of honor at the congress presented the distinctive plaque of membership. The highlight of the meeting was the presentation of the Vail medal to Algernon B. Reese. This gold medal honors Derrick Vail, a founding member, and to quote from Prof. Goldman's citation ". . . is an estimate of the great esteem which the society holds, not only for Dr. Vail's accomplishments in ophthalmology, but also

for his character and leadership." Dr. Reese was cited for ". . . his scientific publications, his textbooks, his versatility as a medical ophthalmologist, ocular and ophthalmic surgeon, which have given him an enviable reputation in each field." The only previous recipient of the award is Count Hernando Arruga, of Barcelona, Spain. The Vail lecture, given by Dr. Reese was entitled "Orbital surgery." It was a most complete and current review of this area of eye surgery by the surgeon who has had the greatest experience with the orbit in the United States, and perhaps the world.

The meeting was meticulously organized, but the time seemed much too short. Nearly 40 summary papers were presented by the membership on a tight schedule of just two half-days. Many excellent papers submitted could not be accepted due to the brevity of the congress.

At the Foresight luncheon for members and wives the feature was a review of the activities and accomplishments of the International Eye Foundation over the last decade. The talk, illustrated with color slides, was presented by the Foundation's Medical Director, J. Harry King, and he has kindly summarized his presentation for JOURNAL readers in an editorial in this issue.

The official reception permitted all the guests and their families to meet Prof. Goldmann and the guests of honor. Dr. and Mrs. Derrick Vail, Dr. and Mrs. Algernon Reese, and Dr. and Mrs. R. Townley Paton were in the receiving line. Ambassadors from the various countries of the members were present as were numerous other dignitaries.

To mark the Memorial Day weekend, the closing ceremonies included a most impressive event. Dr. and Mrs. Reese and Dr. and Mrs. Paton presented a wreath from the Society of Eye Surgeons at the tomb of the unknown soldiers at Arlington National Cemetery, accompanied by Honor Guards and a Marine bugler playing taps.

Each member attending the meeting received a STAR certificate (Surgical Training After Residency) established by the SES as evidence of continuing medical education.

Enthusiasm was obvious among those attending and participating. The meeting did bring out new surgical techniques—some of which were controversial, and even experimental. Many requests were made for more meetings and plans are now being formulated.

John W. McTigue

## NEW YORK MEDICAL COLLEGE OPHTHALMOLOGY SEMINAR

The Department of Ophthalmology of the New York Medical College held its annual Seminar in Aruba, Dutch West Indies, from January 22 through January 30, 1971. The seminar theme was ocular surgery.

David Kasner presented an excellent illustrated demonstration of the surgical anatomy of the limbus. He stressed the importance of the wider upper angle and provided appropriate surgical landmarks for a variety of anterior segment procedures. Ramon Castroviejo discussed adult cataract surgery, corneal surgery, and the advantages and disadvantages of microscopic techniques. Austin Fink spoke on the suction technique of congenital pressure constant. Charles Kelman reviewed the newer methods of cataract surgery, including the use of phakoemulsification and the indication for variations in the size of the limbal incision in cataract extraction.

The session on glaucoma was opened by Ramon Castroviejo, who discussed methods of filtering surgery. Miles Galin then described techniques for surgery of congenital glaucoma including an intracameral approach in cases of totally opaque corneas. Irving Baras presented techniques of combined cataract extraction having of its high rate of success and negligible incidence of complications. Bernard Kronenberg dis-

cussed the value of cyclocryotherapy in glaucoma. He has been forced to limit this procedure to the management of desperate cases because of the low incidence of long-term value.

A corneal symposium was opened by A. Benedict Rizzuti, who discussed surgical approaches to bullous keratopathy. Dr. Castroveijo then presented his 10-year results with keratoprostheses and discussed the optics and techniques necessary to employ the newer methods for preserving and storing donor corneal material.

Ophthalmic surgical films were an integral part of the meeting and covered a wide range of subjects. The next seminar will be held in Puerto Rico at the Dorado Beach Hotel, January 14 through January 22, 1972.

Bernard Kronenberg

---

## JAPANESE MEDICAL ASSOCIATION

The 18th meeting of the Japanese medical association was held April 3-7, 1971, in Tokyo. The opening ceremony was held at the Budokan on the afternoon of the third day. The main theme of the meeting was progress of medicine and ethics of physicians. There were many symposiums, special lectures, and invitational speeches. Some 20,000 physicians, technicians, and exhibitors attended this meeting with its five days of programs held simultaneously in six locations.

The 75th annual meeting of the Japanese association of ophthalmology was held on April 3-4, at the Saitama Hall near Tokyo, under the chairmanship of Shinichi Shikano (Tokyo). Some 15,000 attendants, including 13,000 ophthalmologists and 200 optometrists and exhibitors, registered for the meeting.

There was no invited foreign guest, but one paper was read by a guest speaker and a symposium was held on the second day. Seventy-two free papers were presented on the first day and the morning of the second day.

In the latter half of the morning on the second day Takashi Mizukawa (Osaka), the guest speaker selected by the Japanese Ophthalmological Society, spoke on physiology. and the tears. He dealt with the re-evaluation of Schimer's test and its comparison with Mizuoka-Kamada's modification, the inhibitory effect in man of the closing of the eye on secretion rate of tears examined by an isotope dilution technique, osmotic pressure of tears studied by the Ramsy and Brown technique and inulin space determination by $^{14}$C-inulin and intracellular electrolyte concentration.

A symposium on roadway traffic and the eye featured three speakers in the early afternoon. Akihiro Suzumura (Nagoya) opened a discussion on variation of dynamic visual perception of spatial objects. Harutake Matsuo (Tokyo) presented a paper on visual acuity of car drivers and seamen. In his survey of visual acuity of licensed car drivers, he found 49 (13%) out of 424 car drivers whose visual acuity with or without glasses was below standard, and he stated that accidents were caused by reduced visual acuity in the aged and in those with night myopia. Sodium street lamps caused drivers difficulities in discriminating colors. Iwao Iinuma (Wakayama) closed the session with his report on problems of disabling glare. He concluded that a driver whose eyes are exposed to a glare might become suddenly unable to see when the light goes out. As roadway signals, bright color lights are not always easy to discriminate, a bright red light being sometimes misperceived as yellow.

Among the 72 free papers, one of outstanding interest was presented by Ken Ohta (Sagamihara). He dealt with a peculiar, heretofore unknown eye disease seen in the Saju district in Nagano prefecture caused by organophosphorous insecticides. The patients complained of blurred vision, epiphora, headache, perspiration, polydipsia, dizziness, tremor, and diarrhea. They showed swollen disks, atrophy of the optic disk, spasm of the ciliary muscles, cataract, disturbance of eye motion, miosis or mydriasis in severe cases accompanied by narrowed

visual fields. Neurologic examinations revealed increased or reduced deep tendon reflexes, cranial nerve palsy, atrophy of the limb muscles, gait disturbance, tremor, clonus, and sensory disturbances. He also found abnormal liver function and paranitrophenol in the urine.

Kanji Okuda and associates (Okayama) illustrated ocular disorders in subacute myelo-optics neuropathy. The ocular histopathology of six autopsy cases was discussed ascribing the cause to degeneration of macular fibers of both optic nerves and degenerative disappearance of retinal ganglion cells. They also confirmed that these symptoms could be induced by chinoform administration in animals experimentally.

Hiromitsu Yamanaka (Kobe) related the mode of inheritance of Leber's disease. He examined all members of three families with this disease and was able to establish that inheritance of Leber's disease follows Lossen's law. He strongly supported the assumption, based on investigation of carrier ratio, that every daughter of a carrier inherits the trait. All males examined had a predisposition for this disease. The mode of inheritance was strongly suspected to be cytoplasmic.

Yoshiaki Taniguchi (Kagoshima) presented electron microscopic observations on small blood vessels of the iris of patients with diabetes. The basement membrane of the small vessels became extremely thickened by the increase of reticular fibers and the existence of dense debris. Many glycogen granules were observed in some endothelial cells, pericytes, and the vascular lumen.

The next meeting will be held in Okayama in 1972 under the chairmanship of Kanji Okuda. Noboru Kumitomo (Tokyo) was selected as a guest speaker by the association. A symposium is planned on the subject of infectious diseases of the eye. It will be led by Yukio Uchida (Tokyo), Shusaku Kitano (Tokyo), and Shunsaku Kobayashi (Yamaguchi).

## THE NEED FOR STANDARDS IN TESTS OF VISION

One means of advancing clinical science is the adoption of standard test procedures by all clinicians. This allows the exchange of patient data and comparison of findings by different investigators. For example, such standards exist in tonometry, and in quantitative perimetry. In fact, a major contribution of the Berne and Tübingen schools has been to provide us with equipment for perimetry which may be calibrated and which has controllable and definable stimuli.

In order to progress further in this sense, added standards need to be formulated. In particular, visual acuity and tangent screen field tests need to be defined more effectively.

The late Prof. Paul Fitts of the University of Michigan used to state that a threshold for a psychophysical response could be defined at four levels: detection, recognition, interpretation, and correlation. Each level requires a different degree of neural or cognitive activity. Visual acuity thresholds represent an excellent example of this four-level response scale.

1. A detection threshold (in older terms

"minimum visible") as applied in clinical practice today is really only determined in the optokinetic nystagmus test, where it is assumed that if the repetitive stripes are detected, fixation on the pattern will occur (slow phase of nystagmus).

2. A recognition threshold (minimum separable) requires the patient to report to the clinician the presence of one object or two, or the direction toward which the fingers of the illiterate "E" (or the opening of the Landolt "C") are pointing.

3. An interpretation threshold requires the evaluation or interpretation of pattern, such as the letters usually employed on a Snellen chart. For example, in the English language there is only one letter with a triangular shape, base down—the letter A. In fact, the interpretation of this letter does not even demand resolution of internal structure. Similarly, there are two letters having triangular shapes, base up—V and Y—and so forth. Thus prior knowledge of letter shapes and interpretation of form enters into such judgments.

4. Correlation thresholds involve interactions between forms. Simple examples are words. One implication is that the whole is greater than its parts; that is, even if the word "the" is somewhat blurred, we are familiar enough with the general shape or form of this word that we can detect this letter group readily, particularly when it is used in a proper sequence of words. Most "near" tests of visual acuity involve reading cards requiring this type of advanced cognitive skill.

Thus, the several tests of visual acuity commonly used require different levels of response, varying degrees of education and cognitive skill, and the integrity of different neural processes. The problem is further compounded in near visual acuity tests where there are bewildering arrays of test cards, recording schemes, and poor standardization of test lighting and measurement distances. Here is the perfect example of an area requiring the development of better standardized test procedures in order to advance fine testing of response skills and exchange of data between clinicians.

With the tangent screen, we suffer the indignity of having the wrong unit specified as our standard. The oft repeated figure of "seven foot candles falling on the tangent screen" does not take into consideration the reflectance properties of the screen and targets employed. Hence targets may be flat or spheres, and be coated with anything from matté to luminescent paints. Contrast varies because of the use of different colored backgrounds having nonuniform reflectance properties. In short, we have no standard! Luminance and contrast properties need to be properly specified. In addition, there are absolutely no accepted specifications for colored test targets, and hence this potentially valuable phase of clinical testing has not had general acceptance.

Not only do we need to have such standards formulated, but the professions must be educated toward their application.

### Blow-out fractures

Editor:

American Journal of Ophthalmology:

Articles and books on orbital fractures, especially of the blowout variety, are increasing in frequency. Some emphasize better methods of radiologic diagnosis and some concentrate on clinical evaluation of the factors which indicate or contraindicate surgical exploration. All of them, however, seem to take the position that once a fracture is located, the herniated material reduced, and an alloplastic plate (Supramid Extra, Teflon, Cranioplastic, etc.) used to cover the break so that further herniation cannot occur, a satisfactory end result will automatically result. This isn't true because the vertical rectus muscles—especially the inferior rectus and sometimes the inferior oblique—are

sometimes so damaged that they cannot function properly. All too frequently patients are encountered whose downgaze fusion (which is much more important than upgaze fusion) was better before the fracture was repaired than afterwards.

For those who are carefully studying these patients, as we are, we recommend that at the initial examination careful photographic records be made of the patient's eyes in the primary position, and in upgaze and downgaze. If the horizontal motions seem abnormal, as might result from either an abducens paralysis or a blow-out fracture of the medial orbital wall, photographs with eyes right and eyes left should be added. Since the inferior nasal wall can be broken by a blow from a fist to the orbital rim, special attention should be given to testing the function of the inferior oblique, as this muscle arises from this bony area.

If there is a delay between the time of the first examination and the time of surgery, photographic records should be repeated. Then, several weeks after surgical repair, photographs from the same angles should be taken again. When possible, prism cover measurements and preoperative and postoperative forced duction tests should be made. These will give us a better basis for study and will point particularly towards problems yet unsolved, such as (1) how much damage the inferior rectus muscle has sustained if it is the presenting tissue that batters the orbital floor, and (2) when and how much should the vertical muscles be recessed or resected in trying to correct diplopia.

Richard Dortzbach offers a surgical suggestion: When the incarcerated muscles for which you have been searching comes into view, don't seize and wrench it! This could be the coup de grace for the nerve supply. Fracture the bone some more and let the muscle or its capsule energy.

## METASTATIC ENDOPHTHALMITIS

Editor:

American Journal of Ophthalmology:

I read with interest the article entitled Metastatic endophthalmitis associated with injection of addictive drugs, by H. S. Sugar, G. H. Mandell and J. Shalev. In a recent case report,[1] a rapidly progressive brain abscess was described in a heroin addict. The patient presented with an acute onset of unilateral weakness, dysphasia, hemaniopsia, and there were recent needle punctures in the anticubital fossa. At autopsy, phycomycosis was identified in necrotic brain tissue. The usual sino-orbital syndrome was absent and there was no pathologic evidence of the fungus in any other organ tissue. It is of particular interest that a consulting mycologist described stellate hairs in the tissue which might have represented remnants of the material used to purify the drug before injection. This report seems to lend support to the conjecture by Sugar and his associates that the fungal endophthalmitis in his patient was secondary to emboli from the injection site.

Fungal endocarditis is not uncommon in drug addicts, the most common organisms being Candida and Aspergila. In the absence of endocarditis one should be aware that fungal emboli from the drug injection site might well be the source of ocular as well as focal nervous system infections in this group of patients.

## BOOK REVIEWS

COLOUR ATLAS AND CRITERIA OF FUNDUS CHANGES IN HYPERTENSION. By Kimiho Irinoda. Tokyo, Igaku Shoin Ltd., 1970. Clothbound, 141 pages, table of contents, references, index, 89 color and 100 black and white figures. $19.00

A Japanese cooperative study of hypertensive retinopathy was started in 1961. In 1966 a committee composed of 14 Japanese ophthalmologists was organized to determine the diagnostic criteria for classifying the fundus changes in hypertension. This book represents a consensus of their work.

Diffuse and localized arterial narrowing, the arteriovenous ratio, variations in the width of the arterial light reflex, tortuosity, and arterial branching angulations were studied by means of retinal fundus photographs and measurements were made where possible. Examples of each type of change are illustrated by colored fundus photographs.

The classifications of Keith-Wagener, Wagener-Clay-Gipner, Scheie, and Leishman are then briefly summarized. A new and much more complicated classification is presented which is drawn mainly from Scheie, modified by their own findings. A similar modification of the Keith-Wagener classification is also presented.

The photographs are of such a quality that the changes exemplified cannot always be visualized, and there are no data presented indicating the hypertensive status of the patients photographed. The careful work of Stokoe and Turner (Brit. J. Ophth. 50:21, 1966), which demonstrates the unreliability of measuring arteriovenous ratios, has been ignored as has the effect of venous dilatation on these ratio measurements. In fact, the increasing venous changes, regularly present in both hypertension and arteriosclerosis of sufficient duration, and the secondary effect of venous insufficiency upon the arterial wall, have not been given consideration (see Fig. 22, p. 31; Fig. 23, p. 32; Fig. 24, p. 34; Fig. 29, p. 42).

Other figures (Fig. 72, p. 93; Fig. 73, p. 94; Fig. 76, p. 99 and Fig. 77, p. 100) are labeled as neovascularization in the retina or anastomosis of retinal vessels, whereas they are actually venous collaterals following branch veing obstructions.

Figure 87 (p. 113) may represent fluid beneath the retina or beneaath the pigment epithelium, but certainly not retinal edema as it is labeled, and Figure 61 (p. 80) is certainly a branch vein obstruction rather than obstruction of the central retinal vein.

It is too bad that Leishman's study was not given more weight, for it represents the first good clinicopathologic study of hypertensive retinopathy and includes systemic data as well.

I have some reservation regarding the results of cooperative studies in such a complicated area as hypertensive retinopathy. The cooperative study initiated by the American Ophthalmological Society resulted in the Wagener-Clay-Gipner classification which never gained widespread acceptance despite the labors and excellence of these highly qualified authors.

Finally, the English translation is not always perfectly clear.

CLINICAL EXAMINATIONS IN NEUROLOGY, 3rd ed. By members of the Departments of neurology, physiology, and biophysics of the Mayo Clinic. Philadelphia, W. B. Saunders, 1971. Clothbound, 350 pages, table of contents, index, 85 black and white figures, 1 color figure. $12.50

This compact volume contains a wealth of diagnostic information. It is a very valuable guide to the examination of a patient with neurologic history. An important section is devoted to an examination of infants and children. An anatomical organization

follows, covering the cranial nerves, neuro-ophthalmology, motor function, a sensory examination, mental, language and autonomic functions. Of further interest are diagnostic techniques involving the ancillary specialties such as neuroradiology, electroencephalography, electromyography, and spinal fluid examination.

The section on neuro-ophthalmology is probably of less interest to the ophthalmologist, who will likely derive such information from specialized ophthalmic texts. However, the neurologic examination is so clearly and concisely explained that this volume will be a worthwhile guide to the ophthalmologist.

STEREOSCOPIC ATLAS OF CLINICAL OPHTHALMOLOGY OF DOMESTIC ANIMALS. By H. E. Jensen. St. Louis, C. V. Mosby, 1971. Clothbound, 201 pages, table of contents, index, 187 figures, 16 viewing reels and viewer, $49.50.

Veterinary ophthalmology has grown tremendously in this country. A year ago, the American Society of Veterinary Ophthalmology spawned the College of Veterinary Ophthalmology. It is anticipated that in the near future examinations will be made available for certification of veterinary ophthalmologists.

Dr. Jensen has thus written a timely and much needed atlas. Using the Donaldson stereo camera, the atlas has been heavily annotated with color View-Master stereoscopic photographs. The Mosby publishers have combined text material and stereo photographs in a complementary and easy to use fashion. The text begins with a chapter on instrumentation. It is evident that special instruments have not been designed for animal examination. Instead, the standard tools and methods are employed. The body of the book consists of a discussion of various disease entities organized into chapters on the basis of their location. The index is complete and contains the View-Master reel numbers to further facilitate use of the very fine color stereo photographs.

In the preface the author states that his is strictly a clinical approach and thus references to the available literature have been omitted. In point of fact, only Magrane's textbook of canine ophthalmology is given as a reference to the considerable ophthalmic veterinary literature. It is difficult to take such a position and not be criticized. We do, however, see post-therapeutic photographs which attest to the success of the author's therapeutic regimen. The descriptions and photographs of the diseases have been augmented by only five photomicrographs showing the histology. It must be remembered, however, that animal autopsy material may be as difficult to obtain as human material.

There are two outstanding chapters. The author's descriptions of corneal disease and of the many types of lens opacities are superior. The book clearly and concisely conveys one practitioners's vast clinical experience in veterinary ophthalmology. It is a valuable reference for the veterinarian with a busy practice.

ADVANCE IN KERATOPLASTY. Edited by Nathaniel R. Bronson II and R. Townley Paton. Boston, Little Brown and Company, 1970. Clothbound, 268 pages, table of contents, index, 89 black and white figures. $25.00

The summer, 1970, issue of the International Ophthalmology Clinics deals with a course given in Southhampton. Its availability constitutes a sound lesson in the economy of subscribing to this series rather than purchasing an issue once it has proven its value.

Despite the title, the book deals with far more than keratoplasty. Dohlman, Lemp, and English describe the dry eye syndrome

and the methods of diagnosis of the various types. David Paton and Milauskas describe the results of thin conjunctival (Gundersen) flaps in 122 patients. Katzin, Elstein, and Sehgal describe a new keratome for use in refractive keratoplasty which they have not used clinically. Buxton inserted 64 Cardona-type keratoprostheses during 1962 and 1968; at that time 15% had been removed and 15% extruded. Much of the other work concerning the use of soft contact lenses, measurement of the intraocular pressure, and the postoperative period after keratoplasty, and the Mackay-Marg tonometer have already appeared in print, although they occasioned lively comment at the time of this meeting.

William F. Hughes

THE FIRST CONGRESS OF THE INTERNATIONAL STRABISMOLOGICAL ASSOCIATION. Edited by Peter Fells. St. Louis, C. V. Mosby, 1971. Clothbound, 312 pages, table of contents, index of authors and index of subjects, 155 black and white figures.

The First Congress of the International Strabismological Association was held in March of 1970 with Keith Lyle presiding. Peter Fells has put the transactions of this meeting into a carefully edited and indexed book. The volume consists of three symposia and 20 papers.

The high point of the meeting was the honorary Bielschowsky Lecture given by Gunter von Noorden. This was a report of his subhuman primate studies on amblyopia done with John Dowling and Donald Ferguson. Unfortunately for this text, the papers have already been published. In fact, many of the papers presented at the meeting and organized into this textbook have been published separately. Nonetheless, the volume does represent a concentration of the latest clinical material. Furthermore, it has the considerable advantage of including the discussions following the presentations. In such a controversial field as strabismus, this fact alone makes the book of interest and value. The 41 participants represent some of the leading clinicians specializing in motility in this country and abroad. The first symposium, which was a discussion of early versus late surgery for strabismus, brought the clinicians "eyeball to eyeball." The panel agreed on the terminology for the time of surgery, but that is about all they agreed on. The most divergent views were those of Drs. Arruga of Barcelona and Parks of the United States. Dr. Parks presented data indicating that surgery between six and 18 months of age in the congenitally esotropic patient will result in a high percentage of single binocular vision with peripheral fusion, although not bifoveal fixation. Dr. Arruga stated that this result should be avoided since he believes that many of these children will develop osthenopic troubles by the time they reach school age. The panel emphasized the need for more statistics on both the immediate and long-term effects of early surgery. The second symposium was on the treatment of exodeviation and contained an excellent discussion by Dr. Bagolini on how he uses his striated glasses together with a graded bar of red filters. He pointed out that the correction of the deviation by prisms is a useful indicator for predicting diplopia. The panel agreed on the surgical treatment of intermittent and constant exotropia but there was a difference of opinion regarding the treatment of convergence insufficiency. Dr. Burian did not feel that convergence insufficiency is a true exodeviation and he would not operate on it. Dr. Knapp believes that once orthoptic exercises are stopped convergence insufficiencies become intermittent exotropias. Consequently he recommends resecting both medial rectus muscles. The final symposium on the use of prisms in strabismus also generated perhaps not unanticipated controversy.

The free papers, 20 in number, range from a description of a diplopia field tech-

nique to a discussion of microtropia. As is characteristic of contemporary strabismology, what are concrete data to one investigator may only be controversial observations to another.

There is a tremendous amount of information presented in these reports. The student who wishes to obtain a working knowledge of strabismus will benefit from a careful study of the papers. Further, a perusal of the material contained in this volume by the experienced clinician can only result in a healthy broadening of his information and attitudes toward the many approaches to the diagnosis and treatment of strabismus.

OPHTHALMIC MINIATURE

The sensory equipment of the higher primates is much more dominated by the sense of vision than by the sense of smell. In their tree-climbing world, seeing well is far more important than smelling well, and the snout has shrunk considerably, giving the eyes a much better view. In searching for food, the colors of fruits are helpful clues, and, unlike the carnivores, primates have evolved good color vision. Their eyes are also better at picking out static details. Their food is static, and detecting minute movements is less vital than recognizing subtle differences in shape and texture.

Desmond Morris
*The Naked Ape*
Jonathan Cape, 1967

# ABSTRACT DEPARTMENT

EDITED BY DAVID SHOCH, M.D.

## ACTA OPHTHALMOLOGICA

ELECTRON MICROSCOPIC DEMONSTRATION OF VIRUS PARTICLES IN HUMAN HERPES SIMPLEX KERATITIS. Nilsson, S. E. G. (Department of Ophthalmology, Karolinska Sjukhuset, Stockholm, Sweden), Acta Ophth. 48:76-85, 1970.

Electron microscopic studies of human corneal epithelium from patients with herpes simplex keratitis showed not only large numbers of virus particles in the areas of dendritic lesions but also fewer particles in the clinically undamaged cornea 2 to 5 mm away from the closest lesion. The author believes it to be due to a lower grade of infection and that dormant infection is the cause of recurrences. (5 figures, 21 references)—Saul Sugar

DENDRITIC (HERPETIC) KERATITIS. I. INCIDENCE, SEASONAL VARIATION, RECURRENT RATE, VISUAL IMPAIRMENT, THERAPY. Norn, M. S. (Department of Ophthalmology, Kommunehospitalet, Copenhagen, Denmark), Acta Ophth. 48:91-107, 1970.

A study of 109 patients with dendritic keratitis indicated the incidence to be 1:196 among all ophthalmic patients, 59% males. The first attack occurred most often in children or those between ages forty and fifty. Bilaterality was observed in 10%. No seasonal variations were found. Relapses occurred in 61%, the interval between the first and second attacks averaging 5.7 years. The recurrence rate was higher in I.D.U. treated patients but the course was milder, the final visual impairment being no different in the two groups. Steroids caused greater visual impairment. Iodine cautery had no influence on the recurrence rate. (6 tables, 34 references)—Saul Sugar

CHROMOSOMAL ANALYSIS OF A HUMAN RETINOBLASTOMA. Mark, J. (Department of Ophthalmology, University of Lund, Sweden), Acta Ophth. 48:124-135, 1970.

A study of the chromosomes of a sporadic human retinoblastoma patient revealed a well-defined hyperdiploid stemline and two small sidelines closely related to the stemline. No dilation of a D chromosome was present. Localization of the gene for development of retinoblastomas remains uncertain. (3 figures, 2 tables, 13 references)—Saul Sugar

THE ERG AND OPHTHALMOLOGICAL CHANGES IN EXPERIMENTAL METALLOSIS IN THE RABBIT. I. EFFECTS OF IRON PARTICLES. Knave, B. (Department of Physiology, Karolinska Institutet, Stockholm, Sweden), Acta Ophth. 48:136-158, 1970.

The eye changes and ERG were studied after implantation of pure iron particles into the vitreous in rabbit experiments. The particles were encapsulated in the first few days after implantation. After a week the capsule begins to resorb and the particles reappear after a time which depends on the size of the metal. About six months to a year later a thinner capsule develops. During the first phase after implantation there was a reversible reduction in a and b waves, a normal or slightly increased peak latency of the scotopic b wave and a moderate increase in the peak latencies of the oscillatory potential, all probably due to retinal edema. When the particles reappear there was a reduction of a and b wave amplitude and a marked increase of peak latencies of the oscillations. The b wave peak latency first decreased and later normalized. Later the potentials disappear. (11 figures, 1 table, 34 references)—Saul Sugar

THE ERG AND OPHTHALMOLOGICAL CHANGES IN EXPERIMENTAL METALLOSIS IN THE RABBIT. II. EFFECTS OF STEEL, COPPER AND ALUMINIUM PARTICLES. Knave, B. (Department of Physiology, Karolinska Institutet, Stockholm, Sweden), Acta Ophth. 48:159-173, 1970.

Eye changes and ERG were studied in rabbits after implantation of particles of steel, aluminium and copper. The implantation of steel particles gave results which depended on the alloys used. Steel alloyed with 5% nickel gave results similar to implantation of pure iron particles. Steel alloyed with 5% chromium gave a long-lasting reversible increase in ERG, the b more than the a wave. Later a small decrease occurred. When steel alloyed with 14% chro-

mium was implanted, a slowly developing small reduction of the ERG occurred. With steel alloyed with 18% chromium, 12% nickel and 3% molybdenum the ERG remained normal. In these three steel alloys only thin capsules developed. With aluminum implants there was a slow reduction of the b wave to none, the a wave to 90%, after 300 days. Only a thin partial capsule formed. With copper a rapid deterioration of the ERG occurred. Vitreal damage occurred rapidly. (5 figures, 9 references)—Saul Sugar

## American Journal of Medicine

G-6-PD Worcester: a new variant, associated with x-linked optic atrophy. Snyder, L. M., Necheles, T. F., Reddy, W. J., Calcagni, K. and Reed, F. (Saint Vincent Hospital, 25 Winthrop Street, Worcester, Massachusetts 01604), Amer. J. Med. 49:125-132, July, 1970.

A new variant of glucose-6-phosphate dehydrogenase (G-6-PD Worcester), is described in a caucasian family with associated congenital, nonspherocytic hemolytic anemia, absent erythrocyte G-6-PD activity and optic atrophy. The inheritance of this form of optic atrophy is closely linked to the G-6-PD locus and total color blindness. G-6-PD Worcester is distinguished from previously characterized variants by absent erythrocyte G-6-PD activity, slow electrophoretic mobility, thermolability, a sharp peak at pH 8 and a Michaelis constant for TPN of 11.2 micromolar. (5 figures, 3 tables, 33 references)—Authors' abstract

Benign cystinosis. Brubaker, R. F., Wong, V. G., Schulman, J. D., Seegmiller, J. E. and Kuwabara, T. (The Mayo Clinic, Rochester, Minnesota 55901), Amer. J. Med. 49:546-550, Oct., 1970.

Benign cystinosis is an autosomal recessive disorder characterized by the presence of cystine crystals in the eye and the bone marrow. There are no associated renal or peripheral retinal abnormalities which are typical of nephropathic cystinosis. Patients affected with the benign disorder are asymptomatic and presumably have a normal life expectancy. The youngest known patients, a girl aged eleven and a boy aged sixteen, are described. Biochemical and morphologic evidence suggests that in both forms of cystinosis storage of cystine occurs within the lysosomes, primarily of actively endocytic, mesodermally-derived cells. Although the two forms of cystinosis show points of similarity in the distribution of cystine crystals, they differ quantitatively in the amount of cystine accumulated, substantially less intracellular cystine being present in the benign than in the nephropathic form of the disorder. The abnormal gene products responsible for the accumulation of cystine in the two forms of the disease remain to be demonstrated. (2 figures, 2 tables, 18 references)—Authors' abstract

Familial nephropathy associated with retinitis pigmentosa, cerebellar ataxia and skeletal abnormalities. Mainzer, F., Saldino, R. M., Ozonoff, M. B. and Minagi, H. (University of California School of Medicine, San Francisco, California), Amer. J. Med. 49:556-562, Oct., 1970.

Two siblings were found to be affected by an oculorenal syndrome consisting of familial nephropathy and retinitis pigmentosa, and in addition two other extrarenal manifestations, cerebellar ataxia and skeletal abnormalities, not previously reported, were demonstrated in both patients. The renal abnormality in both siblings was characterized by functional defects of the distal tubules and collecting ducts, manifested by failure to concentrate and acidify the urine. The clinical and histologic findings were compatible with the nephropathy which is known as nephronophthisis or medullary cystic disease. (8 figures, 47 references)—Authors' abstract

Behcet's disease. Kalbian, V. V. and Challis, M. T. (Veterans Administration Center, Martinsburg, West Virginia 25401), Amer. J. Med. 49:823-829, Dec., 1970.

Twelve cases of Behcet's disease are presented, with a discussion of their main clinical features. The multiplicity of the clinical presentations of the disease is stressed. A new type of neurologic manifestation, that of benign intracranial hypertension, is introduced and three such cases are reported. (2 figures, 1 table, 37 references)—Authors' abstract

CATARACTS, GALACTOSURIA AND HYPERGALACTOSEMIA DUE TO GALACTOKINASE DEFICIENCY IN A CHILD. Monteleone, J. A., Beutler, E., Monteleone, P. L., Utz, C. L. and Casey, E. C. (St. Louis University School of Medicine, Missouri), Amer. J. Med. 50:403-407, Mar., 1971.

A nine year old girl with galactosuria, galactosemia and cataracts is described. She was found to have galactokinase deficiency. A large kindred was studied in detail and the disease was found to be autosomal recessive. In addition it is shown that carriers might be affected with cataracts early in life; for this reason we suggest that carriers adhere to a galactose-restricted diet. (3 figures, 1 table, 14 references)—Authors' abstract

## AMERICAN JOURNAL OF PSYCHIATRY

LONG-TERM TREATMENT WITH NEUROLEPTIC DRUGS AND EYE OPACITIES. Crane, G. E., Johnson, A. W. and Buffaloe, W. J. (Psychopharmacology Research Branch, National Institute of Mental Health, Chevy Chase, Med.), Am. J. Psychiat. 127:1045-1049, Feb., 1971.

Approximately 100 chronic schizophrenic patients were examined for drug-induced eye changes. The lens was affected in 36 patients, the cornea in 19. There was a linear relationship between eye opacities and the total intake of drugs. Corneal opacities were also related to the intake of high doses of chlorpromazine over a short period of time. In most instances the ocular changes were irreversible. Despite heavy deposits in the anterior part of the eye, vision was unimpaired and the retina appeared to be intact. (2 tables, 14 references)—Authors' abstract

## AMERICAN JOURNAL OF ROENTGENOLOGY, RADIUM THERAPY AND NUCLEAR MEDICINE

RADIOTHERAPY OF PRIMARY LYMPHOMA OF THE ORBIT. Foster, S. C., Wilson, C. S. and Tretter, P. K. (Department of Radiology, Columbia-Presbyterian Medical Center, New York, New York), Am. J. Roent. Rad. Nucl. Med. 3:343-349, Feb., 1971.

Thirty-three patients with primary lymphoma of the orbit were treated. Thirty had radiotherapy, and three had surgery alone as initial treatment. The results indicate that local control can be obtained and that in a significant percentage of patients the disease does not generalize. (2 figures, 4 tables, 13 references)—Joel G. Sacks

## ANNALI DI OTTALMOLOGIA E CLINICA OCULISTICA

OPTICO-CHIASMATIC ARACHNOIDITIS. CRITICAL REVIEW OF 108 SURGICAL CASES. (Italian) Migliore, A., Massarotti, M., Ettorre, G. and Bozzini, S. (University of Milan, Italy), Ann. Ottal. Clin. Ocul. 156:221-232, Apr., 1970.

Optico-chiasmatic arachnoiditis is a pathologic entity and not a syndrome. There are a variety of etiologies for this finding and no correlation can be made between the history and clinical findings and the pathologic process. There is no consistent visual field defect and encephalography offers very little additional information. The authors feel that over the years the indications for surgery have been restricted and that many of these cases can now be treated satisfactorily medically. (5 figures, 2 tables, 21 references)—David Shoch

## ANNALES D'OCULISTIQUE

STUDY OF THE CHIASMATIC SYNDROME IN THE COURSE OF PREGNANCY. (French) Bonamour, G., Bonnet, M. and Laffay, N. (Hopital de la Croix-Rousse, Lyon, France), Ann. Ocul. 204:235-256, Mar., 1971.

Bilateral, temporal field defects are sometimes seen in the course of pregnancy and it has been assumed that these might be due to a physiologic hypertrophy of the pituitary. The authors feel, on the basis of two cases reported, that it is more likely that a hypophyseal tumor is present in these cases and that it enlarges during pregnancy. If the tumor is discovered in the early months of pregnancy then a therapeutic abortion is advisable. On the

other hand, tumors discovered late in pregnancy can be treated neurosurgically without interruption of the pregnancy. (4 figures, 92 references)—David Shoch

DYSTROPHIC LESIONS OF THE HORIZONTAL RECTI IN COMITANT STRABISMUS. (French) Zolog, N. and Georgescu, L. (Timisoara, Romania), Ann. Ocul. 204:407-414, Apr., 1971.

The authors examined 15 musculo-tendinous fragments provided by 15 strabismic patients who underwent a resection of a horizonal rectus muscle. Histologic examinations of these fragments of tissue revealed an atrophy of muscle fibers, a homogenization of the sarcoplasma and the disappearance of nuclei and of striations. (7 figures, 11 references)—David Shoch

ACUTE GLAUCOMA SECONDARY TO INSTILLATION OF PILOCARPINE. (French) Francois, J., Goes, F. and Stockmans, L. (University of Gand, France), Ann. Ocul. 204: 481-490, May, 1971.

Open-angle glaucoma was diagnosed in a 65-year-old patient and he was treated irregularly with pilocarpine and Diamox. He was advised to use 2% pilocarpine regularly five times a day and the same evening that this treatment was started, he developed an acute angle closure in both eyes. It is felt that this was due to an anterior displacement of the lens due to a contraction of the ciliary body induced by the miotics and consequently a loosening of the zonular fibers. The result was a pupil block and angle closure. Dilatation of the pupil with epinephrine and intravenous mannitol cured the angle closure. (3 figures, 3 tables, 35 references)—David Shoch

## ARCHIV FÜR KLINISCHE UND EXPERIMENTELLE OPHTHALMOLOGIE

HYPERPLASIA OF THE ADVENTITIAL AND MURAL RETICULIN FIBERS IN DIABETIC RETINOPATHY. (German) Daicker, B. (Universitats-Augenklinik Basel), Arch. Klin. Exp. Ophth. 181:192-206, 1971.

The retinal vessels of diabetics, isolated by the trypsin digestion technique show a hyperplasia of the adventitial argyrophilic fibers on the medium-sized vessels and of the mesodermal strands. At the diabetic retinal capillaries a neoformation of mural argyrophilic fibers can be demonstrated as an early sign. A local hyperplasia of such fibers causes the formation of looping microaneurysms; the saccular aneurysms opposite these bulge and dilate the lattice of reticular fibers. This hyperplasia and neoformation of argyrophilic fibers is not pathognomonic for diabetic retinopathy, but is obviously marked and wide-spread in this affection. (10 figures, 1 table, 34 references)—Author's abstract

EXPERIMENTAL INVESTIGATIONS OF THE EFFECT OF GLYCERINE AND GLUCOSE SOLUTIONS UPON THE CORNEAL EDEMA. (German) Meyer, W. and Reinhardt, H. (Universitats-Augenklinik Jena, DDR), Arch. Klin. Exp. Ophth. 181:216-227, 1971.

Glucose and glycerine solutions reduce the thickness of the rabbit cornea to 50% of the original value. Glucose solutions show a more dehydrating effect on experimentally produced corneal edema than glycerine solutions of the same osmolarity. (9 figures, 23 references)—David Shoch

CALCULATION OF THE THERMAL EFFECT GENERATED IN THE RETINA BY PHOTOCOAGULATION. Roulier, A. (Universitats-Augenklinik, Bern, Switzerland), Arch. Klin. Exp. Ophth. 181:281-289, 1971.

The alterations of the retina produced by photocoagulation depend upon the temperature-time-history during and after exposure. A mathematical model is proposed enabling the calculation of a particular biological effect, namely the ophthalmoscopically visible white discoloration. . . . In agreement with experience the calculations show that for purposes of greatest energy efficiency and least damage to the nerve fiber layer, relatively small spot diameters (typically 0.2 mm) and exposure times of not more than a few milliseconds should be used in photocoagulation. (4 figures, 4 tables, 15 references)—Author's abstract

THE INTRAOCULAR TENSION AFTER RETINAL DETACHMENT SURGERY. (German) Uter-

mann, D. and Deichmann, C. R. (Universitats-Augenklinik Hamburg-Eppendorf), Arch. Klin. Exp. Ophth. 181:335-343, 1971.

The intraocular tension of 45 patients with retinal detachment was measured using applanation tonometry, directly pre- and postoperatively over a period of 14 days, with a final control after six months. It could be shown that the intraocular tension of eyes with retinal detachment lay on an average 1.45 mm Hg lower than that of normal eyes. An enormous increase in tension occurred post-operatively, which however always returned spontaneously to normal levels. On the 6th day the tension equalled that of the sound eye, but decreased to preoperative levels after the 12th day. Tonographic investigations showed no difference between either eye pre- or postoperatively. (4 figures, 1 table, 12 references)—Authors' abstract

## Archives of Neurology

ASSOCIATIVE VISUAL AGNOSIA. Rubens, A. B. and Benson, D. F. (Boston Veterans Administration Hospital, 150 S. Huntington Avenue, Boston 02130), Arch. Neurol. 24:305-316, Apr., 1971.

Following an acute hypotensive episode, a patient had unusual residual visual difficulties. A right homonymous hemianopsia was the only primary neurologic deficit, but there were specific behavioral disturbances. He could not read but could write (alexia without agraphia), had difficulty in color recognition (color agnosia), facial recognition (prosopagnosia), and object recognition (visual agnosia). Despite these visual disturbances, adequate primary visual function was demonstrated by his ability to copy drawings. Clinical evidence suggests that the underlying lesion was infarction involving the left medial occipital region and the splenium of the corpus callosum. The possibility of a second lesion in the right hemisphere can be conjectured but not supported by available data. Inability to identify or recognize visually presented objects with perservation of ability to draw them is unusual and can best be termed associative visual agnosia. (6 figures, 2 tables, 36 references)—Authors' abstract

## Archives of Ophthalmology

LIGHT DEPRIVATION FOR EARLY RETINITIS PIGMENTOSA. Berson, E. L. (Massachusetts Eye and Ear Infirmary, 243 Charles St., Boston 02114), Arch. Ophth. 85:521-529, May, 1971.

Evidence is consolidated to support the hypothesis that long periods of almost complete light exclusion will have therapeutic benefit for patients with early stages of hereditary retinitis pigmentosa. The hypothesis is based on observations on effects of light on photoreceptors of normal rats and on photoreceptors of rats with either vitamin A deficiency or hereditary retinal dystrophy, on electrophysiological studies of patients with early retinitis pigmentosa, and on measurements of retinal oxygen utilization in humans and animals with retinal degenerations. Almost complete light exclusion can be best accomplished with an opaque flush-fitting scleral contact lens. If this hypothesis is correct and light exclusion is begun in the earliest stages, it may be possible to double the patient's visual lifetime by keeping one retina in reserve in darkness while the other retina functions but degenerates in light. (3 figures, 52 references)—Author's abstract

DOMINANT MICROSPHEROPHAKIA. Johnson, V. P., Grayson, M. and Christian, J. C. (Department of Medical Genetics, Indiana University, 1100 W. Michigan St., Indianapolis 46202), Arch. Ophth. 85: 534-542, May, 1971.

Microspherophakia, upward subluxation of the lens, myopia, retinal detachment, and inguinal hernias in various combinations were found in 11 individuals and three generations of one family. The mode of inheritance is compatible with a variable expressive dominant trait. There were no other stigmata of Marfan's or Marchesani's syndromes. The basic defect is postulated to be in mesodermal development, resulting in abnormal ciliary and globe development responsible for the myopia and microspherophakia and a milk connective tissue defect to account for the increased incidence of inguinal hernias. (6 figures, 3 tables, 35 references)—Authors' abstract

PSEUDOMONAS: CORNEAL ULCERS IN CONTACT LENS WEARERS. Golden, B., Finger-

man, L. H. and Allen, H. F. (University Hospitals, Iowa City 52240), Arch. Ophth. 85:543-547, May, 1971.

Pseudomonas species were associated with several corneal ulcers in two healthy young contact lens wearers. In both cases the source of contamination was traced to the patient's contact lens storage case. Cultures of wetting and soaking solutions in their bottles were negative. In both patients, the ulcers healed under treatment with specific antibiotics. In one case, topical corticosteroid and enzyme inhibitor therapy may have contributed to a successful result. (8 figures, 10 references)—Authors' abstract

CYCLODUCTION OF THE EYES WITH HEAD TILT. Linwong, M. and Herman, S. J. (University of Illinois Eye and Ear Infirmary, 1855 W. Taylor St., Chicago 60612), Arch. Ophth. 85:570-573, May, 1971.

In ten normal subjects a head tile of 30° to the same shoulder produced a mean incycloduction of 5° and a head tilt of 30° to the opposite shoulder produced a mean excycloduction of 6.5°. Similar results were obtained when the experiment was performed repeatedly on one eye in the same subject. (3 figures, 2 tables, 8 references)—Authors' abstract

CORNEAL TEMPERATURE MEASUREMENTS DURING RETINAL PHOTOCOAGULATION. de Guillebon, H., Pfister, R., Govignon, J., Pomerantzeff, O. and Schepens, C. L. (Retina Foundation, 100 Charles River Plaza, Boston 02114), Arch. Ophth. 85: 712-717, June, 1971.

The corneal temperature elevation of 30 rabbits were measured with thermocouples during a series of retinal photocoagulations. Topical saline irrigation substantially reduced final temperature levels. The head distribution over the illuminated cornea showed higher values centrally. Major temperature rises developed when the pupil was smaller than the cross section of the light beam. With a contact lens, temperature elevation is greatest and may reach 8 C for small pupillary apertures. To avoid high corneal temperatures during clinical photocoagulation, especially with a contact lens, frequent saline irrigations, a beam diameter smaller than the dilated pupil, and long intervals between the photocoagulation applications are required. (8 figures, 5 references)—Authors' abstract

CHRONIC ANGLE-CLOSURE GLAUCOMA. Pollack, I. P. (Wilmer Institute, Johns Hopkins University School of Medicine, 601 N. Broadway, Baltimore 21205), Arch. Ophth. 85:676-689, June, 1971.

Twelve persons with asymptomatic chronic glaucoma and extremely narrow anterior chamber angles that appeared open were treated successfully with peripheral iridectomy. In each case initial examination revealed that there were no symptoms of angle closure and the clinical picture strongly resembled chronic (simple) open-angle glaucoma; intraocular pressure was elevated and frequently aggravated by medical therapy; there were large fluctuations in intraocular pressure; the angle was open to a slit or grade 1, except in one case with partial angle closure; and the mydriatic provocative test was negative. The natural course in this disease is for the chamber angle to become progressively narrowed with eventual appositional closure and later formation of peripheral anterior synechias. If the disease process is interrupted before formation of synechias, then the glaucoma is cured or can be controlled easily. (13 figures, 2 tables, 14 references)—Author's abstract

## AUSTRALIAN ANNALS OF MEDICINE

LEBER'S OPTIC ATROPHY: A POSSIBLE EXAMPLE OF VERTICLE TRANSMISSION OF A SLOW VIRUS IN A MAN. Wallace, D. C. (Queensland Institute of Medical Research, Brisbane, Australia), Aust. Ann. Med. 3:259-262, 1970.

The unusual inheritance of Leber's disease could be caused by the presence of a slow virus acting upon individuals with a variable and partly inherited resistance to infection. A study of a family afflicted by Leber's disease is presented and shows a pattern strongly suggestive of vertical transmission. As usual, no man passed the disease on to his descendents. Affected women and unaffected carriers are considered to pass on the infection to all of

their children, the degree of expression depending upon the virulence of the virus and the resistance of the child. (1 figure, 14 references)—Ronald Lowe

## British Journal of Ophthalmology

SUPERIOR OBLIQUE TENDON SHEATH SYNDROME. AN ELECTROMYOGRAPHICAL STUDY. Catford, G. V. and Dean Hart, J. C. (6 Devonshire Place, London), Brit. J. Ophth. 55:155-160, Mar., 1971.

Electromyographic studies were done on three patients with a superior oblique tendon sheath syndrome. In all these cases there was normal firing although of smaller amplitude than from the inferior obliques. There was no evidence of co-contraction or abnormal innervation and therefore the authors conclude that the superior oblique tendon sheath syndrome is due to a local mechanical problem caused by the inability of the tendon to pass freely in its full extent through the sheath. (9 figures, 16 references)—David Shoch

LOWERING OF INTRAOCULAR PRESSURE IN THE UNTREATED EYE AFTER THE USE OF TOPICAL STEROIDS. Das, S. N. and Hitchings, R. A. (Moorfields Eye Hospital, City Road, London), Brit. J. Ophth. 55: 161-164, Mar., 1971.

The authors studied a group of patients whom they divided into responders and nonresponders. They show that when steroids are introduced into one eye of responders there is an increase in intraocular pressure in the second eye. On the other hand, in the nonresponder group, there was a lowering of the pressure in the untreated eye. The authors feel that these phenomena are explained by systemic absorption of the steroids from the culde-sac and its humoral effect on the second eye. (1 table, 24 references)—David Shoch

RETINAL VASCULAR OCCLUSION AS A PRESENTING FEATURE OF GLAUCOMA SIMPLEX. Soni, K. G. and Woodhouse, D. F. (Wolverhampton and Midland Counties Eye Infirmary, England), Brit. J. Ophth. 55: 192-195, Mar., 1971.

The etiology, incidence and treatment of simple glaucoma in retinovascular occlusion are discussed in relation to a clinical series. Twenty-five percent of patients with central retinal venous occlusion had glaucoma, but only 8.6% of those with tributary venous occlusion. It is emphasized that the diagnosis of simple glaucoma should be considered in all patients presenting as a retinal vacular accident. (2 tables, 11 references)—Authors' abstract

PITUITARY GLAND ABLATION BY $^{90}$YTTRIUM IMPLANTATION FOR ADVANCING DIABETIC RETINOPATHY. Cullen, J. F., Gibson, P. F., MacCuish, A. C., Harris, P., Donaldson, A. A., Munro, J. F. and Duncan, L. F. (Princess Alexandra Eye Pavilion, Chalmers St., Edinburgh), Brit. J. Ophth. 55: 217-224, Apr., 1971.

The authors report the results of pituitary ablation by 90 yttrium implantation for advancing diabetic retinopathy. Of the 20 patients, seven were dead by the end of four years, either as a complication of the surgery or as a complication of their diabetes. Cerebrospinal fluid rhinorrhea occurred in three patients. Ten of the patients are reported as having an arrested retinopathy while four improved. The authors acknowledge that peripheral areas of neovascularization can be effectively eradicated by photocoagulation but they feel that pituitary ablation is the best treatment for neovascularization of the optic nerve head. However, recent data has shown that even these areas may be treated with the new argon laser. (5 tables, 14 references)—David Shoch

TRAUMATIC OPTIC PATHWAY DEGENERATION. Kurz, G. H., Ogata, J. and Gross, E. M. (Hunterdon Medical Center, Flemington, N.J.), Brit. J. Ophth. 55:233-242, Apr., 1971.

A 45-year-old man had been totally blind following a gunshot wound which injured both optic nerves nearly 13 years previously. Post mortem examination revealed degenerative changes in the injured neurons (retinal ganglion cells and distal and proximal stumps of their axons) as well as antegrade trans-synaptic degeneration (lateral geniculate body) and retrograde trans-synaptic degeneration (inner nuclear layer). A macular hole and a chorioretinal scar were also present in one eye. The retinal vascular pattern remained intact. (11

figures, 1 table, 14 references)—Authors' abstract

RETINAL HEMORRHAGES IN NEWBORN INFANTS. Sezen, F. (Capa Goz Klinigi, Capa, Istanbul, Turkey), Brit. J. Ophth. 55:248-253, Apr., 1971.

Of 1,238 newborn infants investigated, 178 (14.3%) were affected. Examination within 24 hours revealed a percentage of 18.9 but between the third and fifth day the figure was only 2.6%. It is concluded that the later the time of fundus examination the less the incidence of retinal hemorrhage found. Comparative studies of the incidence and etiology of retinal hemorrhages have shown that the difference between primiparae and multiparae is significant (P 0.002); retinal hemorrhages were more common in the babies of primiparae, confirming the role of obstetric trauma in the pathogenesis of neonatal retinal hemorrhages. (4 tables, 25 references)—Author's abstract

EXPERIMENTAL ASTEROID HYALOPATHY. Lamba, P. A. and Shukla, K. N. (Jawaharlal Institute of Post-Graduate Medical Education and Research, Pondicherry, India), Brit. J. Ophth. 55:279-283, Apr., 1971.

Experiments were carried out to ascertain whether the ingestion of cholesterol by animals could produce visible vitreous bodies (asteroid hyalitis). On the basis of our investigations and the reports of earlier workers, it may be supposed that hypercholesterolemia per se is not the principal factor in the development of asteroid bodies. Local causes may result in the precipitation of macroscopically visible particles of calcium and cholesterol (normal constituents of vitreous). To investigate the role of local changes in the vitreous, hyaluronidase enzyme was injected into the vitreous humour; this produced white, angular, discrete particles which were clinically and microscopically similar to those seen in asteroid hyalopathy. (2 figures, 12 references)—Authors' abstract

ELECTRON MICROSCOPICAL STUDY OF COATS'S DISEASE. Tripathi, R. and Ashton, N. (Institute of Ophthalmology, Judd St., London $WC1H_9QS$), Brit. J. Ophth. 55: 289-301, May, 1971.

An ultrastructural study of an early case of Coats's disease confirms the widely-held view that an abnormal permeability of the retinal vessels is fundamental in its pathogenesis. It is suggested that the pathological changes may initially derive not from telangiectasis, but from a functional or structural breakdown of the blood-retinal barrier (vascular endothelium), giving rise to plasmatic vasculosis and mural disorganization, and that these result in aneurysmal dilations and telangiectasis. Leakage of blood components then increases to form intraretinal and subretinal exudates, hemorrhages, lipid and fibrin deposits, with phagocytic proliferation, disorganization and destruction of the retinal elements, and eventually glial and fibrous tissue organization. The characteristic profusion of macrophages and "ghost cells" within the affected areas is most likely due to the local proliferation of resting histiocytes in the retina itself, augmented by blood-borne macrophages and migrating pigment epithelial cells. (17 figures, 26 references)—Authors' abstract

## INVESTIGATIVE OPHTHALMOLOGY

COLOR VISION: AN APPROACH THROUGH THE CONE PIGMENTS. Rushton, W. A. H. (Institute of Molecular Biophysics, Florida State University, Tallahassee), Invest. Ophth. 10:311-321, May, 1971.

There are three types of cone in the human retina, one containing erythrolabe, one chlorolabe, and one cyanolabe. . . . Protanopes, deuteranopes, and tritanopes simply lack the erythrolabe, the chlorolabe, or the cyanolabe sensitivity curves (respectively). . . . Color appearance depends (1) upon the quantum catch in the cones and (2) upon the processing of the resulting nerve signals. The first is extremely simple, the second extremely hard to comprehend exactly. Any two colors whose quanta are caught equally by each of the cone pigments will appear identical whatever may be the state of the nerve processing (adaptation, contrast, etc.), for, colors matched at input must also match at output however complex and adaptable that output may be. (6 figures, 20 references)—Author's abstract

THE EFFECT OF HYPOXIA ON VISUAL FUNCTION. PSYCHOPHYSICAL STUDIES. Ernest, J. T. and Krill, A. E. (Eye Research Laboratories, University of Chicago, Illi-

nois), Invest. Ophth. 10:323-328, May, 1971.

Hypoxia raised both cone and rod absolute visual thresholds. However, cone thresholds were elevated to a greater degree than rod thresholds at a 5° retinal eccentricity where both were studied. Hypoxia had a greater effect on peripheral rod thresholds (measured at 45° eccentricity) than on central rod thresholds (measured at 5° eccentricity). Only the later portions of rod and cone dark adaptation curves were affected by hypoxia. The first four minutes of either type of curve was unaffected. (2 figures, 3 tables, 23 references) —Authors' abstract

## LANCET

SMALL BLOOD-VESSELS IN MIGRAINE. Blau, J. N. and Davis, E. (National Hospitals for Nervous Diseases, Queen Square, London W.C. 1), Lancet 2:740-742, 1970.

Conjunctival, lip, tongue, and nailfold vessels have been examined microscopically in 35 migrainous subjects between attacks. The vessels were normal, but 12 out of the 35 showed intravascular red-cell aggregation (I.R.C.A.) —a substantially higher proportion than in controls. Eleven subjects were also photographed during attacks of migraine: conjunctival arterioles, capillaries, and venules became constricted in six and dilated in five. The vasomotor responses were invariably bilateral, although more distinct on the headache side. During attacks all subjects showed I.R.C.A.; and, where this feature had been present between episodes, the aggregation became more pronounced. The conjunctiva became edematous in 3 of the 11. Seven patients were observed in more than one attack and the vascular response remained the same in the particular subject. No changes were observed in tongue vessels. Lip and nailfold vessel responses fell within the normal range of "spontaneous" vasomotor variation. The vascular responses in migraine are bilateral; the headache may be associated with conjunctival vasoconstriction or vasodilatation; edema of the conjunctivae can occur with either vascular response; and the symptoms and the anatomical derivation of the conjunctival vessels support the view that an intracranial component contributes to the pain of a migraine headache. (2 figures, 14 references)—Authors' abstract

PLASMA-COBALAMINS IN NEURO-OPHTHALMOLOGICAL DISEASES. Wilson, J., Linnell, J. C. and Matthews, D. M. (Institute of Neurology, London W.C. 1), Lancet 1: 259-261, 1971.

Plasma-cyanocobalamin levels were found to be significantly raised in Leber's hereditary optic atrophy, dominantly inherited optic atrophy, tobacco amblyopia, and sporadic cases of optic atrophy. This change may be evidence of inborn metabolic errors of cyanide detoxication, varying clinically and genetically according to the particular enzyme involved. (3 tables, 1 figure, 17 references)—Authors' abstract

## NEW ENGLAND JOURNAL OF MEDICINE

PUPILLARY EFFECTS OF LEVODOPA THERAPY. Weintraub, M. I., Gaasterland, D. and Van Woert, M. H. (Yale-New Haven Hospital, New Haven, Conn. 06510), N. Eng. J. Med. 283:120-123, 1970.

In a patient with Parkinson's disease and subclinical postganglionic Horner's syndrome anisocoria developed during chronic oral L-dopa therapy. This provided an opportunity to investigate the mechanism of action of L-dopa and dopamine on the sympathetic innervation of the eye. Five patients, one of whom had a postganglionic Horner's syndrome without Parkinson's disease, served as controls. Topical dopamine and chronic systemic L-dopa produced pupil dilatation only in eyes with intact sympathetic innervation. Single large doses of L-dopa had no effect on the pupil size. L-dopa and topical dopamine appear to produce pupillary dilatation indirectly, through a peripheral increase in activity of intact sympathetic pathways, and not through direct alpha-receptor stimulation. (6 figures, 14 references)—Authors' abstract

RETINOBLASTOMA: EPIDEMIOLOGIC CHARACTERISTICS. Jensen, R. D. and Miller, R. W. (National Cancer Institute, 402 Wiscon Bldg., Bethesda, Md. 20014), N. Eng. J. Med. 285:307-311, 1971.

Nationwide study of 269 death certificates for United States children with retinoblastoma,

1960-67, revealed a peak in mortality at two to three years of age that was 2½ times greater in Negroes than in whites. Nationally, an estimated 81% of children with the neoplasm survived. Study of 1623 hospital records of children with retinoblastoma revealed an excess of mental retardation: 21 cases observed vs. 4.7 expected. Associated malformations in several cases suggested D-deletion syndrome, which has been described by others in six children with retinoblastoma. In accord with previous studies, radiotherapy was associated with an excess of osteosarcoma, soft-tissue neoplasms or carcinoma of the skin. In addition, 11 children had secondary primary cancers not attributable to radiotherapy, a seeming excess over normal expectation. The cell types were diverse, but three were osteosarcomas, suggesting an innate susceptibility that may add to the risk of radiotherapy. (1 figure, 3 tables, 28 references)—Authors' abstract

## Ophthalmic Research

On endocrine orbitopathy. Dardenne, M. U., Poonawalla, N. H., Hanrath, P. and Nocker, D. (University of Bonn, Bonn), Ophth. Res. 1:344-353, 1970.

From previous clinical and experimental observations with animals it is clear that the exophthalmos producing factor (EPF) is not the only factor which is responsible for endocrine orbitopathy. Therefore, a study of the effect of ACTH, cortisol, adrenaline, testosterone, oestradiol and oestriol on experimental exophthalmos in fish was made. Preliminary investigations were also made with a view to finding the most suitable medium of administration of drugs to goldfish and the minimum quantity of EPF that can produce a definite exophthalmos. Two doses of 0.25 mg TSH in 0.7% sodium chloride solution were found to be most suitable for obtaining a minimum but definite exophthalmos. TSH in combination with ACTH and testosterone had a synergistic effect while oestradiol and cortisol were found to inhibit the action of EPF. Adrenaline produced exophthalmos which lasted for a short time; this effect is probably due to its vasoconstrictor action. Progesterone produced exophthalmos and in combination with EPF, their effects were additive. These results show that disturbances in the regulation of different hormones can produce endocrine orbitopathy. (7 figures, 14 references)—Authors' abstract

## Ophthalmologica

Abnormal findings in relatives of patients with juvenile hereditary macular degeneration (Stargardt's disease). Merin, S. and Landau, J. (Department of Ophthalmology, Hadassah University Hospital, Jerusalem), Ophthalmologica 161:1-10, 1970.

A search for ocular anomalies in a family with two cases of typical Stargardt's disease (two brothers, aged 15 and 23) revealed in the apparently healthy mother and in one maternal aunt the peripheral manifestations of the dystrophy without involvement of the central area. (9 figures, 13 references)—Peter C. Kronfeld

Regarding hemorrhages and venous stasis associated with drusen of the optic disc. (German) Otradovec, J. and Vladyková, J. (Second University Eye Clinic and Eye department of the Central Military Hospital in Prague), Ophthalmologica 161:21-30, 1970.

Close observation of patients with drusen of the optic disc reveals phases of bleeding into and under the retina and of venous stasis confined to one or two vessels. These ophthalmoscopic changes suggest activity of the process of drusen formation which is most typically observed in young people. (5 figures, 8 references)—Peter C. Kronfeld

Unstable fixation and vertical nystagmus. (French) Jeannerod, M. (Laboratory for Experimental Medicine, Faculty of Medicine, Lyon), Ophthalmologica 161:31-37, 1970.

In ten patients with diffuse brain stem disease (multiple sclerosis or tumor) the electrooculograms revealed instability of fixation in the form of horizontal saccades which increased in amplitude with reduced illumination and became associated with a vertical nystagmus. These saccades probably represent the same phenomenon as the "flutter-like oscillations" described by Cogan and others as specific signs of cerebellar disease. (4 figures, 12 references)—Peter C. Kronfeld

Occlusion amblyopia. Keiner, E. C. J. F.

(Zwolle, The Netherlands), Ophthalmologica 161:55-62, 1970.

The relationship between occlusion amblyopia and changes in fixation pattern was studied in five cases of convergent strabismus. Two processes may be recognized in the effect of constant occlusion of the fixating eye in cases of strabismic amblyopia, namely, 1) a shift in fixation from the originally fixating eye to the amblyopic eye, and 2) an improvement in acuity of the amblyopic eye and a drop in acuity in the originally fixating eye, both starting at the time of the shift in fixation. The younger the child, the faster is the drop in acuity in the originally fixating eye. Through occlusion of the other eye, the originally fixating eye regains normal acuity very rapidly, even before dominant fixation position has been restored. (10 references)—Peter C. Kronfeld

BILATERAL RECURRENCE OF SALZMANN'S DYSTROPHY AFTER PERFORATING KERATOPLASTY. (French) Houber, J.-P. (University Eye Clinic Geneva, Switzerland), Ophthalmologica 161:90-97, 1970.

The eyes of a 71-year-old female patient became available at autopsy six and 24 years, respectively, after keratoplasty. The dystrophy had slowly extended into the graft. The histologic findings are described in detail. On the basis of these findings large lamellar grafts are considered most suitable for cases of Salzmann's nodular dystrophy. (6 figures, 11 references)—Peter C. Kronfeld

OCULAR CHANGES IN PATIENTS ON LONG-TERM CHLORPROMAZINE THERAPY. (German) Kalberer, M., Atar, Z. and Bider, E. (University Eye Clinic Basle, Switzerland), Ophthalmologica 161:118-124, 1970.

The total dose of chlorpromazine in this series of 22 psychiatric patients ranged from 79 to 1685 grams, the daily dose from 50 to 1600 mg. Aside from the now well-known corneal and lenticular changes, the only signs of ocular toxicity were subnormal or definitely pathologic EOGs. (1 table)—Peter C. Kronfeld

CORTISONE CATARACT AFTER KIDNEY TRANSPLANTATION. (German) Rintelen, F. and Dobrivojevic, D. (University Eye Clinic Basle, Switzerland), Ophthalmologica 161:125-131, 1970.

The development of cataracts was observed in seven out of 11 patients treated with prednisone and azathioprine to suppress immune reactions after kidney transplantation. The large doses of prednisone that had to be used and the early biomicroscopic picture of the cataract spoke for its being caused by the corticosteroid. In the discussion Kern (Zürich) reported the occurrence of cataract in 15 out of 29 patients treated with prednisone and azathioprine after kidney transplantation. The survival period of the patients without cataract was significantly shorter than that of patients with cataracts. In addition to posterior and anterior saucer-shaped opacities Kern observed in his series fleck-shaped, densily opaque areas resembling Vogt's glaucoma flecks. The possibility of their being related to the azathioprine medication was considered. (1 figure, 1 table)—Peter C. Kronfeld

REGARDING THE TREATMENT OF MALIGNANT EXOPHTHALMOS. (German) Della Casa, F. (Burgdorf, Switzerland), Ophthalmologica 161:145-151, 1970.

A case of malignant exophthalmos in a middle-aged female patient which had apparently progressed on 60 to 100 mg of prednisone and 60 to 80 mg of carbimazole per day, slowly improved on retrobulbar depo-Medrol and smaller doses of carbimazole. (2 figures, 2 references)—Peter C. Kronfeld

THE DETERMINATION OF THE RETINAL VISUAL ACUITY IN THE PRESENCE OF CATARACT. (German) Goldmann, H. and Lotmar, W. (University Eye Clinic Berne, Switzerland), Ophthalmologica 161:175-179, 1970.

The authors have tested the resolving power of the retina by means of interference fringes of varying fineness. Interference fringes are virtually independent of the optical characteristics of cornea and lens; stray light due to optical imperfections reduces the contrast (the amplitude) of the pattern, but does not change its fineness (the number of cycles per degree of visual angle). For the production of interference fringes on the retina the authors first used a Michelson-interferometer. In five normal subjects with geometric-optical (or Snellen-) acuities of 1.0 (equaling 1′ of

resolution), the retinal resolving power as measured with interference fringes was only 2′ which the authors attribute to entoptic phenomena and to the large size of their test-field. In four cases of far-advanced cataracts with finger counting or less geometric-optical vision no interference acuity could be measured. In another group of six eyes with cataracts and geometric-optical acuities ranging from LP and P to 0.2, the patients were able to find a position of their heads (that is, relatively clearer portions of their lenses) in which very much better interference acuities could be recorded; these were confirmed by good geometric-optical acuities after the removal of the cataract.

In their most recent work the authors have used an adaptation of the illuminating system of the Haag-Streit #360 slit lamp for the production of retinal interference fringes. (1 figure, 3 tables, 6 references)—Peter C. Kronfeld

VISUAL EVOKED RESPONSE OF THE VISUAL CORTEX IN MACULA DEGENERATIONS. (German) Bider, E. (University Eye Clinic Basle, Switzerland), Ophthalmologica 161:187-195, 1970.

With stimuli of 110 mL in a 2° centrally fixated test field the author has obtained visual evoked responses which were definable in terms of latent period, amplitude and number of waves. In visually normal individuals the latency period ranged from 40 to 60 msec, the amplitude of the first wave from eight to 35 $\mu$V and the differences between right and left eye from one to three $\mu$V. In 16 patients with various types of macula lesions there was a fair degree of correlation between visual acuity and the visual evoked responses. The author considers his method particularly suitable for testing small foveal lesions. (5 figures, 1 table, 30 references)—Peter C. Kronfeld

THE ERG IN BEHÇET'S DISEASE. (German) Kožoušek, V. (University Eye Clinic and Canton-Hospital Zürich, Switzerland), Ophthalmologica 161:196-201, 1970.

Five cases representing a wide range of stages of the disease were examined under photopic and scotopic conditions. The findings were similar to those in tapeto-retinal degenerations, but still sufficiently different to be useful in the differential diagnosis. (3 figures, 1 table, 6 references)—Peter C. Kronfeld

EPIRETINAL FIBROPLASIA AND MASSIVE PRERETINAL RETRACTION. (German) Gloor, B. P. (Department of Ophthalmology, Washington University, St. Louis), Ophthalmologica 161:227-236, 1970.

Previous experimental work aiming at elucidation of the mechanism of epiretinal fibroplasia following photo- or diathermy-coagulation is reviewed. The cells involved in the fibroplasia are predominantly hyalocytes. Their proliferation occurs in areas in which cell-containing vitreous is normally present or has been left behind after detachment of most of the vitreous. This explains the occurrence of macular puckering after coagulations in the periphery. Regarding treatment, steroids in massive doses started at the very beginning of the process may be beneficial. Prophylactically, it seems important to use only non-perforating coagulations and to wait as long as possible before repeating them. (31 references)—Peter C. Kronfeld

CLINICAL EXPERIENCES WITH HYDROPHILIC CONTACT LENSES IN UNILATERALLY APHAKIC CHILDREN. (German) Dreifus, M. (University Eye Clinic Zürich, Switzerland), Ophthalmologica 161:279-285, 1970.

Between 1963 and 1969, 88 unilaterally aphakic children were fitted with hydrophilic (soft) contact lenses. The ages of the children ranged from two to nine years, the period of uncorrected aphakia from one month to more than a year. Thirty-seven of the 88 children became regular contact lens wearers for a minimum of six to eight hours per day. The others wore the lenses only occasionally for which the author blames the parents. Irregularities in the shape and transparency of the cornea accounted for better contact lens than spectacle lens acuity in a significant number of children. Despite the good visual acuity, 54% of the eyes corrected with contact lenses remained in exotropia. (6 figures)—Peter C. Kronfeld

THE TREATMENT OF EPITHELIAL INVASION OF THE ANTERIOR CHAMBER AFTER CATARACT OPERATION. (German) Witmer, R.

(University Eye Clinic Zürich, Switzerland), Ophthalmologica 161:286-291, 1970.

From experiences in eight cases of epithelial downgrowth and five cases of postoperative iris cysts the author strongly recommends early surgical treatment which, in the case of epithelial downgrowth, consists of reopening of the original incision, excision of the affected iris and careful curettage of the affected cornea. (6 references)—Peter C. Kronfeld

FOLLOW-UP AND LATE RESULTS AFTER OPERATIONS FOR CANALICULUS OBSTRUCTION. (German) Huber, P. and Benz, G. (Eye Clinic of the Canton-Hospital St. Gallen, Switzerland), Ophthalmologica 161:313-323, 1970.

The operations under discussion are Bangerter's lacodacryostomy which is an anastomosis between the lower-nasal fornix and the lacrimal sac, and Bangerter's lacoductostomy which is an anastomosis between the lower-nasal fornix and the nasolacrimal duct, with a connecting channel made out of buccal mucous membrane. About 20 days after the operation a piece of rubber tubing is inserted into the surgically created passages which is replaced, two to three weeks later, by a custom-made, individually fitted plastic probe. Probes of the latter type are worn, with changes about every four to five months, for a total of about two years. A fairly common postoperative complication is the formation of a conjunctival fold which blocks the beginning of the surgically created passage. These folds are usually removed surgically. About half of the patients operated upon report complete comfort. (5 figures)—Peter C. Kronfeld

THE OCULAR SIGNS OF LESIONS OF THE CAROTID ARTERY. (French) Babel, J., Gauthier, G., Psilas, K., Ricci, A., Soriano, H. and Tsacopoulos, M. (University Eye Clinic Geneva, Switzerland), Ophthalmologica 161:324-339, 1970.

The paper deals with correlations between arteriographic findings (carotid artery or aortic arch arteriography) and the pressure in the ophthalmic artery (as estimated by ophthalmodyamometry) and arm-retina circulation time in patients with stenoses or thromboses of one or both carotid arteries. In general, the ophthalmic artery pressure estimates correlated better with the arteriographic findings than the arm-retina circulation times. (8 tables, 17 references)—Peter C. Kronfeld

THE CHOICE OF SURGICAL TREATMENT IN V-PATTERN ESOTROPIA. (French) Deller, M. and Brack, B. (University Eye Clinic Lausanne, Switzerland), Ophthalmologica 161;340-345, 1970.

The authors report on a series of 40 children with V-pattern esotropia, 34 of which were less than two years old. The operation consisted of symmetrical recessions of both medial recti and myotomies of both inferior obliques, all done in the same sitting. The incomitance, that is, the V-pattern esotropia was eliminated in 85% of the cases. Some measure of binocular vision was obtained in 62.5% and a good cosmetic result without gain in binocular vision in 22.5% of the cases. A second operation yielded two more good cosmetic results and two failures. Added to horizontal muscle surgery, the inferior oblique myotomies gave decidedly better results than the previously used tucking of the tendons of the superior obliques. (7 references)—Peter C. Kronfeld

BERTALANFFY'S METHOD FOR THE DEMONSTRATION OF TUMOR CELLS IN THE BLOOD OF PATIENTS WITH OCULAR TUMORS. (German) Goder, G. and Velhagen, K.-H. (Eye Clinic of the Humboldt University, Charité, Berlin), Ophthalmologica 161: 372-384, 1970.

The method devised by Bertalanffy is based upon yellow to brown fluorescence emitted by cells with increased protein synthesis after treatment with acridine-orange. In the circulating blood megakaryocytes, endothelial cells and malignant tumor cells may show this type of fluorescence. The test was clearly positive in ten, doubtfully positive in four and negative in four cases of histologically verified cases of malignant melanoma of the uvea. The difficulties and the potential sources of error of the method are stressed. (6 figures, 1 table, 17 references)—Peter C. Kronfeld

THE ASSOCIATION OF LEBER'S CONGENITAL AMAUROSIS WITH STIGMATA OF OCULAR ALBINISM. (French) Holland, M. G. and

Cambie, E. (Department of Ophthalmology, Tulane University, New Orleans, La.), Ophthalmologica 161:425-436, 1970.

An apparently sporadic case of typical congenital amaurosis in a 5-year-old boy was found to have translucent irides. His mother showed translucent irides and the characteristic fundus picture of the carrier of albinism. Her father's eyes were normal except for translucent irides. (6 figures, 50 references)—Peter C. Kronfeld

THE OPTIMAL AGE FOR SURGERY IN STRABISMUS CONVERGENS AND SURSOADDUCTORIUS. (German) Ditzen, K., Grützner, P., Immich, H. and Mattheus, S. (University Eye Clinic Heidelberg and Institute for Documentation, Information and Statistics of the German Cancer Research Center), Ophthalmologica 161:466-476, 1970.

This is a statistical evaluation of the effect on the angle of squint of 3.5 mm recessions of both medial recti or 10 to 15 mm myectomies of one or both inferior obliques. The measurements were made with the prism-cover test 4 to 5 days and in half of the cases, one year after the surgery. The effect of the medial rectus recessions was found to diminish markedly if the child was over six years old at the time of surgery. The effect of the inferior oblique surgery did not appear to be related to the child's age at the time of the operation. (2 tables, 3 references)—Peter C. Kronfeld

THE EXTENT OF THE ACCOMMODATION PHOSPHENE IN THE VISUAL FIELD. (German) Comberg, D. (Eye Clinic of the Charité, the Humboldt-University Berlin), Ophthalmologica 161:499-503, 1970.

The study was prompted by the apparent relationship between the use of strong miotics and the onset of retinal detachments. Purkinje in 1825 described a phosphene associated with accommodation in the completely dark adapted eye which takes the form of a bluish-white ring in the periphery of the visual field. The present author found the inner border of the phosphene to lie between 45 and 55 degrees of eccentricity. The retinal zone peripheral to this border is apparently under the mechanical influence of the ciliary muscle during accommodation. Most retinal breaks lie in that area. A causal relationship between ciliary muscle contraction and retinal atrophy is possible. (2 figures, 11 references)—Peter C. Kronfeld

## PEDIATRICS

ADRENERGIC NEURONE AND RECEPTOR ACTIVITY IN THE IRIS OF THE NEONATE. Lind, N., Shinebourne, E., Turner, P. and Cottom, D. (St. Bartholomew's Hospital, London, E.C. 1, England), Pediatrics 47:105-111, Jan., 1971.

In premature and full-term infants, the response of the dilator pupillae muscle to directly and indirectly acting sympathetic amines was measured. Phenylephrine always produced a mydriasis, whereas the response to tyramine and hydroxyamphetamine, which was positively correlated with age, tended to be absent in the least mature, smaller babies. The results indicate that, in this situation, the end organ has the capacity to respond to the sympathetic neurohumoral transmitter, but that the synthesis, storage, or release of neuronal noradrenaline may be deficient. (6 figures, 19 references)—Authors' abstract

## PLASTIC AND RECONSTRUCTIVE SURGERY

A FOLLOW-UP STUDY ON THE TREATMENT OF KELOIDS WITH TRIAMCINOLONE ACETONIDE. Griffith, B. H., Monroe, C. W. and McKinney, P. (Department of Surgery (Plastic) Northwestern University Medical School, Chicago, Illinois), Plast. Reconstr. Surg. 46:145-150, Aug., 1970.

An aqueous suspension of triamcinolone acetonide (Kenalog) was injected into 151 keloids and 12 hypertrophic scars and reduced the size of the lesion in over 9.0% of the cases. There was no recurrence of keloid formation in 10 patients after a keloid was excised and triamcinolone was injected into the wound edges.—Bartley R. Frueh

## TRANSACTIONS OF THE AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

DIABETES MELLITUS AND PRIMARY OPEN-ANGLE GLAUCOMA. Becker, B. (Washington University, St. Louis, Missouri), Tr. Am. Acad. Ophth. Otolaryng. 75:239-259, Mar.-Apr., 1971.

Primary open-angle glaucoma as well as elevated intraocular pressure, high intraocular pressure response to topical corticosteroids (gg), and C/D diameter ratios greater than 0.3 are more prevalent in diabetics than in nondiabetics. . . . Proliferative retinopathy occurs less often in diabetics with primary open-angle glaucoma, elevated intraocular pressure, gg response to topical corticosteroids, or high myopia.

Diabetes and positive glucose tolerance tests are more prevalent in patients with primary open-angle glaucoma and in high intraocular pressure responders to topical corticosteroids (gg). . . . Positive glucose tolerance tests are much more prevalent in the gg subgroup more "susceptible" to field loss (normal circadian variation and dexamethasone suppression of plasma cortisol, large C/D diameter ratio, and reversible changes in visual field induced by intraocular pressure elevation) than in "resistant" gg subgroup. . . . Positive glucose tolerance tests are more prevalent in glaucoma patients with lower intraocular pressures; glaucoma patients with positive test results appear to lose visual field at lower intraocular pressures and higher outflow facilities than do those with negative test results. (2 figures, 20 tables, 54 references)—Author's abstract

CATARACTS AND PRIMARY OPEN-ANGLE GLAUCOMA: THE EFFECT OF UNCOMPLICATED CATARACT EXTRACTION ON GLAUCOMA CONTROL. Bigger, J. F. and Becker, B. (Washington University, St. Louis, Missouri), Tr. Am. Acad. Ophth. Otolaryng. 75:260-272, Mar.-Apr., 1971.

The effects of uncomplicated, intracapsular cataract extraction on the control of intraocular pressure were determined in a study of 100 eyes with primary open-angle glaucoma . . . Of the eyes in which the glaucoma was well controlled prior to cataract extraction, 88% were either as well or better controlled one year later. For the eyes with marginal or poor control preoperatively, improvement was noted in 74% and 50%, respectively, one year later. Although all 100 eyes required medication before surgery, 20 eyes were adequately controlled without medication postoperatively. Only two eyes required subsequent glaucoma surgery during the first two years after cataract extraction. (9 tables, 12 references)—Authors' abstract

CATARACT EXTRACTION IN MANAGEMENT OF GLAUCOMA. Linn, Jr., J. G. (University of Pittsburgh School of Medicine), Tr. Am. Acad. Ophth. Otolaryng. 75:273-280, Mar.-Apr., 1971.

A review of 98 cataract operations performed on eyes under medical treatment for glaucoma was made to determine the influence of the operation on the control of the glaucoma. No medical treatment for glaucoma was required in 40 eyes. The medical control of the glaucoma after cataract surgery was approximately the same or better in 94 of the 98 eyes. The difficulty in preoperative medical control was not helpful in identifying those patients who would have a problem with glaucoma after cataract extraction. The experience with this group of patients would indicate that the cataract operation is usually an aid in the management of glaucoma and seldom makes control worse. (2 figures, 2 tables, 9 references)—Author's abstract

FAMILIAL AND SECONDARY DRUSEN: HISTOLOGIC AND FUNCTIONAL CORRELATIONS. Farkas, T. G., Krill, A. E., Sylvester, V. M. and Archer, D. (Eye Research Laboratories, University of Chicago, Ill.), Tr. Am. Acad. Ophth. Otolaryng. 75:333-343, Mar.-Apr., 1971.

One patient with familial drusen and another patient with acquired drusen were studied by histologic and functional methods. The patient with familial drusen was found to have abnormalities of retinal function and histologic evaluation revealed a diffuse disturbance of the pigment epithelium. The patient with acquired drusen had normal retinal function and only a focal abnormality of the pigment epithelium, based on histologic studies. The histochemical, light microscopic, and electron microscopic findings in the two types of drusen were identical. Drusen are the result of abnormal behavior of the pigment epithelium and

represent a common response of this structure to a variety of abnormal stimuli. (12 figures, 2 tables, 19 references)—Authors' abstract

TREATMENT OF PROLIFERATIVE SICKLE RETINOPATHY. Goldberg, M. F. (University of Illinois Eye and Ear Infirmary, Chicago), Tr. Am. Acad. Ophth. Otolaryng. 75:532-556, May-June, 1971.

Twenty-seven eyes with PSR were treated, primarily by xenon arc photocoagulation. The average follow-up duration was 30.4 months. The number of retinas with neovascularization was reduced from 100% to 55% and the number of eyes with vitreous hemorrhage was reduced from 41% to 26%. Of the total number of neovascular lesions, 74% were obliterated by photocoagulation. The reduction in extent of retinal neovascularization was statistically significant when compared with an untreated group control group of eyes. Intervention thus appeared to interrupt the natural course of PSR. (12 figures, 8 tables, 10 references)—Author's abstract

PHOTOCOAGULATION OF MACULAR LESIONS. Gass, J. D. (Bascom Palmer Eye Institute, University of Miami, Florida), Tr. Am. Acad. Ophth. Otolaryng. 75:580-608, May-June, 1971.

The author advises photocoagulation of idiopathic central serous choroidopathy if a leak can be demonstrated with fluorescein at least one-fourth disc diameter from the fovea. In general, one should wait four months to allow for spontaneous resolution. Patients with senile macular choroidal degeneration benefit from photocoagulation if there is no hemorrhagic component and if there is a serous detachment of the retina extending into the central macular area. Hemangiomas of the choroid respond very well to photocoagulation and one should particularly treat those lesions that are associated with serous detachments of the macula. Only moderate photocoagulation of the tumor surface is required, and no attempt should be made to destroy the benign tumor with additional photocoagulation. (13 figures, 1 table, 27 references)—David Shoch

ARGON AND RUBY LASER PHOTOCOAGULATION OF DISCIFORM MACULAR DISEASE. L'Esperance, Jr., F. A. (Edward S. Harkness Eye Institute, New York), Tr. Am. Acad. Ophth. Otolaryng. 75:609-625, May-June, 1971.

The use of either the ruby or the argon laser may be beneficial in patients with disciform macular disease. Success rate is 93% in those with central serous choroidopathy and falls to 27% in those with hemorrhagic detachment of the neuroepithelium. In most of these cases there is no return of central vision but the progression of the disciform maculopathy is stopped. (13 figures, 1 table, 15 references)—David Shoch

LASER INTERFEROMETRY IN THE EVALUATION OF POTENTIAL MACULAR FUNCTION IN THE PRESENCE OF OPACITIES IN THE OCULAR MEDIA. Green, D. G. and Cohen, M. M. (University of Michigan, Ann Arbor), Tr. Am. Acad. Ophth. Otolaryng. 75:629-637, May-June, 1971.

A subjective test for evaluating retinal function in patients with moderate to dense cataractous changes is described. This test uses coherent light from a low-output, helium-neon laser to form striped interference frings on the retina. The patient's ability to see interference fringes of varying fineness provides a basis for estimating potential visual acuity through opacities in the ocular media.

The validity of the test has been assessed by comparing estimated visual potential with the actual visual acuity present after cataract surgery. The correlation between preoperatively predicted visual acuity and best corrected aphakic vision is high enough to suggest that this test is a useful addition to present methods of preoperatively determining macular function. (5 figures, 7 references)—Authors' abstract

PHOTOCOAGULATION OF IRIS-CILIARY BODY EPITHELIAL CYSTS. Cleasby, G. W. (Presbyterian Hospital of Pacific Medical Center, San Francisco), Tr. Am. Acad. Ophth. Otolaryng. 75:638-642, May-June, 1971.

Many types of treatment and surgical procedures have been advocated for elimination of iris-ciliary body epithelial cysts. All of these methods carry certain hazards and photocoagulation is at least as effective and is much safer than any of the techniques used in the past. (9 figures, 11 references)—Author's abstract

# NEWS ITEMS

EDITED BY THOMAS CHALKLEY, M.D.
*700 North Michigan Avenue, Chicago, Illinois 60611*

For adequate publicity, notices of postgraduate courses, meetings and lectures must be received *at least* three months prior to the date of occurrence.

### ULTRASONICS: WORLD CONGRESS IN ROTTERDAM

The second world congress on ultrasonics in medicine will be held June 4–8, 1973, in "de Doelen" Congress Center in Rotterdam under the Chairmanship of the Dutch neurologist, M. de Vlieger, M.D. This congress on medical diagnostics with the aid of ultrasound is held under the auspices of the medical faculty at Rotterdam and the World Federation for Ultrasound in Medicine and Biology.

For further information, contact the secretariat of the Second World Congress on Ultrasonics in Medicine, Holland Organizing Center, 16 Lange Voorhout, The Hague, Netherlands.

### VISUAL SCIENCE INFORMATION CENTER

The Visual Science Information Center, a computer-based bibliographic information center covering the world's literature on vision, has been established at the University of California, Berkeley. Its bibliographic information services are available to the public.

The data base begins with publications released after November, 1970. Some entries before that date are included, but no comprehensive coverage is intended. An index of authors and subjects, Vision Index, will be issued quarterly, with each quarterly issue containing an annual accumulation expected to be approximately 2500 individual entries. Annual subscription price in the United States, Canada, and Mexico is $20; in other countries it is $21. Volume 1, number 1 (March, 1971) is now available.

For subscription to Vision Index, demand search request forms, and further information write Harold R. Gibson, Director, Visual Science Information Center, University of California, Berkeley, California 94720.

### AMERICAN BOARD OF OPHTHALMOLOGY EXAMINATIONS

The written qualifying test of the American Board of Ophthalmology is held annually on the third Monday in January in approximately 35 locations throughout the world. Applications to take this test in any one year must be in the Board's office, postmarked not later than July first of the preceding year.

The dates for the forthcoming oral examinations are as follows: Thursday, October 21 thru Sunday, October 24, 1971, at the Sheraton Hotel in Chicago; Thursday, May 18 thru Sunday, May 21, 1972, at the Sheraton-Palace Hotel in San Francisco; and Thursday May 17 thru Sunday, May 20, 1973, at the Sheraton Hotel in Boston.

For further information contact the American Board of Ophthalmology, 8870 Towanda Street, Philadelphia, Pennsylvania 19118.

### PROJECT VISION EXPANDED: INTERNATIONAL EYE FOUNDATION

John Harry King, founder and medical director of the International Eye Foundation, announced that Project Vision, supported through private donations and funding granted by the USAID, has been expanded to include the countries of Ethiopia, Kenya, and Saudi Arabia. A teaching team headed by Dr. King visited these countries during the month of August, while at the same time, Dr. A. Benedict Rizutti, New York, heads a team of surgeons flown to Saudi Arabia under the auspices of the Foundation. Project Vision, sponsored by the IEF, is a continuous program to upgrade world eye care, and to help in the prevention and cure of blindness. At the request of the host countries, the IEF teaching teams will help set up an eye bank program and programs to teach the latest eye surgery techniques.

### POSTGRADUATE CONFERENCE: ESTELLE DOHENY EYE FOUNDATION

The Estelle Doheny Eye Foundation will sponsor its third annual postgraduate conference at the Ambassador Hotel in Los Angeles, Monday and Tuesday, October 18 and 19.

The A. Ray Irvine and Wendell C. Irvine Memorial Lecturers will be Ramon Castroviejo, Professor of Clinical Ophthalmology, City University of New York Postgraduate School of Medicine, and Frank W. Newell, Professor and Chairman, Department of Ophthalmology, University of Chicago School of Medicine.

Registration information may be obtained by writing to Robert E. Levine, M.D., or T. Rodman Wood, M.D., Program Chairmen, Estelle Doheny Eye Foundation, 272 South Lake Street, Los Angeles.

### MICROSURGERY COURSE: DOWNSTATE UNIVERSITY OF NEW YORK

The State University of New York Downstate Medical Center will hold an intensive course in microsurgery of the eye, March 25–28, 1972. Speakers will include Richard C. Troutman, Professor of Ophthalmology, State University of New York, Gunter Mackensen, Freiburg, Germany, and Enrique S. Malbran, Buenos Aires, Argentina, together with the members of the ophthalmology staff of the medical center.

Registration will be limited to 22 students. Each

student will be provided with a zoom surgical microscope. Instruction will be carried out by films, closed-circuit television and by lectures. The course will be directed to the practical application of microscope magnification in surgery of the anterior segment, with particular emphasis on cataract surgery and surgery of the cornea, but including aspects of surgery for glaucoma, the uveal tract, and trauma.

Further information is available from Mrs. Sylvia Baer, Division of Ophthalmology, State University of New York, 450 Clarkson Avenue, Brooklyn, New York 11203.

### Conference on Craniofacial Anomalies: New York University Medical Center

An international conference on the diagnosis and treatment of craniofacial anomalies will be held at the New York University Medical Center October 25–28, 1971, under the joint-chairmanship of a physician, John Marquis Converse, and a dentist, Samuel Pruzansky. The subjects covered will be a classification of the various syndromes including a review of the embryology and development of the craniofacial area, premature craniofacial synostosis, otocephalic syndromes and maxillomandibular disharmonies. Registration fee is $200 ($50 for residents in training).

### Wills Eye Hospital: Annual clinical conference

The 24th annual clinical conference of the Wills Eye Hospital will be held at the Bellevue Stratford Hotel, Philadelphia, February 3–5, 1972. Lorenz E. Zimmerman of Washington, D.C., will deliver the Bedell lecture. Robert D. Mulberger is chairman of the conference committee.

### Postgraduate courses: Mount Sinai School of Medicine

The Mount Sinai School of Medicine of the City University of New York and the Page and William Black Postgraduate School of Medicine will offer the following postgraduate courses for ophthalmologists during the 1971–72 academic year: Edward L. Raab will offer an introduction to strabismus. On Tuesdays, January 13 and 20, from 3:00 to 5:00 P.M. Heskel M. Haddad will instruct in a course on metabolic and pediatric ophthalmology, to be held February 7 through 28 from 8:00 to 10:00 A.M. A course in accommodative and non-accommodative esodeviations will be instructed by Edward L. Raab on Thursdays, February 10, 17, and 24, from 3:00 to 5:00 P.M.

The fee for each of the first two courses is $40. The fee for the last course is $60. For a descriptive catalogue and an application, write to the registrar, Page and William Black Postgraduate School of Medicine, Fifth Avenue and 100th Street, New York, New York 10029.

### New Jersey Academy of Ophthalmology and Otolaryngology

The New Jersey Academy of Ophthalmology and Otolaryngology will hold its annual meeting at the Robert Treat Hotel in Newark November 10, 1971.

The program for ophthalmologists is as follows: Treatment of corneal ulcers and burns will be presented by Stuart Brown, New York; advances in retinal detachments will be the subject of MacKenzie Freeman, Boston; photocoagulation therapy will be discussed by Harold F. Spalter, New York; etiology, diagnosis, and results of treatment of superior oblique palsy will be presented by Donelson R. Manley, Philadelphia; cryosurgical method for the treatment of retinal detachment will be discussed by Harvey Lincoff, New York; A-V patterns is the subject of Webb Chamberlain, Cleveland; some complications in cataracts surgery will be described by Samuel D. McPherson, Durham, North Carolina; and management of bacterial corneal ulcers will be discussed by Frederick H. Theodore, New York.

### Alumni meeting: Washington Hospital Center

The annual meeting of alumni of the Department of Ophthalmology of the Washington Hospital Center, Washington, D.C., will be held June 3, 1972.

For further information contact Seymour Dubroff, M.D., Chairman, 1111 Spring Street, Silver Spring, Maryland 20910.

### Soft lens course: University of Florida

A practical course on soft contact lenses sponsored by the University of Florida will be held January 26–29, 1972, in Gainesville. The course is designed to provide instruction in the selection, fitting, and uses of all types of soft contact lenses. The faculty includes: J. Aquavella, J. Baldone, C. Black, V. Chiquiar Arias, G. Feldman, M. Friedberg, A. Gasset, J. Hartsein, H. Kaufman, M. Poster, W. Sampson, M. Uotila, and K. Whitman.

Registration fee will be $100 for the seminar and $300 for the seminar and workshop. Deadline for applications is December 1, 1971. For information contact Antonio R. Gasset, M.D., Department of Ophthalmology, University of Florida College of Medicine, Gainesville, Florida 32601.

## Personals

### Jorge Vasco Posada

Jorge Vasco Posada, auxiliary professor of ophthalmology at the Medical College of the University of Antioquia, Medellin, Colombia, was awarded the 1971 silver medal, Ignacio Barraquer y Barraquer, by the Honor Tribunal of the National Academy of Medicine. The ceremony took place in Bogota. Dr. Vasco Posada received this award for his outstanding achievements in the field of ophthalmology, and especially for his work in the modification of circulation of the posterior segment of the eye.

### George N. Schoonover

On September 30, George N. Schoonover, Chairman and Chief Executive Officer of the House of Vision, Inc., resigned from the company. H. Clinton Green, who has been president of House of Vision since 1968, was elected to the additional post of Chief Executive Officer.

# DMV Contact Lens Remover

ACTUAL SIZE

**The NO STRETCH Method of Contact Lens Removal**

So simple, so far superior to the manual method of stretching the eyelids, that every one of your patients should use this procedure for removing contact lenses. Just the wetting of the cup and a gentle touch to the lens does it. Complete with carrying case, as shown.

Colors: Yellow, Pink, White, Avocado and Aqua

*Available from your contact lens laboratory*

**OVERSEAS OUTLET:**

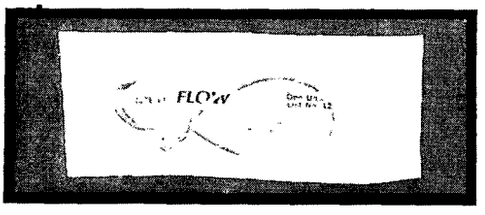
Stauffacherstrasse 5
8004 Zurich, Switzerland

## DMV Contact Lens Company



**BOX 2829** **ZANESVILLE, OHIO 43701**

**PHONE: (614) 452-4787**

7-year-old boy with severe gunpowder burns on both corneas, treated 24 hours with lactated Ringer's solution administered via medi-FLOW device. Right, two weeks after patient discharged.

# *medi-FLOW*™

battle-proved in Viet Nam* . . . now amplifying the armamentarium of civilian ophthalmology.

The medi-FLOW device delivers controlled medication to the cornea and conjunctiva either rapidly or slowly, as you desire.

It is a uniquely designed clear plastic scleral lens with a polyethylene tube and Luer-lock adaptor for attaching either a syringe or I.V. set. The lens incidentally protects the cornea from eyelid trauma, reduces discomfort rapidly, and aids in the prevention of symblepharon formation—all outstandingly valuable assets of medi-FLOW.

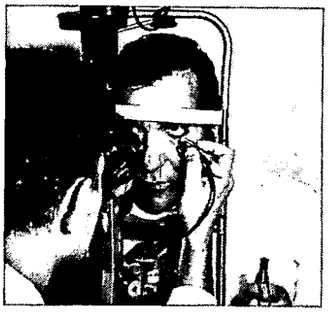
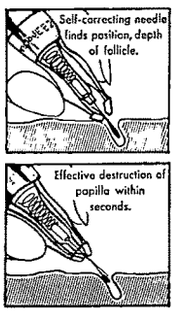
# Contact Lens Diagnostic Sets

*(*As suggested in the text, Corneal Contact Lenses, Ed. by Girard, L. J., Sampson, W. G., Soper, J. W.— C. V. Mosby Co.)*

A set of optically perfect (Modern Arc inspected) diagnostic corneal lenses — each lens is finished in exacting reproducible detail.



Invaluable for:



1. Eliminating vertex distance errors.
2. Evaluating best visual acuities in cornea disease.
3. Predetermination of lens fit.
4. Analysis of patient reaction.
5. Analysis of visual acuities in subnormal vision.

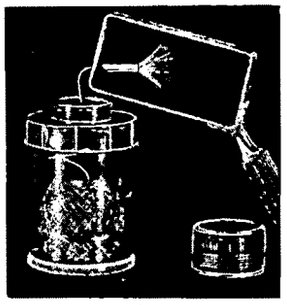
# SOFT CONTACT LENSES

*A Practical Course Sponsored by University of Florida to be held January 26-29, 1972 in Gainesville, Florida*

(Immediately preceding the Florida Midwinter Seminar)

The course is designed to provide practical instruction in the selection, fitting and use of all types of soft contact lenses. It will consist of lectures, roundtable discussions, demonstrations and workshops on fitting techniques. An outstanding faculty will include:



J. Aquavella
J. Baldone
C. Black
V. Chiquiar Arias
G. Feldman
M. Friedberg
A. Gasset
J. Hartstein
H. Kaufman
H. Leibowitz
S. Mishima
M. Poster
M. Uotila
K. Whitham

Registration fee will be $100 for the seminar or $300 for the seminar and workshop. Attendance will be limited and the deadline for applications is December 1, 1971. For application forms and additional information please write:

Antonio R. Gasset, M.D.
Department of Ophthalmology
University of Florida
College of Medicine
Gainesville, Florida 32601

*THE TISSUE-FRIENDLY*

# SUPRAMID EXTRA®

**SUTURE.** Polyfilament but neither braided nor twisted. New cable-type construction with several strands enclosed in a perfectly smooth cover of the same material, gives great pliability and superior strength. Strong as steel wire, handles as silk. No stitch irritation, no growth of tissue into suture. Sizes 10-0 to 8.

**SPECIAL NEEDLES:** Our CT needle for cataracts (wire size 0.30mm, length 9mm), CA needle for corneal work (wire size 0.30mm, length 6mm), and EX needle for special keratoplasties (wire size 0.2mm, length 5mm), a flattened reverse cutting needle to prevent "leaking wounds," equal to the smallest hand made eyed needles No. 82F, **and finally the smallest spatula needle on the market, length 5 millimeters, wire size 0.2mm, double armed with 10-0, 9-0 and 8-0 black Supramid Extra. Code Nos. 2SC-100, 2SC-90 and 2SC-80.**

**A NEW PRODUCT:** Implants—Sleeves (Tubes) for preventing adhesions in Eye Muscle Surgery. Method development by Edward A. Dunlap, M.D. Reference: Dunlap, Edward A.: Plastic Implants in Muscle Surgery, Archives of Ophthalmology, 80: 249-257, August 1968.

**TUBING.** *Fully inert because it is made of the same material as the suture;
* Thinnest walls of any surgical tubing, fully transparent and can be *repeatedly* autoclaved;
* Most economical. It is in your interest to compare prices and quality.

**FOIL.** Excellent results with our suture created the demand for Foil for plastic and reconstructive surgery in such cases as orbital fractures, lid reconstruction, etc. Foil is chemically identical with the sutures, thus just as inert when buried in the tissue.

Available in thickness from 0.05mm to 2.00mm, in sheets 15 x 20cm.

Can be steam-autoclaved, cut to size, and carved to shapes and forms.

# Title 21—FOOD AND DRUGS

## Chapter I—Food and Drug Administration, Department of Health, Education, and Welfare

SUBCHAPTER A—GENERAL

(Abstract)

## PART 3—STATEMENTS OF GENERAL POLICY OR INTERPRETATION

### Use of Impact-Resistant Lenses in Eyeglasses and Sunglasses

In the FEDERAL REGISTER of October 2, 1970 (35 F.R. 15402), a notice was published in which the Commissioner of Food and Drugs proposed that Part 3 be amended by adding a statement of general policy regarding the use of impact-resistant lenses in eyeglasses and sunglasses. The notice provided for the filing of comments within 30 days, and this time period was extended to January 30, 1971, by a document published in the FEDERAL REGISTER of November 3, 1970 (35 F.R. 16937). An announcement was published in the FEDERAL REGISTER of November 6, 1970 (35 F.R. 17116), advising interested parties that the effective date of the proposal when adopted would be December 31, 1971. . . . . .

Therefore, pursuant to provisions of the Federal Food, Drug, and Cosmetic Act (secs. 502(j), 701(a), 52 Stat. 1051, 1055; 21 U.S.C. 352(j), 371(a)) and under authority delegated to the Commissioner (21 CFR 2.120), Part 3 is amended by adding thereto the following new section:

§3.84 Use of impact-resistant lenses in eyeglasses and sunglasses.

(a) Examination of data available on the frequency of eye injuries resulting from the shattering of ordinary crown glass lenses indicate that the use of such lenses constitutes an avoidable hazard to the eye of the wearer.

(b) The consensus of the ophthalmic community is that the number of eye injuries would be substantially reduced by the use in eyeglasses and sunglasses of either plastic lenses, heat-treated crown glass lenses, or lenses made impact-resistant by other methods.

(c) To protect the public more adequately from potential eye injury, eyeglasses and sunglasses must be fitted with impact-resistant lenses, except in those cases where the physician or optometrist finds that such lenses will not fulfill the visual requirements of the particular patient, directs in writing the use of other lenses, and gives written notification thereof to the patient.

(d) The physician or optometrist shall have the option of ordering heat-treated glass lenses, plastic lenses, laminated glass lenses, or glass lenses made impact resistant by other methods; however, all such lenses must be capable of withstanding an impact test in which a 5/8-inch steel ball weighing approximately 0.56 ounce is dropped from a height of 50 inches upon the horizontal upper surface of the lens. The ball shall strike within a 5/8-inch diameter circle located at the geometric center of the lens. The ball may be guided, but not restricted, in its fall by being dropped through a tube extending to within approximately 4 inches of the lens. In order to pass the test, the lens must not fracture (for the purpose of this section, a lens will be considered to have fractured if it cracks through its entire thickness and across a complete diameter into two or more separate pieces or if any lens material visible to the naked eye becomes detached from the ocular surface). The test shall be conducted with the lens supported by a tube (1-inch inside diameter, 1¼-inch outside diameter, and approximately 1-inch high) affixed to a rigid iron or steel base plate. The tube shall be made of rigid acrylic plastic, steel, or other suitable substance and shall have on the top edge a 1/8- by 1/8-inch neoprene gasket having a hardness of 40±5, as determined by ASTM Method D 1415; a minimum tensile strength of 1,200 pounds, as determined by ASTM Method D 412; and a minimum ultimate elongation of 400 percent, as determined by ASTM Method D 412. The diameter and/or contour of the lens support may be modified as necessary so that the 1/8- by 1/8-inch neoprene gasket supports the lens at its periphery. Each finished impact-resistant glass lens (including each impact-resistant laminated glass lens) for prescription use shall be subjected to the impact test prescribed by this paragraph. To demonstrate that all other types of impact-resistant lenses are capable of withstanding this impact test, the manufacturer of such lenses shall subject to the impact test a statistically significant sampling of lenses from each production batch, and the lenses so tested shall be representative of the finished forms as worn by the wearer (including finished forms that are of minimal lens thickness and that have been subjected to any treatment used to impart impact resistance). This statement of policy will be appropriately amended to provide for use of alternate methods of testing the impact resistance of lenses if it can be shown that the alternate method is equal to or superior to the method prescribed in this paragraph.

(e) In addition to the invoice(s) and shipping document(s), all packages and/or shipping containers of impact-resistant lenses, other than impact-resistant glass lenses (including impact-resistant laminated glass lenses) for prescription use, shall bear a code or mark in a form or manner that will permit future identification of any given production batch by the manufacturer.

(f) The manufacturer of the lenses shall make, keep, and maintain for 3 years records of sale, distribution, and the results of tests conducted in accordance with paragraph (d) of this section. The manufacturer shall make such records available upon request at all reasonable hours by any officer or employee of the Food and Drug Administration or by any other officer or employee acting on behalf of the Secretary of Health, Education, and Welfare and shall permit such officer or employee to inspect and copy such records, to make such inventories of stock as he deems necessary, and otherwise to check the correctness of such inventories.

(g) For the purposes of this section, the term "manufacturer" includes an importer for resale. Such importer may have the tests required by paragaph (d) of this section conducted in the county of origin; however, such importer of impact-resistant lenses is subject to and must comply with the records and inspections provisions of paragraph (f) of this section.

(h) The transition to impact-resistant lenses must start immediately and be completed as promptly as possible; however, to provide for the development of an adequate supply of impact-resistant lenses and to facilitate an orderly change over to these lenses, the effective date of this statement of policy will be December 31, 1971. After that date eyeglasses and sunglasses must be fitted with impact-resistant lenses, except when the physician or optometrist finds that impact-resistant lenses will not fulfill the visual requirements of a particular patient.

(i) This statement of policy does not apply to contact lenses.

(Secs. 502(j), 701(a), 52 Stat. 1051, 1055; 21 U.S.C. 352(j), 371(a)) . . . . . .

# NATIONAL SPRING MEETING

THE AT *Greenbrier*

April 26-29, 1972

*Ophthalmology Speakers*
Miles A. Galin, M.D., New York, N.Y.
Louis J. Girard, M.D., Houston, Tx.
Frank W. Newell, M.D., Chicago, Ill.
John T. Simonton, M.D., New York, N.Y.
Frederick Stocker, M.D., Durham, N.C.

*Otolaryngology Speakers*
Phillip Anthony, M.D., Fort Worth, Tx.
William R. Hudson, M.D., Durham, N.C.
Jerrie Cherry, M.D., Nashville, Tenn.
James R. Leonard, M.D., Philadelphia, Pa.

Sponsored by W.Va. Academy of Ophthalmology and Otolaryngology

RESERVATIONS—Write directly to the Greenbrier, White Sulphur Springs, W.Va. for hotel accommodations.

ADVANCE REGISTRATION—Fee of $75 required; checks payable to W.Va. O & O. Send to J. Elliott Blaydes, Jr., M.D. 107 Federal Street, Bluefield, W.Va.

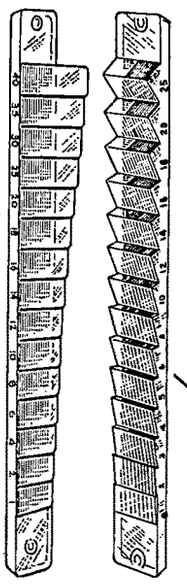
# NEW ORLEANS ACADEMY OF OPHTHALMOLOGY

Announces its Twenty First Annual Symposium

## CONTACT LENSES

An In Depth Symposium Concerning Contact Lenses—"Hard", "Soft" and Scleral —Their Legal, Medical and Cosmetic Applications.

April 9-14, 1972—Roosevelt Hotel, New Orleans



Guest Speakers

| | |
|---|---|
| Chester J. Black, M.D. | Elmhurst, Illinois |
| Jorge N. Buxton, M.D. | New York City, N.Y. |
| Herbert L. Gould, M.D. | White Plains, N.Y. |
| G. Peter Halberg, M.D. | New York City, N.Y. |
| Herbert E. Kaufman, M.D. | Gainesville, Florida |
| Ian A. Mackie | London, W.I. |
| Perry Rosenthal, M.D. | Brookline, Mass. |
| Whitney G. Sampson, M.D. | Houston, Texas |

Registration Fee

| | |
|---|---|
| $175.00 | For Practicing Ophthalmologists |
| 75.00 | For Residents Outside Louisiana |

NEW ORLEANS ACADEMY OF OPHTHALMOLOGY
515 Audubon Bldg., 931 Canal St.
New Orleans, Louisiana 70112

**For speedier performance in screen tests:**

# BERENS PRISM BARS

**(horizontal and vertical)**

Horizontal bar measures heterophoria or heterotropia in prism diopters. Vertical bar measures hyperphoria. Both bars useful in orthoptic training. Furnished individually or by the pair in leather containers. At all optical and surgical suppliers.

# R. O. GULDEN

**225 CADWALADER AVENUE, ELKINS PARK, PA. 19117**

## INDIRECT OPHTHALMOSCOPY OF THE PERIPHERAL RETINA

Purpose: To teach this new technique—the normal anatomy of the peripheral retina to residents and ophthalmologists.

Contents: Demonstrates and discusses normal anatomy of the equatorial and oral region of the retina as viewed during indirect ophthalmoscopy and scleral indentation. All normal anatomy and variations are discussed, and presented in views of post mortem eyes and shown in scenes taken with the Stenstrom cine. This technique demonstrates the actual views of the fundus as seen during clinical examinations.

Running Time: 41 minutes—16 mm sound

Cost: Rental $25.00 per week
Purchase price $300.00

For information contact: Retinal Service

Iowa City, Iowa 52240

## THE UNIVERSITY OF TEXAS MEDICAL SCHOOL AT HOUSTON BASIC SCIENCE COURSE IN OPHTHALMOLOGY

**January 3 through February 25, 1972**

**Texas Medical Center, Houston, Texas**

This course consists of 270 hours of lectures and demonstrations by an experienced faculty of forty ophthalmologists and basic scientists. It is directed toward the requirements of residents and prospective residents in ophthalmology.

The curriculum includes:

| | |
|---|---|
| Anatomy | Pharmacology |
| Physiology | Optics |
| Pathology | Refraction |
| Biochemistry | Glaucoma |
| Neuro-ophthalmology | Motility |
| Embryology and Genetics | Visual Fields |
| Microbiology | External Disease |
| Medical Ophthalmology | Surgery |

Tuition is $600.00. For further information and application forms please write to Whitney G. Sampson, M.D., Coordinator of Basic Science Programs, Department of Ophthalmology, The University of Texas Medical School, 530 West 20th Street, Houston, Texas 77008.

**As a contact lens fitter, you're getting better all the time.**

**But how about the solutions, cleaners and cases you recommend?**

*In just three years, every new concept in contact lens care has come from just one source– Flow Pharmaceuticals.*

the *first* hypertonic wetting solution. hy-FLOW® . . . refreshing and hygienic, with a unique emolliency and a tonicity more natural to precorneal film.[1,2]

the *first* combination cleaning and storage solution. duo-FLOW®. . . the original such solution for germicidal hydration, easy and effective two-in-one action.

the *first* combination cleaning and storage kit– porta-FLOW®. . . absolute cleaning and germicidal hydration in one simple leakproof, breakproof compact unit.

the *first* gel cleaner. d-FILM™ . . . the basic lens cleaner that erases patient confusion and eliminates the danger of irritating or damaging elements being instilled into the eyes inadvertently.

*Flow Care–to compliment your proficiency.*

The Bascom Palmer Eye Institute
Department of Ophthalmology of the
University of Miami School of Medicine
and the Florida Lions Eye Bank at Miami
Announces a Symposium on

# OPHTHALMIC PLASTIC AND CORNEAL SURGERY

To be held at the Diplomat Hotel,
Miami Beach (Hollywood), Florida

March 26-31, 1972

Faculty for the course will include:

| | |
|---|---|
| Dr. Crowell Beard | Dr. J. H. King |
| Dr. Jorge Buxton | Dr. James Major |
| Dr. Ramon Castroviejo | Dr. A. E. Maumenee |
| Dr. Claes Dohlman | Dr. Gordon Miller |
| Dr. Max Fine | Dr. Edward W. D. Norton |
| Dr. Richard Forster | Dr. Frank Polack |
| Dr. J. Donald M. Gass | Dr. Marvin Quickert |
| Dr. Russell Harner | Dr. Norman Sanders |
| Dr. Danny Jones | Dr. Byron Smith |
| Dr. A. Dalma Kende | Dr. David Soll |

Dr. Richard Tenzel

This symposium will cover the corneal and ophthalmic plastic field. Multiple lectures will be given with ample time for panel discussion and questions from the registrants.

Afternoons will be set aside for recreation including tennis and golf tournaments. There will be planned entertainment for most evenings.

Tuition will be $175, breakfasts included. Special rate of $75 available for residents upon application from their Department Head. Checks should be made payable to "Bascom Palmer Eye Institute" and mailed to Ophthalmic Plastic and Corneal Surgery Symposium, Bascom Palmer Eye Institute, P.O. Box 875, Biscayne Annex, Miami, Florida 33152.

# Apollo Space Flight Veteran: Methulose, for dry eyes!

Methulose artificial tears lubricate sensitive ocular tissues to provide comfortable, soothing relief from eye dryness and irritation without blurring vision. Little wonder it is a big item on Apollo flights where dry eyes could present serious problems.

Meanwhile, back on earth, Methulose might be the simple solution to the dry-eye problems of many of your patients. A non-irritating buffered aqueous solution containing Methylcellulose U.S.P. preserved with Benzalkonium Chloride 1:25,000, it is available in 15cc and 30cc direct application plastic containers. Write for a generous supply of 5cc starter samples.

## There's no biting sting with "comfort strength" Epifrin ½%, 1%

Epifrin® (l-epinephrine) has long offered the most economical, convenient l-epinephrine available to glaucoma patients. Now, with "comfort strength" Epifrin ½% and 1%, the biting sting is gone too! Evaluate our "comfort strengths" with your glaucoma patients. Have them compare the comfort of EPIFRIN ½% with any other l-epinephrine. You'll find there is no significant difference in patient acceptance. There is growing documentation of the efficacy of these lower concentrations. (1, 2) Lower concentrations also mean reduced side effects and no blurring or impaired vision. Now the economy and convenience of "comfort strength" Epifrin® ½% and 1% make a lot more sense.

References: 1. Kronfeld, P.C.: Invest. Ophth. 3258 (June) 1964. 2. Harris, L. S.; Galin, M.A.; and Lerner, R.: Annals of Oph. 219 (June) 1970. **Prescribing Information:** Contains: levo-epinephrine (as the HCl)...2%, 1%, ½%. with: benzalkonium chloride, sodium metabisulfite, disodium edetate, and purified water. **Indications:** Chronic simple glaucoma. **Contraindications:** Should not be used in patients who have had an attack of narrow angle glaucoma since dilation of the pupil may trigger an acute attack. **Warnings:** Undesirable side reactions may include: eye pain or ache, browache, headache, conjunctival hyperemia, and allergic lid reactions. Adrenachrome deposits in the conjunctiva and cornea after prolonged epinephrine therapy have been reported. Epinephrine has been reported to produce macular edema in some aphakic patients. **Precautions:** Should be used with caution in patients with a narrow angle since dilation of the pupil may trigger an acute attack of glaucoma. **Dosage:** The usual dosage is one drop in the affected eye(s) once or twice daily. However, the dosage should be adjusted to meet the needs of the individual patient. **Note:** Protect from excessive light and heat. If the solution discolors or a precipitate forms it should be discarded. **How Supplied:** 0.5% and 1.0% strengths in 15 cc plastic dropper bottles. 2% in 5 cc and 15 cc plastic dropper bottles. On prescription only.

**Epifrin** (l-epinephrine)

DESCRIPTION: Sterile solution containing: *Active:* Pilocarpine Hydrochloride 0.25%, 0.5%, 1%, 2%, 3%, 4%, 5%, 6%, 8% or 10%; Vehicle: Hydroxypropyl Methylcelulose 0.5%; Preservative: Benzalkonium 0.01% (0.004%, and Phenylmercuric Nitrate 0.00133% in 0.25% and 0.5% strengths); *Inactive:* Boric acid, Sodium Chloride (in 1% only), Sodium Citrate, Citric Acid (in 0.25% and 0.5% only) to adjust pH, Purified Water.
CONTRAINDICATION: When constriction is undesirable such as in acute iritis.
WARNING: Rare systemic reactions.
PRECAUTION: Avoid overdose.
ADVERSE REACTIONS: Slight ciliary spasm with temporary reduction in visual acuity. Sensitivity is infrequently observed. Contact allergy may occur with prolonged use.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

XONIX

# the xonix porta-pak

***For: Indirect Ophthalmoscopy, gonioscopy and portable refractions***

The XONIX PORTA-PAK is another new* product from XONIX especially designed for the ophthalmologist. It is primarily to be used with the XONIX BINOCULAR INDIRECT OPHTHALMOSCOPE, or, other indirect ophthalmoscopes.

The XONIX PORTA-PAK allows the ophthalmologist to move about freely and make hospital rounds without the inconvenience of carrying a bulky transformer and searching for an electrical outlet.

The XONIX PORTA-PAK is excellent as a teaching aid for indirect ophthalmoscopy — hospitals, schools, courses.

The XONIX PORTA-PAK is well suited for sales representatives to demonstrate indirect ophthalmoscopes or gonioscopes.

*The XONIX PORTA-PAK was first introduced at the AAOO National Meeting in Las Vegas, October, 1970.

## *FEATURES:*

Portable power supply

1½ hours of continuous power at maximum light intensity*

Rechargeable nickel cadmium batteries (overnight recharging)

2 years of service under normal use**

Lightweight and comfortably worn for extended periods

Worn in pocket, or, worn with comfortable shoulder strap

Rugged aluminum construction assures long life

Variable light intensity with "off" position

Fused for extra safety

Standard twist-lock plug accommodates the *XONIX* and MIRA Indirect Ophthalmoscope; *and* can be adapted to fit the AO and Keeler Ophthalmoscopes.

*Operation at other than maximum intensity will extend the 1½ hours considerably. The batteries have a capacity of 4.0 ampere-hours.

**If the battery is discharged and charged every working day, the batteries should give satisfactory service for at least 2 years.

*For additional information, call or write:*

## GENERAL

Address manuscripts and other scientific communications to Frank W. Newell, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Manuscripts must be original material submitted solely to the AMERICAN JOURNAL OF OPHTHALMOLOGY. Two original typed copies must be submitted. The entire manuscript, including case reports, footnotes and references, must be typed in double space, with wide margins, on 8½ by 11-inch heavy white bond paper. See Suggestions to Authors (Am. J. Ophth. 70: Advertising pages 85–88, December, 1970). Receipt of manuscript is acknowledged immediately.

Author's proofs must be corrected and returned within 48 hours to Manuscript Editor, 160 East Grand Avenue, Chicago, Illinois 60611.

Fifty reprints of each article will be supplied to the senior author without charge. Additional reprints may be obtained from Ophthalmic Publishing Company, 160 East Grand Avenue, Chicago, Illinois 60611, if ordered at the time proofs are returned.

Address news items and society proceedings to Thomas Chalkley, M.D., 700 North Michigan Avenue, Chicago, Illinois 60611.

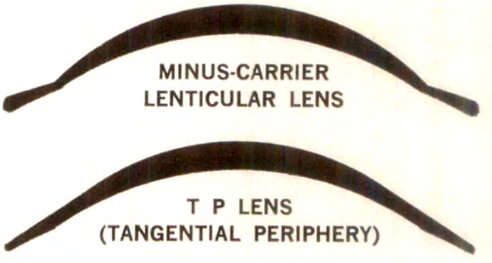
Exchange copies of medical journals should be sent to David Shoch, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Subscriptions, requests for single issues, notices of changes of addresses, advertising and other communications should be sent to 160 East Grand Avenue, Chicago, Illinois 60611.

Change of address notices must be received at least 60 days in advance and must include both old and new addresses.

Claims for copies lost in the mail must be received within 60 days from the date of issue.

Advertisement insertion orders and copy must be received before the first day of the preceding month for which the advertisement is scheduled.



# CONTACT LENSES AND THE APHAKIC PATIENT

## Part 3: Round, Centered Pupils

The aphakic patient with a round, centered pupil can often be fitted with either a MINUS-CARRIER LENTICULAR LENS or a TP (TANGENTIAL PERIPHERY) LENS. The following factors should be considered:

(1) UPPER LID TENSION: The TP LENS eliminates the major disadvantage of the LENTICULAR LENS, namely the "lid bump" which occurs at the sharp juncture between the central and carrier front surface curves. The TP LENS, whose front surface has a cone-shaped carrier section tangent to the central lens curve, has *no physical juncture whatsoever;* thus, "lid bump" is prevented and there is greater lens stability (less lens motion) due to minimizing of the effects of the upper lid on the lens. These advantages may be minor for the usual soft-lidded aphakic patient, but they are quite important for the patient with tight upper lids, in preventing lid irritation and excessive lens movement.

(2) LENS POSITIONING: When there is sufficient upper lid cover to grab the lens and pull it up, it will be found that the TP LENS centers better than the LENTICULAR LENS. This is due to the fact that the upward vector component of the upper lid pull is considerably less on the tangential-carrier of the TP LENS than on the minus-carrier of the LENTICULAR LENS. Thus, the TP LENS is not as readily pulled into an "above-center" position as is the LENTICULAR LENS.

(3) LOWER LID POSITION: When there is a lower lid, it is often desirable for the lens to position up somewhat, so that it will not ride low and irritate the lower limbus. In such a case, the MINUS-CARRIER LENTICULAR LENS should be used to try to achieve this positioning.

(4) LENS SIZE: Prescribing lenses of minimum weight becomes increasingly important as lens diameters are reduced. MINUS-CARRIER LENTICULAR LENSES can be made even thinner than TP LENSES, and much thinner than SINGLE-CUT LENSES, by using anterior optical zones of about 7.0 mm. Therefore, if the patient does not have a tight upper lid, and a lens of less than 9.0 mm diameter is desired, the MINUS-CARRIER LENTICULAR LENS should be prescribed.

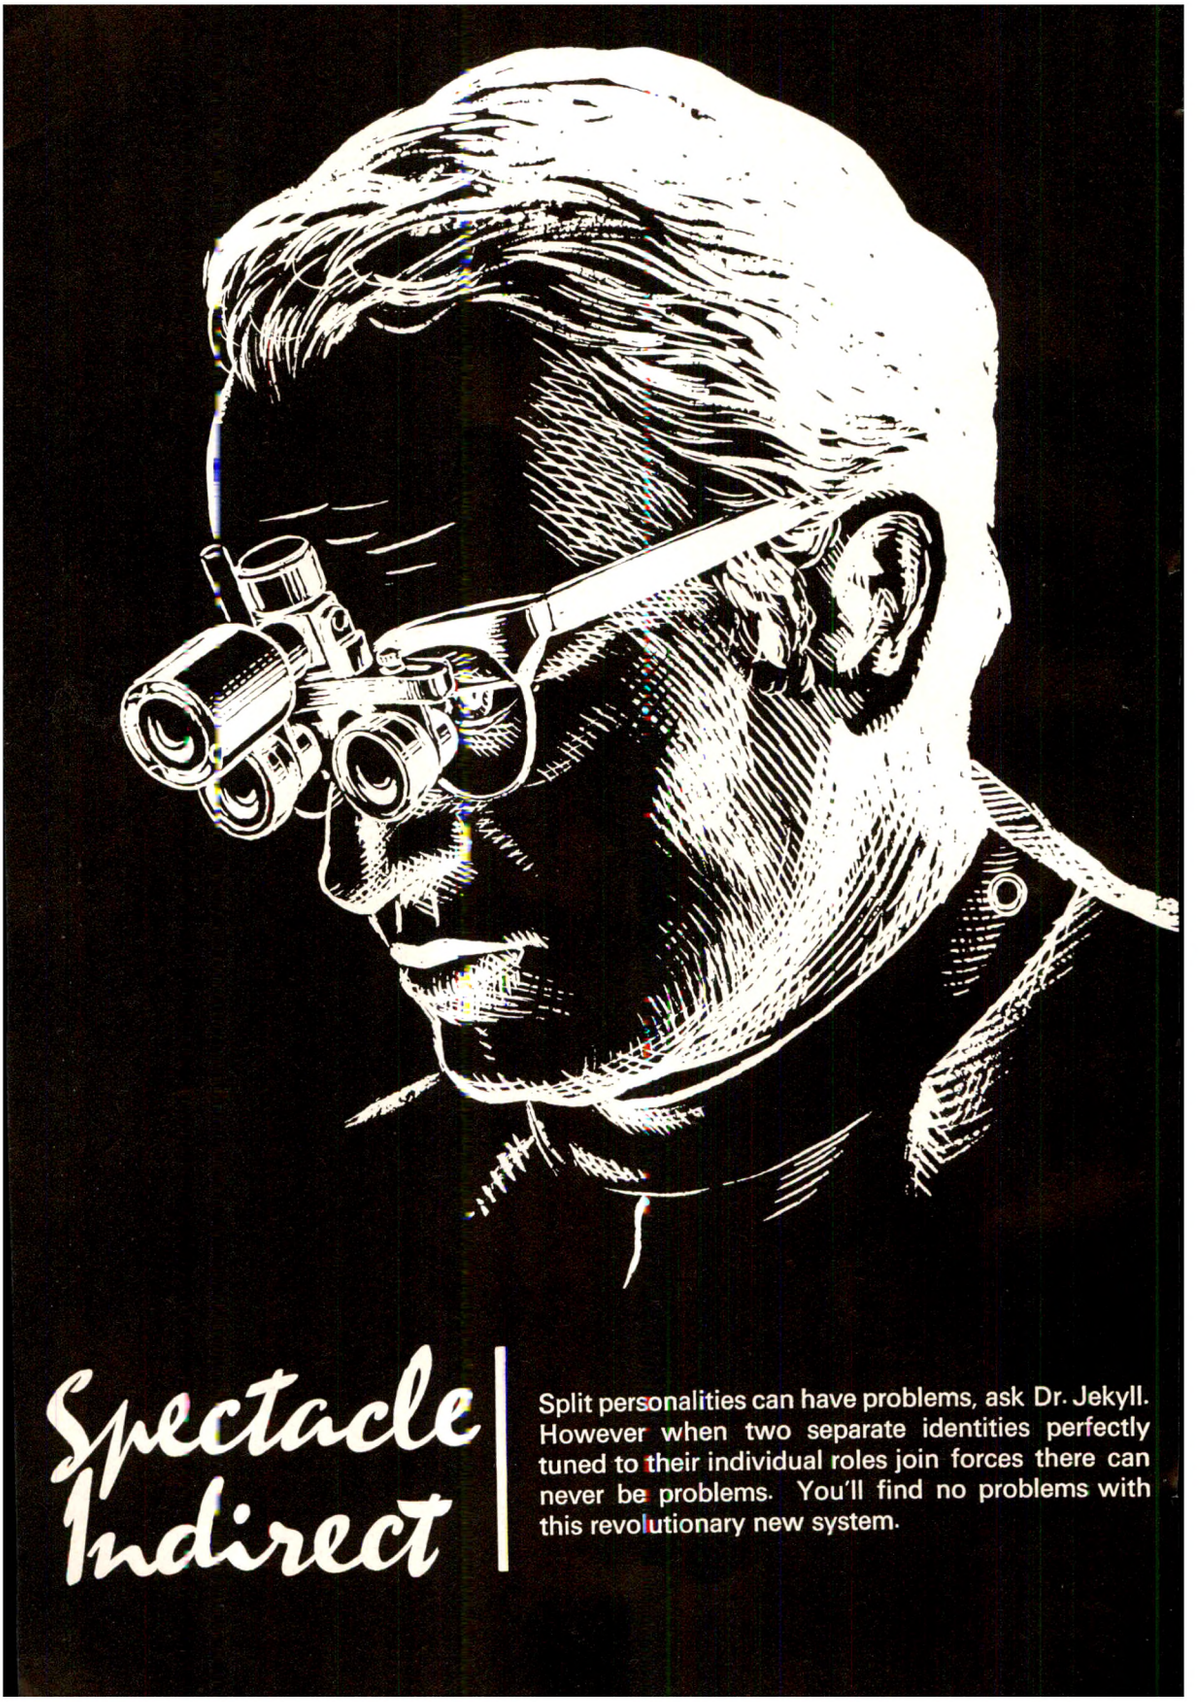
## Behind the smile . . . a new lease on life.

Temps* glasses help post cataract recovery with their cosmetically attractive shape, their lightness, and their protectiveness. Clear or tinted, the excellent optics are the thinnest, least distorting of the temporaries – perfectly adequate for spares later on. Available in wide or narrow P.D. (63 to 68mm, 57 to 62mm), bifocal or single vision.



- We invite you to try six pairs of Temps glasses, or six Day-Nite Paks (clear and tinted pairs together, economically priced). Included with each is a carrying case and a helpful booklet for your patient, "I Can See Again," by Paul Tisher, M.D. We're sure you will be impressed by Temps glasses, a full return refund if you're not. Mentor Division, Codman & Shurtleff, Inc., Randolph, Mass. 02368.

Spectacle Indirect
Split personalities can have problems, ask Dr. Jekyll. However when two separate identities perfectly tuned to their individual roles join forces there can never be problems. You'll find no problems with this revolutionary new system.

The light, bright, stereo-vision Spectacle Indirect Ophthalmoscope (that's fitted so easily) converts in seconds to a spectacle magnifier, with a removable light source and flip-up loupes.

Split personality or marriage of the year? Either way you win with the Spectacle Indirect.

**KEELER**
456 Parkway, Broomall, PA 19008

Nancy's classmates won't call her names now...

## and her accommodative esotropia no longer affects her grades

Over two years ago, Nancy showed an esophoria of 6 Δ at distance and an intermittent esotropia of 15 Δ at near, with imperfect fusion. She was put on PHOSPHOLINE IODIDE 0.125% O.U., at first once a day. This dosage regimen was reduced gradually to once a week. Orthoptic measures were employed to increase binocular control. Nancy now has an esophoria of 12 Δ at near, no tropia, and excellent stereopsis. Fusion is still variable for near. Vision is 20/20 in each eye. She no longer requires eyedrops.*

## for diagnosis

One drop of PHOSPHOLINE IODIDE 0.125% instilled in both eyes for two or three weeks can help determine if there is an accommodative basis for the esotropia.

## in treatment

If there is a significant accommodative factor present, the continued use of PHOSPHOLINE IODIDE alone is often sufficient for treatment.

If surgery is necessary, postoperative use of PHOSPHOLINE IODIDE may help correct a residual deviation.

*Case history courtesy of Orthoptic Clinic, Department of Ophthalmology, N.Y.U. Medical Center, N.Y. School of Medicine, New York, N.Y. Other children are professional models.

**BRIEF SUMMARY**
**(For full prescribing information, see package circular.)**

**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, browache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local):* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have also been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic):* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

# Phospholine Iodide®

## (echothiophate iodide for ophthalmic solution)

# Introducing
# SWIRL CLEAN™
## electric contact lens cleaner by Contique™

## the professional way to clean contact lenses

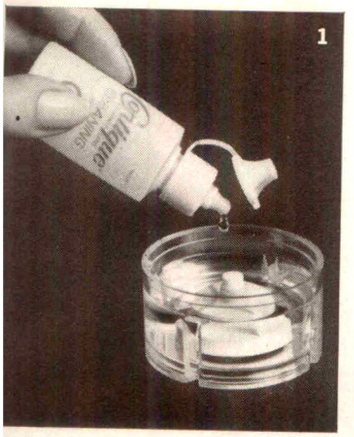
Until now, the most common method cleaning contact lenses has been to rub the between the fingers. As you know, this syste has three serious drawbacks: 1) it doesn't clea properly; 2) it *can* scratch or warp lenses; 3) may not be sanitary.

### A new, more efficient technique

The new Swirl Clean electric contact le cleaner by Contique approaches the problem a totally different manner: It combines th cleaning power of a high-speed agitator wi the detergent action of Contique Cleaning Sol tion. The result is thorough but gentle clea ing—with a minimum of handling and le chance of lens loss.

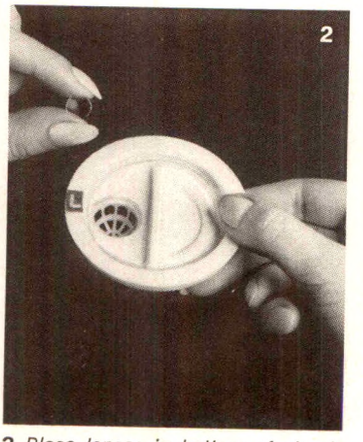
Swirl Clean doesn't stop there. It provid a convenient place to soak and store lenses b tween wearings.

### Perfect for office use



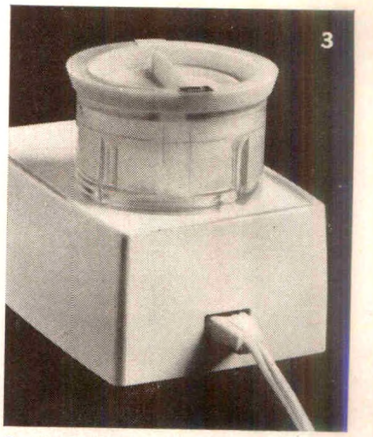
How many times have you wished for ju such an efficient way to clean your patien contacts—when you are delivering a new pa or after making an adjustment?

Swirl Clean fills this long-felt need pe fectly. It's compact. Easy to use. And it *loo* highly professional. Your patients can s you've gone to the expense of securing the mo advanced cleaning device available to mal sure their lenses are clean and comfortable.



And it takes only a few seconds to clea contacts with the Swirl Clean. Once you get in the habit, you'll wonder how you managed wit out it.

### Your patients will want one, too



When they see how effortlessly you clea their contacts with the Swirl Clean, your ne contact lens wearers will want one of their ow to use at home. That's why it makes good bus ness sense to stock a few units to sell or recor mend to your patients. They'll never be mo psychologically receptive than at the mome

1 *Fill cleaning chamber ¾ full with cold water. Add 6-8 drops of Contique Cleaning Solution and place on base.*

2 *Place lenses in bottom of clearly marked LEFT and RIGHT baskets of lens holder. Close lid. Place lens holder on cleaning chamber.*

3 *Flip "ON" switch and run Swirl Clean 30-60 seconds. You can see the lenses being swirled clean before your eyes.*

hey get their new contacts. It's also a good way of starting them off on a proper lens-care regimen and helping them become satisfied wearers.

### Read what Swirl Clean users say

An O.D. in Knoxville, Tenn. writes: "The compactness of this unit makes its use a pleasure in my office." An M.D. in Bakersfield, Calif. calls Swirl Clean "a very valuable asset to our office." An optician in Long Beach, Calif.: "Excellent method of cleaning lenses after lab adjustment."

Enthusiastic comments have also come in from contact lens wearers all over the country. "My vision is so much better with clean contacts." (Boston, Pa.) "I enjoy its convenience and notice my lenses are more comfortable." (East Point, Ga.) "Cleans lenses 100% better than by hand." (Hyde Park, Mass.) "I wear lenses 16 hours a day and find their comfort greatly increased." (Indianapolis, Ind.)

These comments are on file at Alcon Laboratories and may be examined by anyone interested.

### Complete lens care by Contique

Used with the new Swirl Clean, *Contique Cleaning Solution* dissolves eye-irritating deposits such as mucus, oil and film. Yet it's so gentle you can recommend it with complete confidence. *Contique Soaking Solution* "conditions" lenses by keeping them chemically moist when stored in the special Swirl Clean soaking dish, increasing wettability and wearing comfort. *Contique Wetting Solution* creates a liquid cushion between lens and eyes, makes placement smooth and easy, and can also be used to re-wet lenses during the day.

This family of lens care products from Contique can help your patients become successful, satisfied contact lens wearers. Almost $6 worth of Contique solutions are packed with every Swirl Clean at no additional cost. For more information about the new Swirl Clean and other Contique products, call your optical wholesaler today.

OPTICAL PRODUCTS DIVISION, ALCON LABORATORIES, INC., P.O. BOX 1959, FORT WORTH, TEXAS 76101

**Indications:** Relief and management of nonpurulent Blepharitis and Conjunctivitis.

**Dosage:** Initially, 1 or 2 drops placed in the conjunctival sac every hour until improvement occurs.

Thereafter, 1 or 2 drops 2 to 4 times daily.

**Composition:**

Prednisolone-21-phosphate sodium .....0.25%
(Equivalent to Prednisolone 0.2%)
Sulfacetamide sodium ....10.0%
Phenylephrine HCl .....0.125%
Methylparaben .....0.02%
Propylparaben .....0.005%

In a stabilized aqueous solution containing sodium thiosulfate and *SMP-68 (a combination of polyoxypropylene compound and polysorbate 80).

**Effectiveness:** The antibacterial spectrum of Vasocidin is particularly effective against the gram positive pyogenic cocci; E. coli, N. gonorrhoeae, Koch-Weeks bacillus and other bacteria susceptible to sulfacetamide. Because Vasocidin is a true solution, dosage is uniform and each drop is free of any irritating particles. The Vasocidin vehicle enhances the dispersion of active components. Sulfacetamide combats a wide range of pathogens; prednisolone reduces inflammatory reaction; phenylephrine relieves hyperemia. Local effects of active therapeutic agents appear to be prolonged by phenylephrine-induced vasoconstriction.

**Caution:** Federal law prohibits dispensing without prescription.

**Contraindications:** Steroids are contraindicated in dendritic ulcers (herpes simplex), vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, as well as in fungal and tubercular ocular disease. Contraindicated in the treatment of purulent conjunctivitis or blepharitis. Should not be used by persons with narrow-angle glaucoma or those sensitive to sulfonamides. If irritation persists or increases, discontinue use and consult physician.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.

Vasocidin is sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area with the dropper tip of bottle. Keep container tightly closed.

**Supplied:** Plastic dropper-tipped vials, 5 cc.

**Smith, Miller & Patch, Inc.**
401 Joyce Kilmer Avenue
New Brunswick. N.J. 08902

It's a lousy feeling
to wake up in the morning
with your eyelids
stuck together.

No medication residue with Vasocidin.
Nothing to wash away in the morning.
It's an antibacterial, steroid, decongestant combination in true solution.
Works fast because it disperses fast.
Helps relieve nonpurulent blepharitis and conjunctivitis more effectively.
Starts the day right.

# Vasocidin

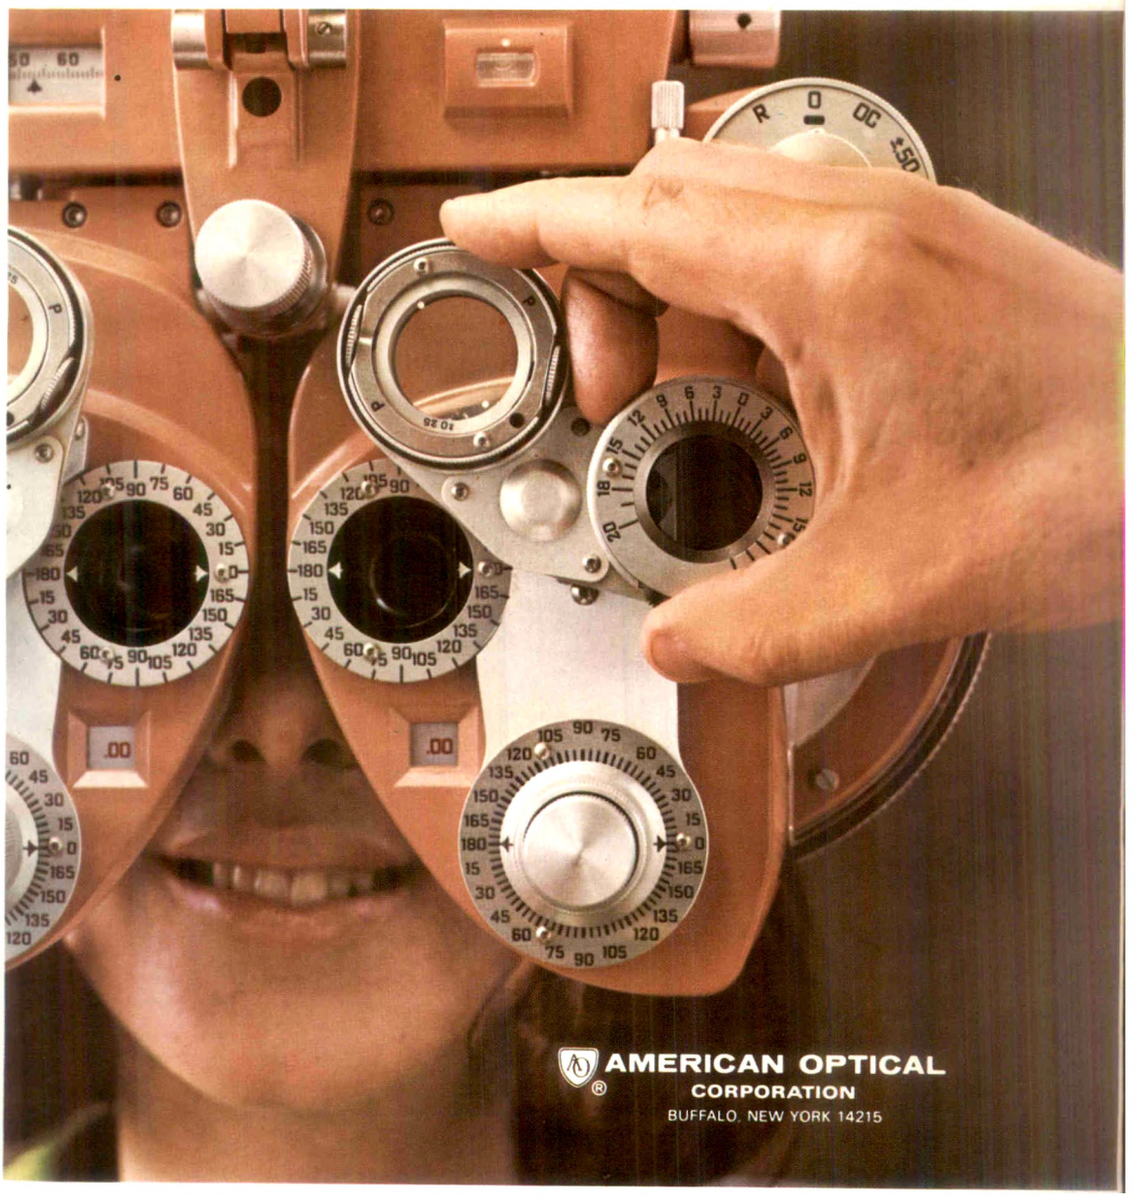
a clear solution that isn't sticky

# The crystal drop assures stability

As you may be aware, the first sign of deterioration in a product containing epinephrine is a color change . . . reddish-brown or "yellowing." Each clear drop of PE* Ophthalmics is its own proof of stability . . . as also evidenced in clinical studies involving unrefrigerated shelf life, temperature changes and exposed-to-air studies simulating patient use. Proven shelf life, over 3 years (for maximum assurance, vials are date-coded on a 2 year basis). No change in clarity or potency was evidenced in any tests. The crystal clarity of every drop assures your patient full therapeutic effect, first drop to last.

PE* Ophthalmics provide simple *one-solution* treatment of open angle glaucoma . . . eliminating patient error, assuring the physician exact evaluation of therapy. Available in 5* strengths, in 15cc color-coded vials, nationwide and in Canada.

*Pilocarpine Hydrochloride 1%, 2%, 3%, 4%, 6% with Epinephrine Bitartrate 1% (½% Epinephrine Base).



**Contraindication:** Narrow angle glaucoma. **Precautions:** Use with caution in unverified glaucoma and hypertension. If irritation or sensitization occurs, discontinuance may be necessary.

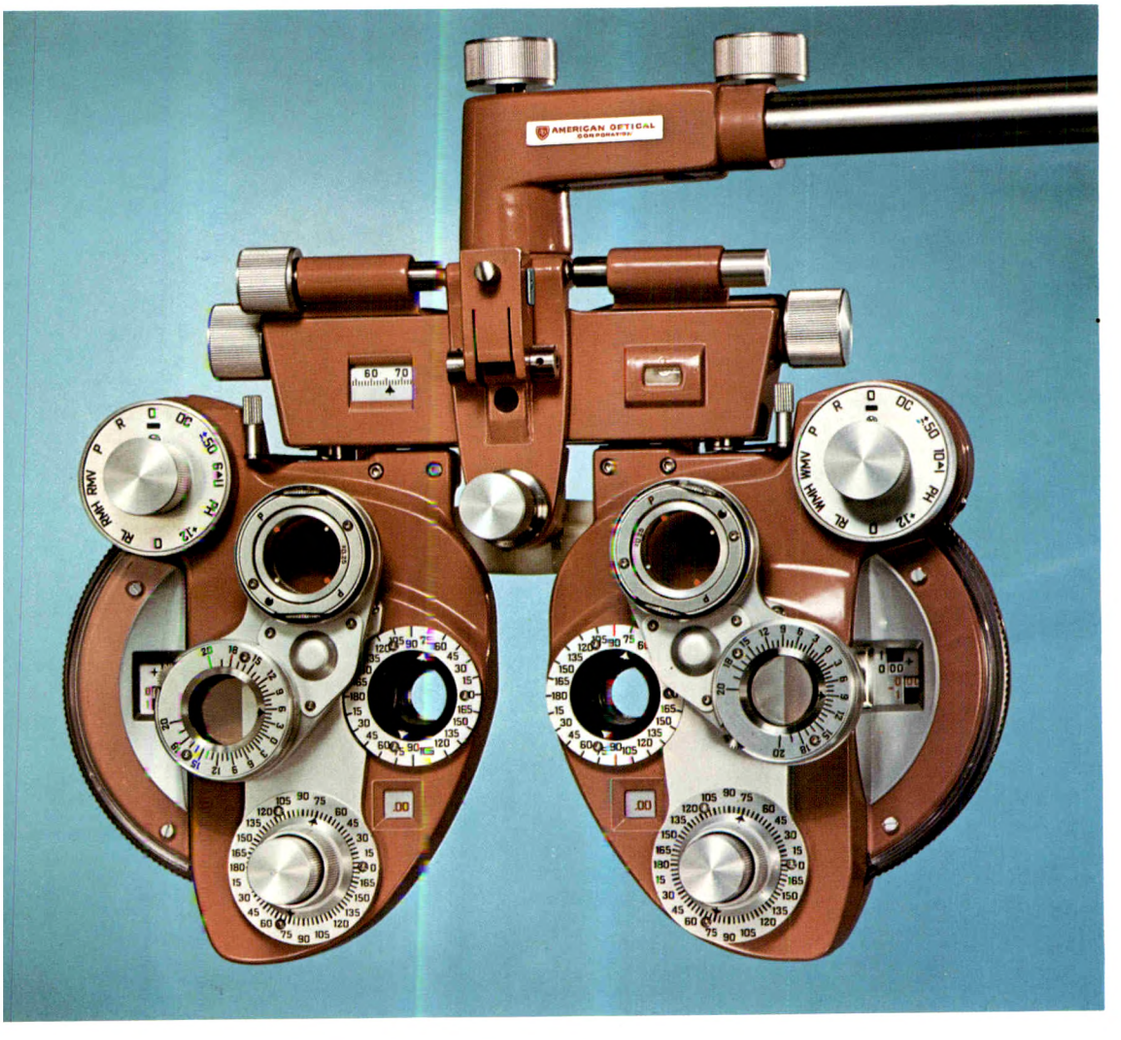
GLENDALE, CALIF. 91

# With the AO Ultramatic Phoroptor you take one reading, once, with one scale.

With the AO Ultramatic Phoroptor, you save time and simplify refracting technique every time you turn the dial. The secret: synchronization. The Cross Cylinder Loupe is synchronized so that it rotates automatically to a corresponding axis—every time you change the correcting cylinder axis. This feature alone eliminates numerous cross cylinder axis settings, saves valuable time. And when the axis check test is completed you make only one reading, once. The AO Ultramatic Phoroptor makes refraction easier for you—through synchronization.

*Turn the page for more.*

# A converging lens system is also exclusive with the AO Ultramatic Phoroptor.



One of the major features of the Ultramatic Phoroptor is its exclusive Ful-Vue convergence lens system, for precision measurement in near as well as distance testing. This Ful-Vue convergence is easy to operate and provides the ideal near-test conditions for your patients. The patient looks through the optical centers of the instrument lenses, insuring overlapping fields and the widest field of view. In addition, ten most-used auxiliary lenses (plus 2 open apertures) in each side offer an unmatched choice to facilitate comprehensive testing in the shortest time.

High-contrast scales are another time-saving convenience. Large and easy to read, they're legible even in soft illumination.

Ask your AO Representative for more information about the AO Ultramatic Phoroptor.

# When epinephrine is indicated for the management of chronic simple (open-angle) glaucoma

# Ayerst Epitrate® BRAND OF epinephrine bitartrate

BRIEF SUMMARY

*(For full prescribing information, see package circular.)*

**Epitrate®** (epinephrine bitartrate)

***For management of chronic simple (open-angle) glaucoma***

**Description:** A sterile aqueous solution of levorotatory epinephrine bitartrate 2% (equivalent to 1.1% base), it is stable, retains its potency throughout use, and requires no refrigeration. It has a low surface tension.

**Action:** Intraocular pressure is lowered by reducing the rate of aqueous formation. Improvement in outflow facility is also observed in certain cases following prolonged therapy.

**Indications:** Useful in management of chronic simple (open-angle) glaucoma, either alone or in combination with miotics. In selected cases, it may also be used with carbonic anhydrase inhibitors.

**Contraindications:** Prior to peripheral iridectomy, an epinephrine preparation is contraindicated in eyes that are capable of angle closure since its relatively weak mydriatic action may, nevertheless, precipitate angle block. Gonioscopy should be carried out on all patients before initiating therapy.

**Warnings:** Topical use of epinephrine in any form should be interrupted prior to general anesthesia with certain anesthetics such as cyclopropane or halothane which sensitize the myocardium to sympathomimetics.

**Precautions:** EPITRATE (epinephrine bitartrate) should be used with caution in the presence of hypertension, diabetes, hyperthyroidism, heart disease, and cerebral arteriosclerosis because of the possibility of systemic action.

**Adverse Reactions:** As with other epinephrine solutions, transitory stinging on initial instillation may be expected. Headache or browache frequently occur on beginning EPITRATE therapy, but usually diminish as treatment is continued. Conjunctival allergy occurs occasionally. Pigmentary deposits in the lids, conjunctiva or cornea may occur after prolonged use of epinephrine eyedrops. In rare cases, maculopathy with a central scotoma may result from the use of topical epinephrine in aphakic patients; prompt reversal generally follows discontinuance of the drug. Systemic effects have occasionally been reported, such as: palpitation, tachycardia, extrasystoles, hypertension, trembling, sweating, and pallor.

**Dosage and Administration:** 1 drop, with frequency of instillation being individualized, from every two or three days to twice daily. More frequent instillation than one drop four times daily does not usually elicit any further improvement in therapeutic response.

**How Supplied:** No. 1015—EPITRATE—ophthalmic solution of epinephrine bitartrate 2% (equivalent to 1.1% base). [Also contains chlorobutanol (chloral derivative) 0.5%, methylaminoaceto pyrocatechol HCl, sodium bisulfite, sodium chloride, polyoxypropylene-polyoxyethylene-diol, and disodium edetate.] Package containing 7.5 cc. bottle with separate dropper-screw cap attachment.

## BRITISH JOURNAL OF OPHTHALMOLOGY

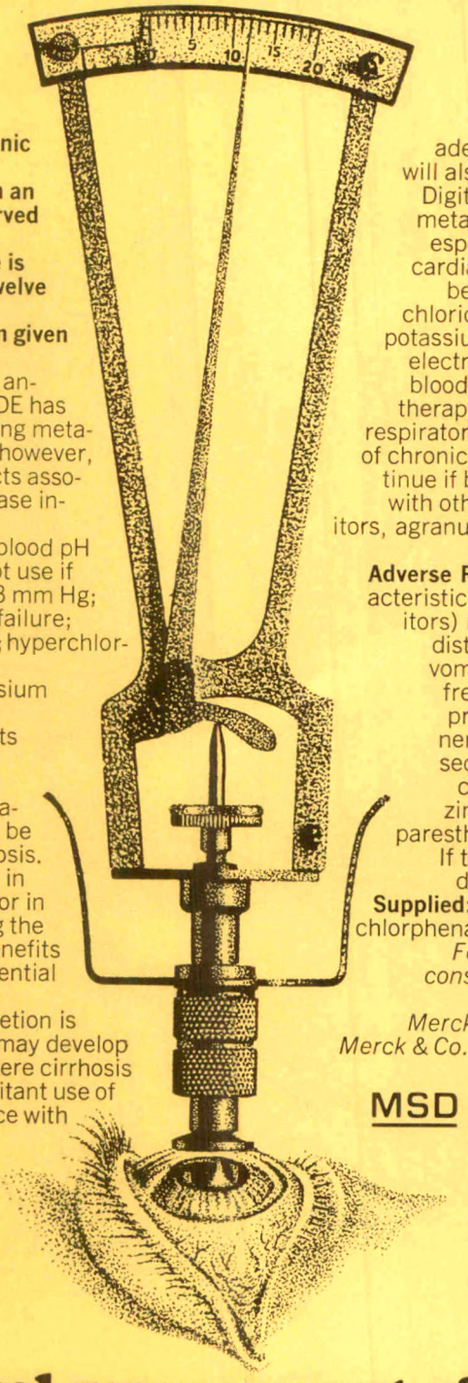
This Journal publishes original articles on every aspect of the ophthalmological sciences by practising ophthalmologists and research workers all over the world. While welcoming reports on experimental work, the editors nevertheless pay special attention to the practical problems of eye disorders and their treatment, to give as much help as possible to ophthalmic surgeons and all concerned with clinical ophthalmology. All articles are in English and carry summaries wherever appropriate.
Book reviews, shorter notes, and correspondence also appear at frequent intervals.

*Published Monthly* *Annual Subscription $26.50*

## OPHTHALMIC LITERATURE

OPHTHALMIC LITERATURE is the key to virtually all published information on ophthalmology. Each issue consists of carefully prepared, informative abstracts in English of relevant articles in medical and scientific journals throughout the world; each abstract is classified under one of forty specific headings, with cross references where necessary. Summaries of new books and new editions on the subject are included under the appropriate headings. An author index is also included in each issue.

In its comprehensiveness OPHTHALMIC LITERATURE is unique among abstracting journals in the world.



*Six issues a year, plus index* *Annual Subscription $26.50*

*These two world famous ophthalmic journals can be ordered at the special combined subscription rate of: $45.50*

**Subscriptions in the United States can be ordered through the BRITISH MEDICAL JOURNAL, 80 Brighton Avenue, Boston, Mass., 02134.** Subscriptions for all other countries should be ordered direct from the Subscription Manager.

**BRITISH MEDICAL JOURNAL, B.M.A. House, Tavistock Square, London, WCIH 9JR, England**
***or through any leading subscription agent or bookseller***

# the measure of success...

- **orally effective, potent carbonic anhydrase inhibitor**
- **onset of action usually within an hour; maximal effect is observed in two to four hours**
- **lowered intraocular pressure is often maintained for six to twelve hours**
- **usually most successful when given in conjunction with miotics**

Compared to other carbonic anhydrase inhibitors, DARANIDE has a lesser propensity for causing metabolic acidosis. Please note, however, that this and other side effects associated with carbonic anhydrase inhibitors may occur.

**Contraindications:** To avoid blood pH decreases below 7.20, do not use if arterial $pCO_2$ greater than 63 mm Hg; hepatic insufficiency; renal failure; adrenocortical insufficiency; hyperchloremic acidosis; conditions in which sodium and/or potassium serum levels are depressed. Should not be used in patients with severe pulmonary obstruction who are unable to increase their alveolar ventilation since their acidosis may be increased to the point of narcosis.

**Warning:** Should not be used in women of child-bearing age or in pregnancy, especially during the first trimester, unless the benefits to be expected outweigh potential adverse effects.

**Precautions:** Potassium excretion is increased and hypokalemia may develop with brisk diuresis, when severe cirrhosis is present, or during concomitant use of steroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Hypokalemia may be treated by use of potassium chloride or giving foods with a high potassium content. A close check on electrolyte balance, blood pH, and blood gases should be kept during therapy. Use with caution in severe respiratory acidosis or in the presence of chronic pulmonary infection; discontinue if blood pH falls below 7.20. As with other carbonic anhydrase inhibitors, agranulocytosis, thrombocytopenia, or renal calculi are possible.

**Adverse Reactions:** Side effects (characteristic of carbonic anhydrase inhibitors) may include gastrointestinal disturbances (anorexia, nausea, vomiting), constipation, urinary frequency, mild skin eruptions, pruritus, headache, weakness, nervousness, globus hystericus, sedation, lassitude, depression, confusion, disorientation, dizziness, ataxia, tremor, tinnitus, paresthesias of hands, feet, tongue. If they occur, reduce dosage or discontinue drug temporarily.

**Supplied:** Tablets containing 50 mg dichlorphenamide each, in bottles of 100.

*For more detailed information, consult your MSD representative or see the Direction Circular.*

# In Your O.R.... have the added protection and convenience of Dropperettes®

Both contents and container are sterile inside and out—virtually no chance of contamination from the dispensing unit itself. ☐ You'll find the DROPPERETTE easy to handle... with an extended spout and accurate drop control. ☐ Less chance for drug mix-ups in your O.R.: each DROPPERETTE is boldly marked with drug name and strength... color coded caps for extra assurance. ☐ Realistic quantity of medication for your O.R.

Order a supply of DROPPERETTES for use in your O.R.: nine frequently used ophthalmic formulations are available in this unique drug delivery system.

ARGYROL® S.S. 20% (1 cc.) / ATROPISOL® (1 cc.) (Atropine Sulfate) 0.5%, 1%, 2% / EPINEPHRINE 1:1000 (1 cc.) (as the hydrochloride) / FLUORESCEIN SODIUM 2% (1 cc.) HOMATROPINE HBr (1 cc.) 2%, 5% / PHENYLEPHRINE HCl 10% (1 cc.) / PILOMIOTIN® (1 cc.) (Pilocarpine HCl) 1%, 2%, 4% / SULFACETAMIDE SODIUM 10% (1 cc.) / TETRACAINE HCl 0.5% (1 cc.) /

NOW YOU CAN PERFORM OFFICE SURGERY, INDIRECT OPHTHALMOSCOPY AND GONIOSCOPY ON ONE EXAMINING TABLE BY ADDING MODULAR ACCESSORIES TO MEET YOUR OWN INDIVIDUAL NEEDS.

FROM DA-LAUR

# World's most Versatile Ophthalmic Examining Table

- Heavy anodized aluminum construction
- Tarnish resistant, lightweight, but extremely stable and durable.
- 4-inch rubber wheels roll freely with heaviest patients, yet lock securely when desired.
- Legs adjustable to compensate for uneven floors.
- 2" thick solid foam rubber mattress covered with durable, washable Ebony Black vinyl material. Other colors to order.
- Standard Dimensions: 34" high x 76" long x 24" wide. Other sizes made to order.

**OPTIONAL ADD-ON ACCESSORIES**

**A** Formica Roll Out Storage Compartment No. 110 interior lined with washable plastic laminate. 17½" wide, 9" deep, 22" long.

**B** Formica Instrument Shelf No. 120. Raises to level of patient's eye. Swings under table when not in use.

**C** Electric Transformer System No. 130. Exclusive Da-Laur smoothly variable voltage control system assures satisfactory examination. Has proper connections for your instruments. System has pilot light . . . . is fused and grounded.

**D** Universal Overhead Projection Fixation Light No. 140

**E** Steel Step Stool No. 170. Bright chrome finish. Non-skid rubber top and rubber-tipped feet.

# Hooves pound Dust flies Eyes weep

Back at the ranch, he'll need Vasocon-A. Long-acting vasoconstrictor-decongestant, antihistamine combination. Rides herd on burning, itching, watering eyes, even for the toughest cowpuncher.

Reduces conjunctival hyperemia in minor eye irritation and ocular allergies. Helps after contact lens insertion and removal. Vasocon-A. Keeps them on the trail.

CAUTION: Federal law prohibits dispensing without prescription. See package insert before prescribing.

COMPOSITION: Naphazoline HCl, 0.05%; antazoline phosphate, 0.5%; boric acid, 1.2%; sodium carbonate anhydrous; sodium chloride; phenylmercuric acetate (preservative) 0.002%.

SIDE EFFECTS: Except for transitory stinging, side effects have rarely been encountered.

CONTRAINDICATIONS: Should not be used by patients with narrow angle glaucoma. If irritation persists or increases, patient should be advised to discontinue use and return to physician.

SUPPLIED: 15 cc plastic dropper-tip vials.

## NO MORE ACCIDENTAL ADHESIONS!

ONCE YOU GRASP THE LENS, AT NO TIME DOES THE IRIS OR ANY OTHER TISSUE ADHERE TO THE PROBE, EVEN WHEN THERE IS DIRECT CONTACT!. THIS EXCEPTIONAL ADVANTAGE IS DUE TO ITS SPECIALLY DESIGNED TIP.

OTHER IMPORTANT ADVANTAGES:

- Thin tip (2.75 mm.) with special shape for better visibility.
- Light weight (11 g.) Just like your ball pen.
- Heat-resistant, so it can be autoclaved repeatedly.
- Durable, it can be used a great number of times.
- Rechargeable, uses gas *"FREON" 12; commercially available.
- Low price.

**ALCON introduces the EDT-103™—the first electronic digital tonograph and automated recorder. Only the EDT-103 provides accurate, simplified tonography for routine office use. And any member of your staff can be trained to use it in less than half an hour.**

**easy to read:**
direct digital display of tonometric scale readings
conveniently...at tonometer head

**easy to operate:**
self-activating recorder, automatically controlled and timed
permanent patient record on "fan-fold" strip chart
automatic chart drive—maximum accessibility for easy loading

**easy to maintain:**
self contained tonography system is compact, lightweight, portable, in its own carrying case
all solid state circuitry
carries a one-year warranty, easily serviced
meets or exceeds all requirements of Specification 5

Write for additional information, or to have our representative arrange for a personal demonstration.

# CONFORM-A-SPHERIC™ and ELLIP-SEE-CON™

## ASPHERIC CORNEAL LENSES

**ARE WE NUTS?** Imagine . . . we're advertising a NEW corneal lens design when everyone's interested in soft lenses!

**WE HAVE OUR REASONS!** First, soft lenses are in a transition phase. (It may be 12 to 18 months before everyone may fit soft lenses.) Also, the new soft lens materials are not expected to solve **all** contact lens needs nor to completely replace the hard lens.

**THE PUBLIC MUST BE SATISFIED!** Aspheric designs will challenge soft materials for future comfort and fitting simplicity. In fact, aspheric lenses will:

1) Eliminate peripheral flare without gimmicks. They furnish a wider, brighter peripheral field of vision.

2) Assured reproductibility! A distinct advantage over convential sperical curves.

3) Their gentle, more evenly distributed bearing areas minimize corneal changes and spectacle blur problems.

When properly managed, aspheric lenses will increase patient comfort and decrease fitting time.

**ASPHERIC LENSES COST LESS!** Aspheric lenses cost less than soft lenses. And, in these inflationary times, you'd better believe that this is meaningful.

**ASPHERIC LENS VERSATILITY** We have two aspheric corneal lens designs:

1) CONFORM-A-SPHERIC™—aspheric values replace the conventional spherical peripheral curve (s). Can be used with any existing fitting philosophy (spherical or toric base curves).

2) ELLIP-SEE-CON™—an ellipsoidal central curve and an aspheric bevel.

**LEARN HOW** to use Aspheric Corneal Lenses.

Most ophthalmic solutions start out sterile. But the OCUMETER® helps this one stay that way.
OCUMETER helps steroid solution stay sterile by eliminating a major cause of contamination —the eye dropper. Sterile, highly stable
Ophthalmic Solution
DECADRON®
Phosphate
(Dexamethasone Sodium Phosphate|MSD)
0.1% Dexamethasone Phosphate Equivalent
for mild acute iritis and nonpurulent conjunctivitis
For prescribing information, please see next page.

## for mild acute iritis and nonpurulent conjunctivitis

Not all steroid ophthalmic solutions stay sterile during the days and weeks of therapy. But this one is more apt to—Ophthalmic Solution DECADRON Phosphate (Dexamethasone Sodium Phosphate, MSD) in the OCUMETER® eliminates a common source of contamination—the eye dropper.

*Uniform dosage, drop after drop*

Each drop of Ophthalmic Solution DECADRON Phosphate contains the same dosage of steroid. And, with a gentle squeeze, the OCUMETER measures out one drop at a time. So your patient can conveniently get the steroid dose you want her to have, wherever she is.

Each cc. contains dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate. Also available as DECADRON® Phosphate Ophthalmic Ointment (0.05%); and as NeoDECADRON® Ophthalmic Solution containing dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base in each cc.; and NeoDECADRON® Ophthalmic Ointment, containing dexamethasone sodium phosphate equivalent to 0.5 mg. (0.05%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base per gram.

Sterile, highly stable

Ophthalmic Solution

**DECADRON®** Phosphate

Dexamethasone Sodium

Phosphate (MSD)

ONTRAINDICATIONS:
)ECADRON and NeoDECADRON
hould not be used in the
resence of infectious tuberculous
esions of the eye, chickenpox,
arly acute herpes simplex,
accinia, the early acute stages of
ost viral diseases of the cornea
nd conjunctiva, acute purulent
ntreated infections of the
onjunctiva and lids, suspected
cular or aural fungal infection,
erforated ear drum. Sensitivity
o components is also a
ontraindication.

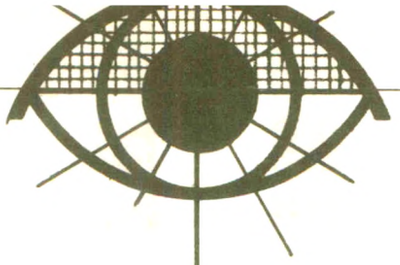
RECAUTIONS: DECADRON: Like
ll adrenal corticosteroids, may
ometimes mask, activate, or
nhance incipient infection.
/henever possibility of infection
xists, suitable antibiotic agents
r a steroid-antibiotic preparation
such as NeoDECADRON) should
e considered. If infections do not
espond promptly, therapy should
e discontinued until the infection
as been adequately controlled
y other measures.

ystemic side effects may occur
/ith extensive use of steroids.
'arely, ocular herpes simplex has
een reported in patients
eceiving adrenocortical steroids
ystemically or locally in the eye
or other conditions.

As with other corticosteroids, increased intraocular tension can follow extended local use (1-2 weeks or more) of dexamethasone sodium phosphate. Since increased intraocular tension can lead to loss of vision, this possibility should be kept in mind and topical administration used only under adequate tonometric supervision, particularly in patients known to have glaucoma, or whose family history includes glaucoma.

In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids. Reports in the literature indicate that, rarely, protracted use of topical corticosteroids in the eye may be associated with the development of posterior subcapsular cataracts. Hereditary and degenerative eye diseases in general do not show any response to treatment with these preparations.

Stubborn cases of anterior segment eye disease may require systemic adrenocortical hormone therapy. When the deeper ocular structures are involved, systemic therapy is necessary.



NeoDECADRON: A few individuals may be sensitive to one or more of the components of NeoDECADRON. If any reaction indicating sensitivity is observed, discontinue use. Sensitivity to neomycin may occasionally develop, especially when it is applied to abraded skin. Some reports in the current literature point to an increase in the number of persons sensitive to neomycin.

Use of any antibiotic agent may result in overgrowth of fungi or other organisms not susceptible to the antibiotic, necessitating prompt medical attention for such new infections.

As the safety of topical steroids during pregnancy has not been confirmed, they should not be used for extended periods during pregnancy.

# ADVANCES IN OPHTHALMOLOG

1 *New!* **MANAGEMENT OF DIABETIC RETINOPATHY: A Stereoscopic Presentation.** For the first time in book form, full-color stereophotographs demonstrate the pathogenesis and various changes that can occur in the retina of a diabetic patient. This includes comprehensive material on the appearance and management of microaneurysms, hemorrhages, exudates, and blood vessel changes. Each lesion is illustrated as it appears before treatment, immediately after treatment, as well as months and even years later. You'll especially welcome the up-to-date details on current treatment methods which employ xenon and argon photocoagulation. Other timely discussions encompass pituitary ablation and scleral buckling in retinal detachment. Throughout, the authors emphasize case selection, and suggest which types of eyes should be treated and what therapy is most effective. *By EDWARD OKUN, M.D.; GLEN PAUL JOHNSTON, M.D.; and ISAAC BONIUK, M.D. October, 1971. Approx. 208 pages, 8½" x 11", 315 illustrations and 112 full-color stereoscopic views on 16 View-Master® reels and a View-Master® compact viewer. About $50.75.*

2 *New 2nd Edition!* **EYE SYMPTOMS IN BRAIN TUMORS.** The definitive work in this specialized area, this new revision is an unmatched correlation of ocular symptoms with the recognition and localization of brain tumors. Updated in light of current progress, this comprehensive study describes methods for the neuro-ophthalmologic examination, evaluates symptoms of general and localizing significance, and discusses differential diagnosis. *By ALFRED HUBER, M.D.; edited and new material translated by FREDERICK C. BLODI, M.D. July, 1971. 392 pages, 6¾" x 9¾", 233 illustrations. $32.50.*

3 *New 2nd Edition!* **THE OPHTHALMIC ASSISTANT: Fundamentals and Clinical Practice.** This clear explanation of procedures and their scientific rationale can help your assistants increase office efficiency and upgrade the quality of patient care. This updated new edition remains the *only* reference written specifically for their level of knowledge. *By HAROLD A. STEIN, M.D., M.Sc.(Ophth.), F.R.C.S.(C); and BERNARD J. SLATT, M.D., F.R.C.S.(C). September, 1971. 484 pages, 7" x 10", 754 illustrations. $22.50.*

*Occupational Vision Studies*
*(From Study #36, Volume II, Guide to Occupational and Other Visual Needs)*

# Desk clerk

(Hotel-Motel Registration)

That affable, smiling clerk behind the motel or hotel desk has a lot on his mind when it comes to vision. In one smooth operation, he may use near vision to check the register you sign, intermediate vision to see you with and distance vision to locate the bellboy.

This is indicative of the varied seeing tasks confronting the desk clerk. Behind the scenes, of course, there is more of the same — checking the mail, picking out keys or observing guest traffic.

To perform his many tasks might not involve any exotic lens forms, but his performance demands accurate fitting of the lenses he does wear, especially multifocals. Your skills in specifying and fitting are vital to the desk clerk's good vision and one or more of the many Vision Ease multifocal forms might be the ideal vehicle for completing the Rx. The Vision-Ease Product Handbook lists and describes these lens forms. Ask your distributor or write to Vision-Ease for a copy.

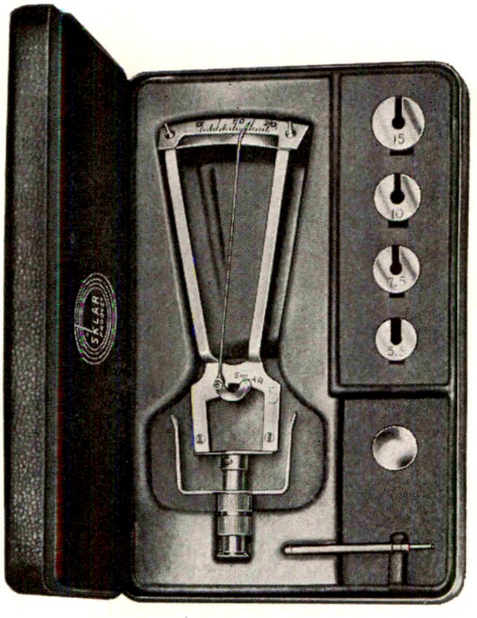
# SKLAR



## "JEWEL" SCHIOTZ

# TONOMETER

*made by Sklar in the United States with certification.*

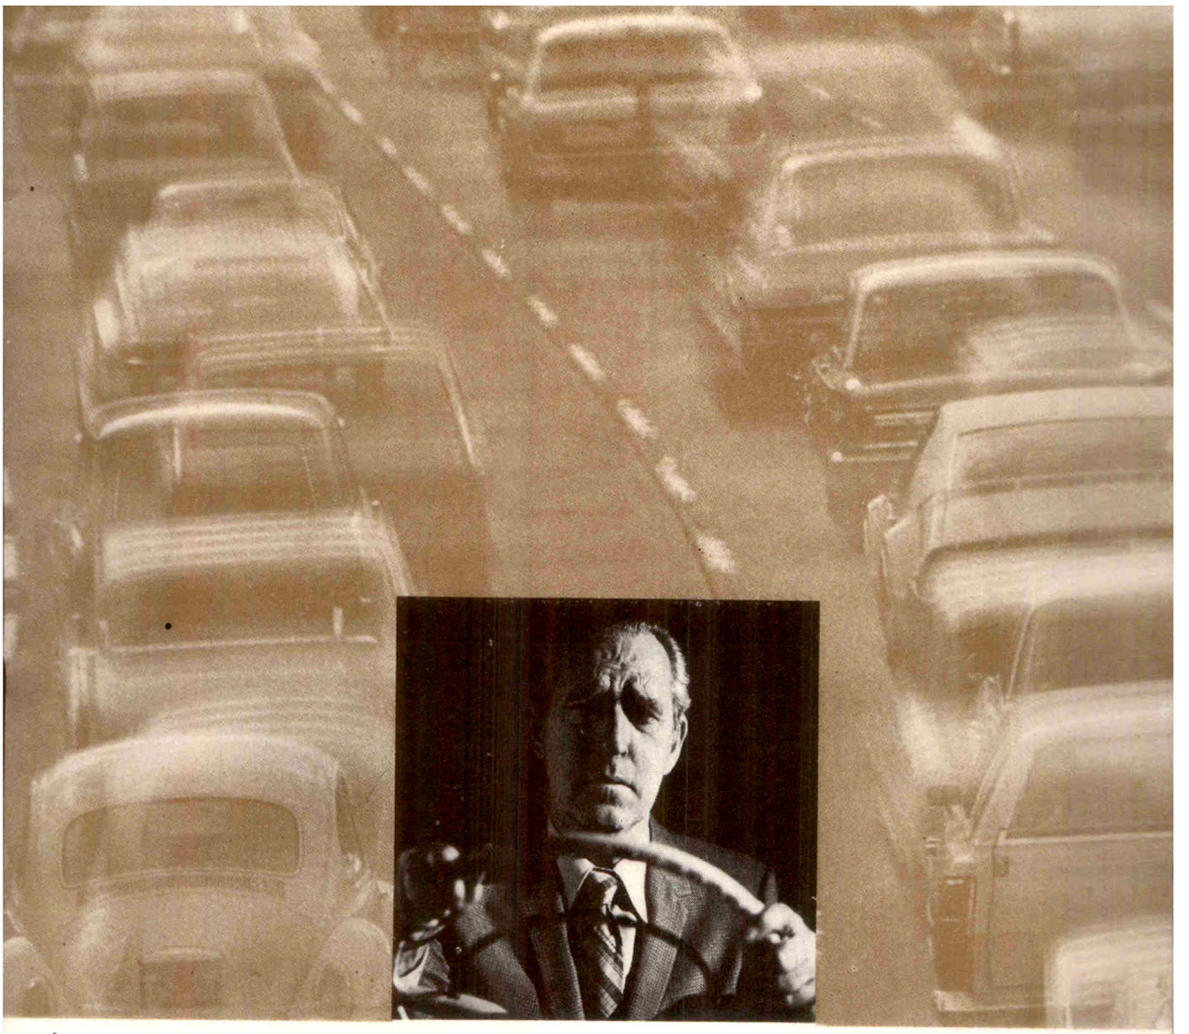
**Accuracy is assured by certification of our TONOMETER, as to compliance with all requirements of Specification 5.**

The Electrical Testing Laboratories of New York certifies that every SKLAR TONOMETER meets all the requirements of Specification 5 of the Committee on Standardization of Tonometers of the American Academy of Ophthalmology and Otolaryngology.

**Easier and more accurate reading—**

Error due to parallax is overcome by SKLAR'S patented (#3,2666,301) inclined scale, combined with the bayonet frame and mirror.

**Friction is minimized** between the plunger and hammer by the jewel mounted in the plunger. There are no sharp edges which may be harmful to the patient.



**Electric Sterilizer and Stand with cover are available.** The SKLAR TONOMETER may be fitted with the Allen Plunger Retractor on special order.

Write for comprehensive catalogs:
**A**—Eye Instruments
**B**—Ear, Nose & Throat Instruments

The profession has known for more than 75 years that any instrument with the name SKLAR is the better buy.

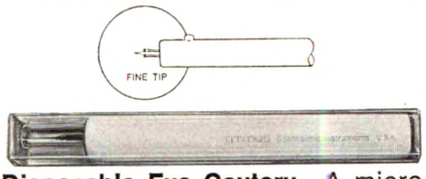
In an environment of repeated irritation...

## one drop of Albalon™ provides over 190 minutes of the most potent decongestant activity.

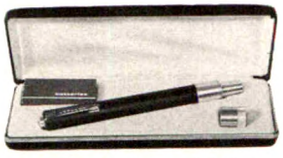
In a recent double blind study,* the superior decongestant activity of Albalon™ Liquifilm® was clearly demonstrated. Compared to three of the most familiar vasoconstrictors, just one drop of Albalon™ provided both immediate, effective eye-whitening, and 190 minutes of the most potent protection against repeated ocular insult.

Additionally, Albalon™ comes in the Liquifilm® vehicle to soothe, lubricate and comfort itchy, smarting, red eyes.



*from an independent study conducted on a controlled population; data on file, Allergan Research Department.

**Contains:** naphazoline HCl, 0.1%; Liquifilm® (polyvinyl alcohol), 1.4%; with benzalkonium chloride, disodium edetate, citric acid, sodium citrate, sodium chloride, sodium hydroxide and purified water. **Indications:** For use as a topical ocular vasoconstrictor. **Contraindications:** Hypersensitivity to the components of this preparation. **Precautions:** This preparation should be used only with caution in the presence of hypertension, cardiac irregularities, hyperglycemia (diabetes), hyperthyroidism. **Adverse Reactions:** Pupillary dilatation, increase in intraocular pressure, systemic effects due to absorption (i.e. hypertension, cardiac irregularities, hyperglycemia). **Warnings:** Should not be used in patients with narrow angle glaucoma. If irritation persists, or increases, discontinue use. **Dosage and Administration:** One to two drops instilled in each eye every three to four hours or less frequently, as required to relieve symptoms.



Rx **Albalon**™ LIQUIFILM® Ophthalmic Solution
(naphazoline HCl)

# Does your contact lens replacement program work for you...or do you work for it?

Strictly speaking, any means of contact lens protection you provide for your patient is probably better than none at all. There are those however, that you would be better off without.

These plans, while sounding quite simple on the surface, many times become paperwork monsters once they're installed. Countless forms for each patient must be filled out and mailed. When a loss occurs the whole process begins all over again filling out lengthy forms and waiting for results. The recall system, should there be one, is usually clumsy, inefficient and at *your* expense.

RLI is the better way. No complicated application form to fill out. One easy "sign your name" claim form for fast replacement service. An automatic, 80% effective recall system is available and you needn't lift a finger to benefit from it. Find out about just how simple and easy contact lens protection can be. Contact RLI today for full details.

With RLI . . . you take care of your patients and we take care of protecting their lenses—*we work for you.*

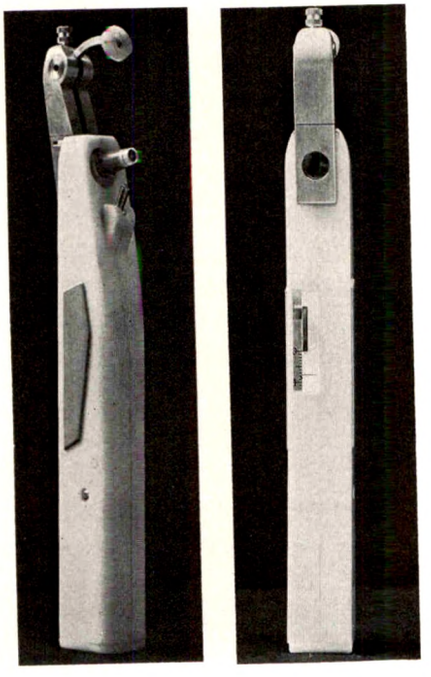
RLI

# NEW DEVELOPMENTS . . .



## ORA SERRATA ATTACHMENT TO THE GOLDMANN 3 MIRROR LENS

The periphery of the fundus near the ora serrata and the ciliary body cannot be examined under normal conditions with the 3-mirror lens alone. The ora serrata attachment along with the 3-mirror lens allows the observation of these most peripheral parts in its entire circumference.

The attachment is shaped like the 3-mirror lens. Half a steel-ball is fixed to the scleral part of the attachment which presses on the sclera above the ora serrata so that the fundus at its periphery near the ora serrata can be seen in the gonio mirror of the 3-mirror lens. The ora attachment can be used either with the 3-mirror lens in a locked or moveable position.

# Before you buy a $25,000 argon laser photocoagulator, invest  in research.

For such a small investment, you'll discover that our new instrument, with its fiber optics transmission system, is uniquely designed for effective retinal photocoagulation. Here are just a few of the reasons why.

By using fiber optics to transmit argon laser energy, you get significant improvement in operating freedom. The fiber optics cable is lightweight, flexible and reliable. It replaces heavy, rigid, mirror transmission systems.

Fiber optics also results in delivery instrument flexibility. You can now choose the delivery technique best suited to your particular needs, whether it be a slit lamp; a direct viewing, handheld ophthalmoscope; or an erect image, indirect ophthalmoscope. And changing from one to another only takes a few minutes.

You're also concerned with economy. The simple adapter allows you to attach or detach your slit lamp to the laser quickly and accurately. This means that you don't have to purchase an additional slit lamp for permanent dedication to photocoagulation. And most important for economy, our unit is priced at less than $25,000.

We can't tell you the whole story here, so invest 8¢ in postage and send for the data. And if you're interested in learning more about argon laser photocoagulation, check the box on the coupon. We'll tell you about our regional seminars, clinical discussions to back up your 8¢ investment.

*THE TISSUE-FRIENDLY*

# SUPRAMID EXTRA®

**SUTURE.** Polyfilament but neither braided nor twisted. New cable-type construction with several strands enclosed in a perfectly smooth cover of the same material, gives great pliability and superior strength. Strong as steel wire, handles as silk. No stitch irritation, no growth of tissue into suture. Sizes 10-0 to 8.

**SPECIAL NEEDLES:** Our CT needle for cataracts (wire size 0.30mm, length 9mm), CA needle for corneal work (wire size 0.30mm, length 6mm), and EX needle for special keratoplasties (wire size 0.2mm, length 5mm), a flattened reverse cutting needle to prevent "leaking wounds," equal to the smallest hand made eyed needles No. 82F, **and finally the smallest spatula needle on the market, length 5 millimeters, wire size 0.2mm, double armed with 10-0, 9-0 and 8-0 black Supramid Extra. Code Nos. 2SC-100, 2SC-90 and 2SC-80.**

**A NEW PRODUCT:** Implants—Sleeves (Tubes) for preventing adhesions in Eye Muscle Surgery. Method development by Edward A. Dunlap, M.D. Reference: Dunlap, Edward A.: Plastic Implants in Muscle Surgery, Archives of Ophthalmology, 80: 249-257, August 1968.

**TUBING.** *Fully inert because it is made of the same material as the suture;
* Thinnest walls of any surgical tubing, fully transparent and can be *repeatedly* autoclaved;
* Most economical. It is in your interest to compare prices and quality.

**FOIL.** Excellent results with our suture created the demand for Foil for plastic and reconstructive surgery in such cases as orbital fractures, lid reconstruction, etc. Foil is chemically identical with the sutures, thus just as inert when buried in the tissue.

Available in thickness from 0.05mm to 2.00mm, in sheets 15 x 20cm.

Can be steam-autoclaved, cut to size, and carved to shapes and forms.

# Kowa RC-2

## fundus camera

*The simple approach to fundus and fluorescein photography.*

FLUORESCEIN FUNDUS PHOTOGRAPHY

• To be fully meaningful to the medical profession, all instrumentation must function as an extension of the user's eyes, hands, and mind. The Kowa RC-2 fundus camera fully embodies this principle.

• *Fundus and External Photography* The basic RC-2 incorporates every conceivable advance in optics, mechanics, and electronics. Standard are built-in flash, 2X magnifying lens, automatic frame numbering for patient coding, and more. It will produce impeccable 35mm results even for inexperienced users.

• *Fluorescein Photography* By simply adding an auto-wind back, filters, and a quick-cycling power unit, the RC-2 becomes a flawless fluorescein photographic instrument.

• *Polaroid® Photography* An attachment gives you 60-second fundus photographs.

To see why the *total systems approach* has made Kowa's RC-2 the standard by which all others are measured, contact the representative in your area.

## in open-angle glaucoma

# HUMORSOL®

## (DEMECARIUM BROMIDE | MSD)

OPHTHALMIC SOLUTION, 0.125% and 0.25%

## the cholinesterase inhibitor that needs no pampering

IN OCUMETER® OPHTHALMIC DISPENSER

**FOR TOPICAL APPLICATION INTO THE CONJUNCTIVAL SAC ONLY**

**Contraindications:** Known hypersensitivity; active uveal inflammation; most cases of narrow-angle glaucoma.

**Warnings:** Should be administered with extreme caution to patients with myasthenia gravis who are on systemic anticholinesterase therapy; conversely, systemic anticholinesterase drugs for myasthenia gravis should be added cautiously. Succinylcholine should be administered with extreme caution before or during general anesthesia, because of possible respiratory and cardiovascular collapse.

*Use in Pregnancy:* Safe use in pregnancy has not been established, nor has the absence of adverse effects on the fetus or on respiration of the neonate. During pregnancy weigh potential benefits against possible hazards.

**Precautions:** Gonioscopy is recommended before therapy. Do not use, or use cautiously, when an intraocular inflammatory process is present.

Compression of the lacrimal sac during and following instillation for a minute or two minimizes drainage into the nasal chamber. Wash hands immediately after instillation. Discontinue use if salivation, urinary incontinence, diarrhea, profuse sweating, muscle weakness, respiratory difficulties, shock, or cardiac irregularities occur.

Persons exposed to organophosphate-type insecticides and pesticides (gardeners, organophosphate-manufacturing plant or warehouse workers, farmers, residents of communities which are undergoing insecticide spraying or dusting, etc.) should be warned of added systemic effects possible from absorption through the respiratory tract or skin. Wearing of respiratory masks, frequent washing, and clothing changes may be advisable.

Use with extreme caution, if at all, in patients with marked vagotonia, bronchial asthma, spastic gastrointestinal disturbances, peptic ulcer, pronounced bradycardia and hypotension, recent myocardial infarction, epilepsy, parkinsonism, and other disorders that may respond adversely to vagotonic effects. Use extreme caution before intraocular surgery because of the possibility of hyphema.

Despite observance of all precautions, repeated administration may cause depression of the concentration of cholinesterase in the serum and erythrocytes, with resultant systemic effects.

**Adverse Reactions:** Stinging, burning, lacrimation, lid muscle twitching, conjunctival and ciliary redness, brow ache, headache, and induced myopia with visual blurring; activation of latent iritis or uveitis; retinal detachment has been reported occasionally. Iris cysts may form, enlarge, and obscure vision, more frequently in children; cysts usually shrink when the miotic is discontinued but, rarely, may rupture or break free into the aqueous. Frequent examination is advisable.

Prolonged use may cause conjunctival thickening and obstruction of nasolacrimal canals. If systemic effects occur (e.g., salivation, urinary incontinence, nausea, abdominal cramps, vomiting, diarrhea, dyspnea, bradycardia, cardiac irregularities), parenteral administration of atropine is indicated: 0.4 to 0.6 mg or more for adults, proportionately less for children; artificial respiration may be required. Similar therapy is indicated for overdosage.

Lens opacities have been reported, and routine slit-lamp examinations should accompany prolonged use. Paradoxical increase in intraocular pressure may occur and be alleviated by a mydriatic.

**Dosage and Administration:** Initial titration and dosage adjustments must be individualized to obtain maximal therapeutic effect. Patient must be observed closely during initial period. If response is not adequate within first 24 hours, consider other measures. Keep frequency of use to a minimum in all patients, but especially in children.

Since technic is crucial to proper and safe administration, consult Direction Circular for full details.

**Supplied:** In 5-cc OCUMETER® Ophthalmic Dispenser containing 0.125 or 0.25 percent solution and sodium chloride; benzalkonium chloride 1:5000 added as preservative.

*For more detailed information, consult your MSD representative or see the Direction Circular. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486*

MSD
MERCK SHARP & DOHME

# in post-operative retinal or cataract surgery

## Murocoll Phenylephrine, Scopolamine and Prednisolone (Murocoll Product #2c)

**FORMULA:** Sterile ophthalmic solution containing Phenylephrine Hydrochloride 10%, Scopolamine Hydrobromide 0.3% and Prednisolone 0.2%; preservatives chlorobutanol 0.5%; sodium bisulfite; polysorbate 20 and distilled water as inactive ingredients.

**CLINICAL INDICATIONS:** Used in intraocular inflammation such as uveitis and iritis, where it is desirable to maintain dilation, rest ciliary body as well as to decrease inflammation with post-operative retinal or cataract surgery.

**CONTRAINDICATIONS:** (a) Acute herpes simplex, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva. (b) Tuberculosis. (c) Fungal diseases. (d) Acute purulent untreated infections which, like other diseases caused by microorganisms, may be masked or enhanced by the presence of the steroid. (e) Purulent conjunctivitis and purulent blepharitis. Individuals with hypersensitivity to belladonna alkaloids.

**PRECAUTIONS:** (a) Extended use of topical steriod therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. (b) In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids.

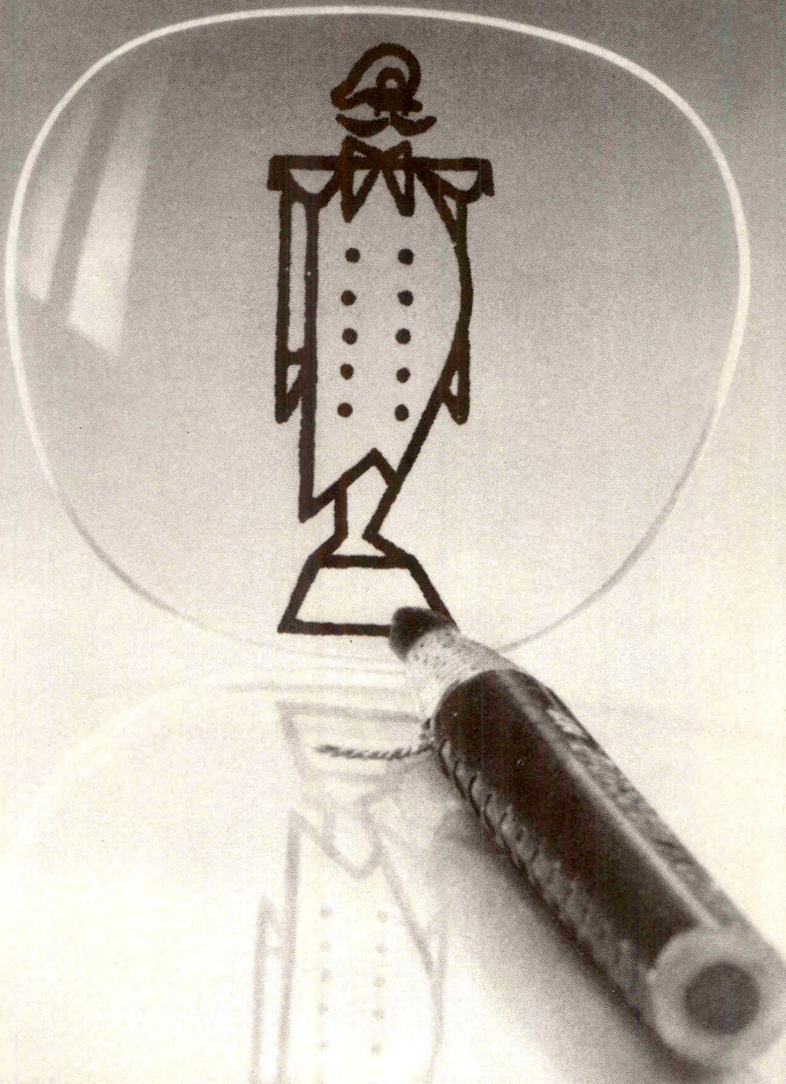
**CAUTION:** Should be used with caution in patients with narrow chamber angles.

**DOSAGE:** One or two drops in eye three or four times daily until all signs of intraocular inflammation are absent.

Use of this combination reduces the number of instillations that would be required if separate agents were prescribed, and materially reduces the cost of therapy.

**AVAILABLE:** 7.5 cc glass bottle with plastic dropper on prescription only.

**Complete ophthalmologic formulary available on request**



Muro preparations are available to all community pharmacists and hospitals through their drug service wholesaler.

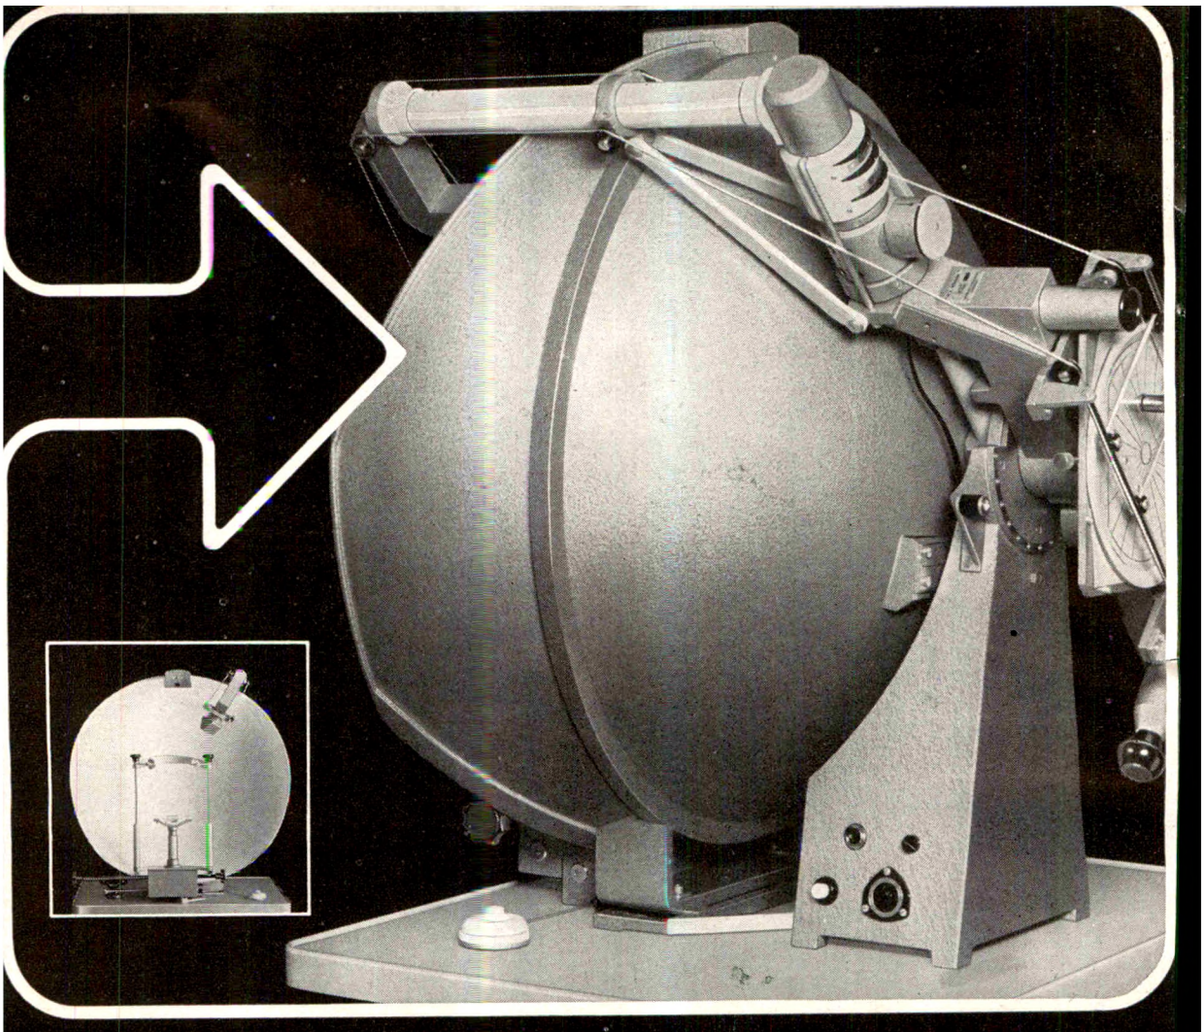
# Optemp®

## terile, disposable cautery designed especially or the ophthalmic surgeon

**temp offers the ocular surgeon these important advantages...**



**imal temperature**
temp is only 300°C at the tip...hot enough instant occlusion of individual pillaries, "cool" enough to minimize mage to surrounding tissues

**cellent visibility**
temp, with an elongated operating tip, rs the surgeon an unrestricted d of vision...the instrument, being light ght and well balanced, is easily maneuverable with no cumbersome cords to get in the way.

**sterility, economy**
Optemp is sterile as received, eliminates the possibility of cross-infection... battery powered and inexpensive, it saves on resterilization and reprocessing.

Ask for Optemp at your local hospital and see why it's the dependable ophthalmic cautery that meets your needs in every way.

soflens™
CONTACT LENS
(polymacon)
See full prescribing information which follows.

# comfort... from the beginning

# soflens
## CONTACT LENS (polymacon)

Conventional methods of fitting contact lenses do not apply to SOFLENS Contact Lenses (polymacon). For a detailed description of the fitting technique, refer to the SOFLENS Fitting Guide, copies of which are available from: SOFLENS Division, Bausch & Lomb Incorporated, Rochester, New York 14602.

**DESCRIPTION:** The SOFLENS Contact Lens (polymacon) is a hemispherical shell of approximately 13mm chord diameter and 0.1 to 1.0mm thickness. It consists of 61.4% poly (2-hydroxyethyl methacrylate) and 38.6% water by weight when immersed in normal saline. The SOFLENS Care Kit is a package required for lens asepticizing, cleaning, and storage consisting of the following:

| | |
|---|---|
| SOFLENS Carrying Case | Cat. #140301 |
| SOFLENS Aseptor-Patient Unit | Cat. #140302 |
| SOFLENS Squeeze Bottle | Cat. #140304 |
| SOFLENS Salt Tablets | Cat. #140305 |
| SOFLENS Patient Instruction Book | Cat. #140300-100 |

**ACTIONS:** The SOFLENS Contact Lens (polymacon) absorbs water to 38.6% of its dry weight when equilibrated in normal saline solution. In its hydrated state a SOFLENS Contact Lens (polymacon) becomes soft and pliable. When placed on the human cornea the hydrated SOFLENS Contact Lens (polymacon) acts as a refracting medium to compensate spherical ametropias. The material has a refractive index of 1.43 and the lens has a visible light transmittance greater than 97%.

**INDICATIONS:** SOFLENS Contact Lenses (polymacon) are indicated for the correction of visual acuity in persons with non-diseased eyes who have spherical ametropias; refractive astigmatism of 1.50 diopters or less and/or corneal astigmatism of 2.00 diopters or less.

**CONTRAINDICATIONS:** SOFLENS Contact Lenses (polymacon) are contraindicated by the presence of any of the following conditions. (1) Acute and subacute inflammations of the anterior segment of the eye. (2) Any eye disease which affects the cornea or conjunctiva. (3) Insufficiency of lacrimal secretion. (4) Corneal hypoesthesia. (5) Any systemic disease which may affect the eye or be exaggerated by wearing contact lenses. (6) Early stages of pregnancy.

**WARNINGS: Medicants and Eye Drops**—SOFLENS Contact Lens (polymacon) must be stored ONLY in normal saline solution. No ophthalmic solutions or medicants, including conventional contact lens solutions, can be used by SOFLENS Contact Lens (polymacon) wearers prior to or while the lens is in place on the eye. Also, no solutions, including conventional contact lens solutions, other than normal saline may be used on SOFLENS when the lens is off the eye.
**Abrasions and Infections**—If the lenses become less comfortable to the wearer than when they were first placed on the wearer's corneas, this may indicate the presence of a foreign body. The lens should be removed immediately and the patient examined. If any eye abrasion, ulceration, irritation or infection is present, a physician should be consulted immediately.
**Wearing Restrictions**—SOFLENS Contact Lenses (polymacon) should be removed before sleeping or swimming and in the presence of noxious and irritating vapors.
**Visual Blurring**—When visual blurring occurs the lens must be removed until the condition subsides.
**Lens Sanitation**—Patients who would not or could not adhere to recommended daily sanitary care of SOFLENS Contact Lenses (polymacon) should not be provided with them.

**PRECAUTIONS: Storage**—SOFLENS Contact Lenses (polymacon) must be stored ONLY in normal saline solution. If left exposed to air, the lenses will dehydrate, become brittle, and break readily. If a lens dehydrates, it should be soaked in normal saline solution until it returns to a soft, supple state.
**Cleaning and Asepticizing**—SOFLENS Contact Lenses (polymacon) must be BOTH cleaned and asepticized daily. One procedure does not replace the other. CLEANING is necessary to remove mucus and film from the lens surface. ASEPTICIZING with the SOFLENS Aseptor-Patient Unit has been shown to prevent the growth of certain organisms, namely Staphylococcus aureus, Pseudomonas aeruginosa, Bacillus subtilis, Candida albicans, and Herpes simplex, on the lens and in the SOFLENS Carrying Case. Fresh normal saline must be prepared daily for cleaning and storing the lenses. The carrying case must be emptied and refilled with fresh normal saline solution just before asepticizing the lenses. If a SOFLENS Aseptor-Patient Unit is not available for asepticizing the lenses, the lenses must be boiled in their carrying case in a pan of water for 15 minutes.
**Hygiene**—Hands must be washed, rinsed thoroughly, and dried with a lint-free towel before handling the lenses. Cosmetics, lotions, soaps, and creams must not come in contact with the lenses since eye irritation may result. If hair spray is used while the lenses are being worn, the eyes must be kept closed until the hair spray has settled.
**Fluorescein**—Never use fluorescein while the patient is wearing the lenses because the lenses will become discolored. Whenever fluorescein is used, flush the eyes with normal saline solution and wait at least one hour before replacing the lenses. Too early replacement may allow the lenses to absorb residual fluorescein irreversibly.

**ADVERSE REACTIONS:** Serious corneal damage may result from wearing a lens which has been soaked in a conventional contact lens solution containing preservatives. Eye irritation may occur within a short time after putting on a hypertonic lens. Removal of the lens will relieve the irritation. Very rarely a lens may adhere to an eye as a result of the patient sleeping with the lens on or wearing a hypotonic lens. If a lens adheres for any reason, apply normal saline and wait until the lens moves freely before removing it. Clinical studies indicate visual blurring is experienced by less than 5% of SOFLENS Contact Lens (polymacon) wearers. Rainbows or halos around objects or blurring of the vision may occur if the lenses are worn continuously for too long a time. Removal of the lenses and a rest period of at least one hour generally relieves these symptoms. Excessive tearing, unusual eye secretions, and photophobia are not normal; if these symptoms occur, the patient should be examined to determine their cause.

**DOSAGE AND ADMINISTRATION:** There may be a tendency for the patient to overwear the lenses initially. Therefore, the importance of adhering to the following initial daily wearing schedule should be stressed to the patient:

| Day | Wear Time (hours) | Rest Period (hours) | Wear Time (hours) | Rest Period (hours) | Wear Time (hours) |
|---|---|---|---|---|---|
| 1 | 3 | 1 | 3 | 1 | 3 |
| 2 | 3 | 1 | 3 | 1 | 3 |
| 3 | 4 | 1 | 4 | 1 | 4 |
| 4 | 4 | 1 | 4 | 1 | 4 |
| 5 | 6 | 1 | 6 | 1 | 4 |
| 6 | 6 | 1 | 6 | 1 | 4 |
| 7 | 8 | 1 | 8 | | |
| 8 | 8 | 1 | 8 | | |
| 9 | 8 | 1 | 8 | | |
| 10 | 10 | 1 | balance of the waking hours* | | |
| 11 | 12 | 1 | balance of the waking hours* | | |
| 12 | 14 | 1 | balance of the waking hours* | | |

*Lenses should never be worn 24 hours a day.

Care must be taken on the initial visit to assure that the patient is supplied with a SOFLENS Care Kit and fully understands all care and handling instructions for the lenses. As with any contact lens, regular recall visits are necessary to assure patient health and compliance with instructions.

**HOW SUPPLIED:** Each lens is supplied sterile in a glass vial containing sterile normal saline solution. The glass vial is marked with the dioptric power (black for plus power lenses; red for minus) and the manufacturing lot number of the lens. To assure proper lens care and handling, each SOFLENS patient must be supplied with a complete SOFLENS Care Kit.

**BAUSCH & LOMB**
SOFLENS DIVISION

Specific for
Herpes Simplex Keratitis

**STOXIL®**
**brand of IDOXURIDINE**

the only brand of IDU
available in two forms:
Solution—Ointment

Both now available in Canada

# The choice is yours

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.

**Indications:** Only in the treatment of herpes simplex keratitis.

**Description: 'Stoxil' Ophthalmic Solution** contains idoxuridine (5-iodo-2'-deoxyuridine) **0.1% (1 mg./ml.)** in distilled water; sterile when packaged. Preserved with thimerosal, 1:50,000. **'Stoxil' Ophthalmic Ointment** contains idoxuridine **0.5% (5 mg./gram)** in a petrolatum base. (White petrolatum and liquid petrolatum are inactive ingredients.)

**Contraindications:** Contraindicated in patients with known or suspected hypersensitivity to any of its components.

**Precautions:** Some strains of herpes simplex appear to be resistant. If there is no response in *epithelial infections* after 7 or 8 days of treatment, other forms of therapy should be considered.

The recommended frequency and duration of administration should not be exceeded.

'Stoxil' is not effective in corneal inflammations in which the virus is not present.

Corticosteroids are usually contraindicated in herpes simplex keratitis.

Boric acid should not be used during the course of therapy.

'Stoxil' Ophthalmic Solution should not be mixed with other medications.

**Adverse Reactions:** Occasionally, irritation, pain, pruritus, inflammation, edema of the eye or lids and, rarely, allergic reactions have been reported. Photophobia has occurred. Occasionally corneal clouding, stippling and small punctate defects in the corneal epithelium have been observed. The punctate lesions may be a manifestation of the infection.

**How Supplied:** 0.1% Ophthalmic Solution (1 mg./ml.), in 15 ml. bottles with dropper; 0.5% Ophthalmic Ointment (5 mg./gram) in 4 gram tubes.

**Stability:** The Solution should be stored in refrigerator until dispensed. The Ointment does not require refrigeration.

SK&F Smith Kline & French Laboratories

# A little innovation is a big help

**Nothing is quite as satisfying as finding a new way to help the patient.**

**You will help a beginning presbyope** adjust to his bifocal correction by simply adding Press-On™ lenses to his present single vision spectacles. The interim Press-On lenses establish usefulness and acceptance. Also, they will help determine the proper seg height, shape and size before the permanent Rx is produced.

**Reading aids for low vision patients** have been a real problem. Adds above +3.00 have been impractical for everybody concerned. Press-On lenses give you bifocal segments of any size and shape incorporating proper prism to insure comfortable binocular vision. They can be applied in minutes.

**Post-operative cataract patients** are apprehensive. Wouldn't it be a happy innovation to hand these patients their own comfortable glasses with an interim aspheric Press-On lens correction that provides a panoramic field of view. They will see better and look better, immediately.

These are a few examples. Clip the coupon, and we'll send you more ideas plus a Press-On lens for your own use.

All OSG Fresnel lenses provide optimum asphericity regardless of power.

# The new Zeiss Zoom OpMi 7... a true ophthalmological specialist.

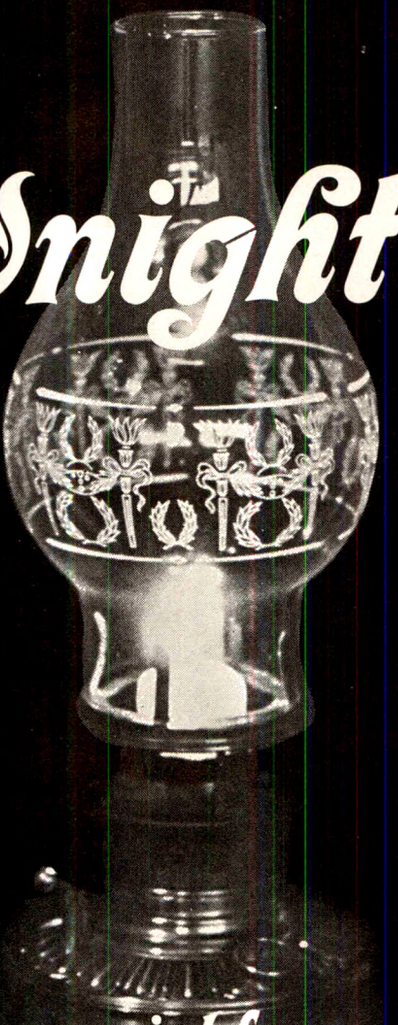
The new OpMi 7 is truly special in every sense of the word. It's special in that it is designed only for ophthalmological microsurgery. And special too in price—its many outstanding design features are shared only with instruments costing considerably more.

**Wide field of view:** 55 mm at 3.6x — 95% more area than other instruments in its price range.

**Building block design:** it accepts all the valuable Zeiss accessories, including the Beam Splitter System for still and motion picture photography and TV, the unique high-eyepoint eyepieces for spectacle wearers, a fiber-optic "cool-light" illumination system, the assistant's stereo microscope with the same high quality optics as the surgeon's, and the 2x operating field magnifier.

**Choice of 3 stands:** including the new Ceiling Suspension System.

**Choice of 3 working distances:** 6", 7" or 8" to your specification.



That's only a start. For complete details, write or call Carl Zeiss, Inc., 444 5th Ave., New York, N. Y. 10018. (212) 736-6070.

Nationwide Service.

# Look what fluorescein fundus photography can tell you.

This fluorescein angiogram of a diabetic retinopathy, revealing a gross vasculopathy in micro and macro vessels, is only one example of the results that can be easily obtained with the new Zeiss Fundus Flash II. Of the many features of this unique instrument, four are particularly worth citing here:

(1) The light source, adjustable for low, medium or high intensity, with low heat, fast recycling, short warm-up (0.5 sec.) and long flash tube life.

(2) The built-in digital data timing system which indicates automatically the time lapse between photographs.

(3) The control system which allows preselection of frame sequences from 1 to 4 frames/sec., time exposures, and automatic shutoff of film transport after a selected number of frames.

(4) The exclusive Allen Stereo Separator for taking stereo photographs automatically with no equipment adjustment.

For complete details on the many other features of this easy-to-use instrument, write Carl Zeiss, Inc., 444 5th Avenue, New York, N.Y. 10018.

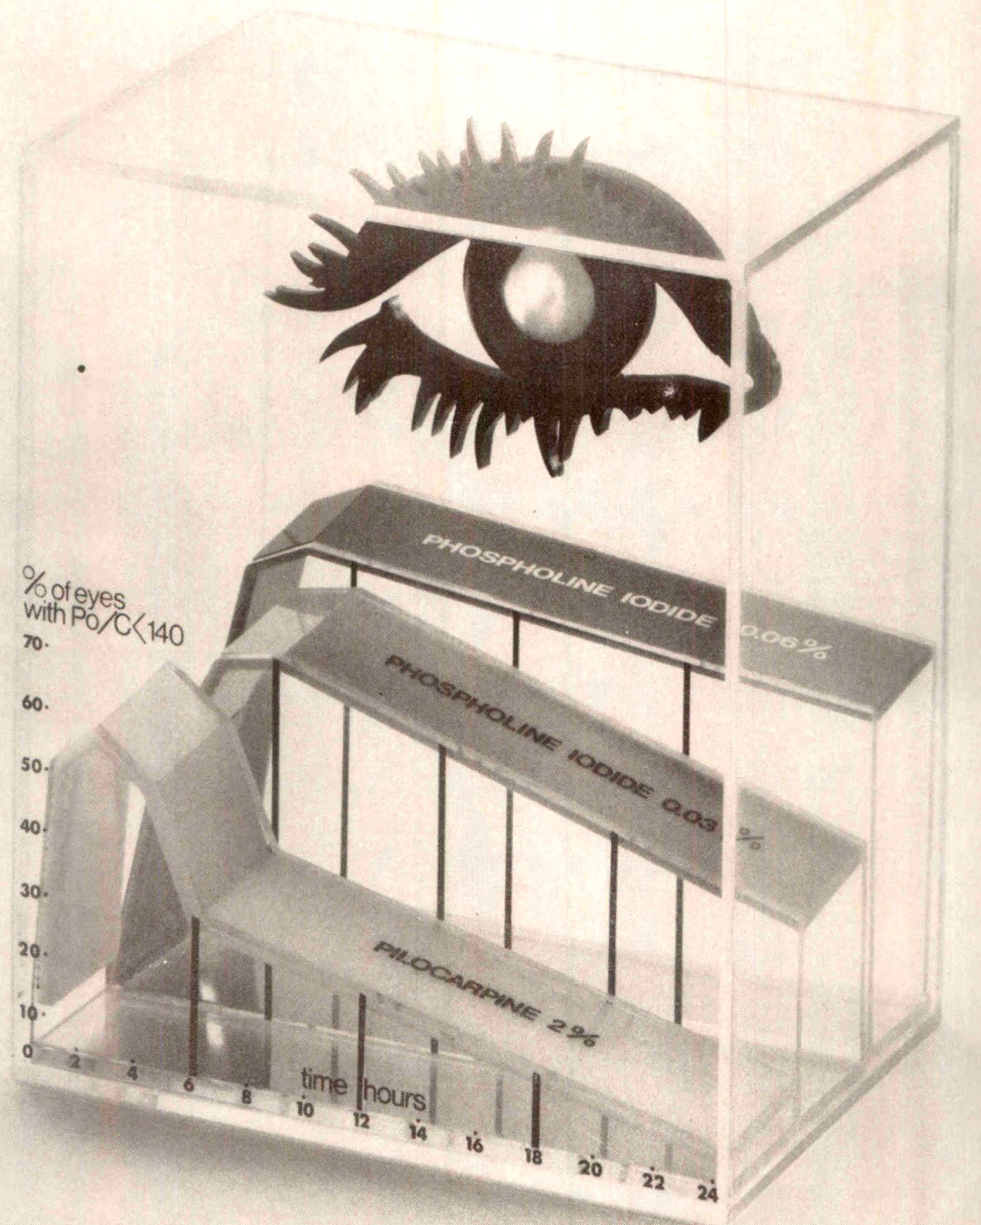
# Not more potent, but longer acting*...

PHOSPHOLINE IODIDE 0.03% and 0.06% were compared with pilocarpine 2% in a study of the time course of changes in outflow facility and intraocular pressure after single dose administration in patients with open-angle glaucoma. While Phospholine Iodide 0.06% showed little diminution in effect on intraocular pressure after 24 hours, the effect of pilocarpine 2% declined markedly in the first few hours, and was almost completely dissipated after 24 hours. The action of Phospholine Iodide 0.03% was intermediate between that of pilocarpine 2% and Phospholine Iodide 0.06%.

## An important consideration in the management of glaucoma



When treated with short acting miotics, the patient with open-angle glaucoma runs the risk of an undetected intraocular pressure buildup during the night—a "silent emergency."

The longer acting Phospholine Iodide® (echothiophate iodide) may protect against this nightly insult. A single instillation of the 0.03% or 0.06% strength before retiring will act through the critical hours, and is especially recommended when you have found pilocarpine to be inadequate.

When initiating therapy... Phospholine Iodide 0.03% can often maintain 24 hour control of intraocular pressure with a single instillation at bedtime. It provides a smooth transition to the higher strengths—0.06%, 0.125%, 0.25% —when necessary. When indicated, epinephrine or carbonic anhydrase inhibitors may be prescribed with any strength of Phospholine Iodide.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide for ophthalmic solution)

Effect of Phospholine Iodide and pilocarpine on intraocular pressure control.

*Adapted from Barsam, P. C., Boston U. School of Med.: Time Curves of the Effect of Miotics on Intraocular Pressure and Outflow Facility, Scientific Exhibit, Annual Convention, American Academy of Ophthalmology and Otolaryngology, Las Vegas, Oct. 5-9, 1970.

See next page for Brief Summary of prescribing information.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide)

for 24 hour control in chronic simple (open-angle) glaucoma and glaucoma secondary to aphakia

just 1 or 2 instillations a day
- for long lasting effect on ocular tension—
helps protect against a "silent emergency" at night
- may be substituted for the bedtime dose of a short acting miotic
that controls intraocular pressure by day, but
fails to provide adequate control during the night and early morning
- choice of four strengths for individualized therapy—
may be used alone or as a complementary agent

**BRIEF SUMMARY (for full prescribing information, consult package circular)**
**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

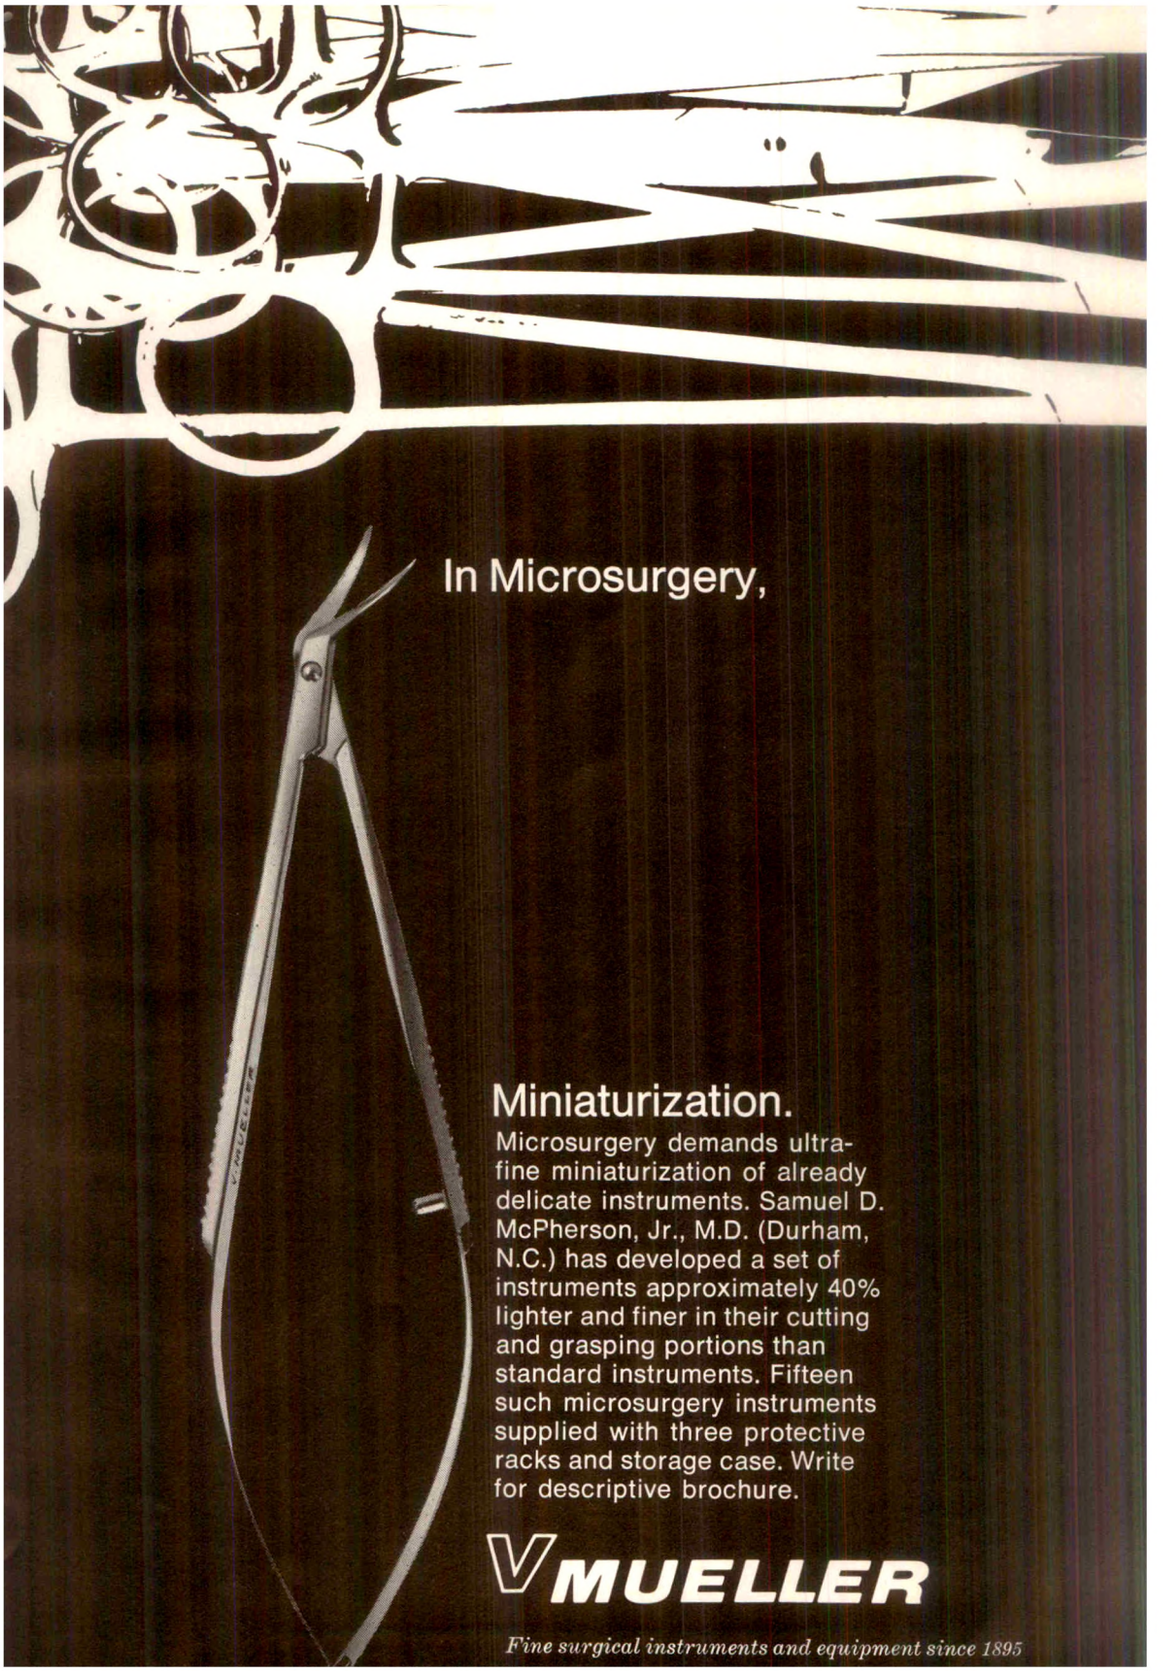
**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE (echothiophate iodide) concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, brow-ache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local)* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE (echothiophate iodide) therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.



Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic)* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.

And DIAMOX does not interfere with other forms of glaucoma therapy which influence the outflow mechanism. In fact, a complementary effect may be obtained when DIAMOX is used in conjunction with miotics.

Treatment with DIAMOX may retard progress of glaucoma by reducing secretion of aqueous humor and thus intraocular pressure. With DIAMOX SEQUELS, acetazolamide is slowly released, and concentrations peak at 8 to 12 hours. A single dose may provide a therapeutic effect for as long as 18 to 24 hours. It is thus possible to maintain the inhibitory effect on aqueous humor formation with a twice-daily regimen . . . an important consideration for the patient's rest and for minimization of side effects.

# DIAMOX®
## ACETAZOLAMIDE
# SEQUELS® 500 mg
## Sustained Release Capsules

**ontraindications**—Situations in which sodium and/or potassium serum evels are depressed, in kidney and liver disease or dysfunction, supra-enal gland failure and hyperchloremic acidosis. Long-term administration contraindicated in chronic noncongestive angle closure glaucoma.

**arning**—Although teratogenic and embryocidal effects demonstrated in ice at more than ten times the equivalent therapeutic doses have not een evidenced in humans, DIAMOX Acetazolamide should not be used in regnancy, especially during the first trimester, unless the expected enefits outweigh these potential adverse effects.

**recautions**—Increasing the dose may increase drowsiness and paresthesia and decrease diuresis. Reactions common to sulfonamides may occur: fever, rash, crystalluria, renal calculus, bone marrow depression, thrombocytopenic purpura, hemolytic anemia, leukopenia, pancytopenia, agranulocytosis. If such occur, discontinue drug and institute appropriate therapy.

**Side Effects**—During short-term therapy: paresthesias, loss of appetite, polyuria, drowsiness, confusion. In long-term therapy an acidotic state may supervene. Transient myopia has been reported. Other occasional reactions: urticaria, melena, hematuria, glycosuria, hepatic insufficiency, flaccid paralysis, convulsions. 354-1

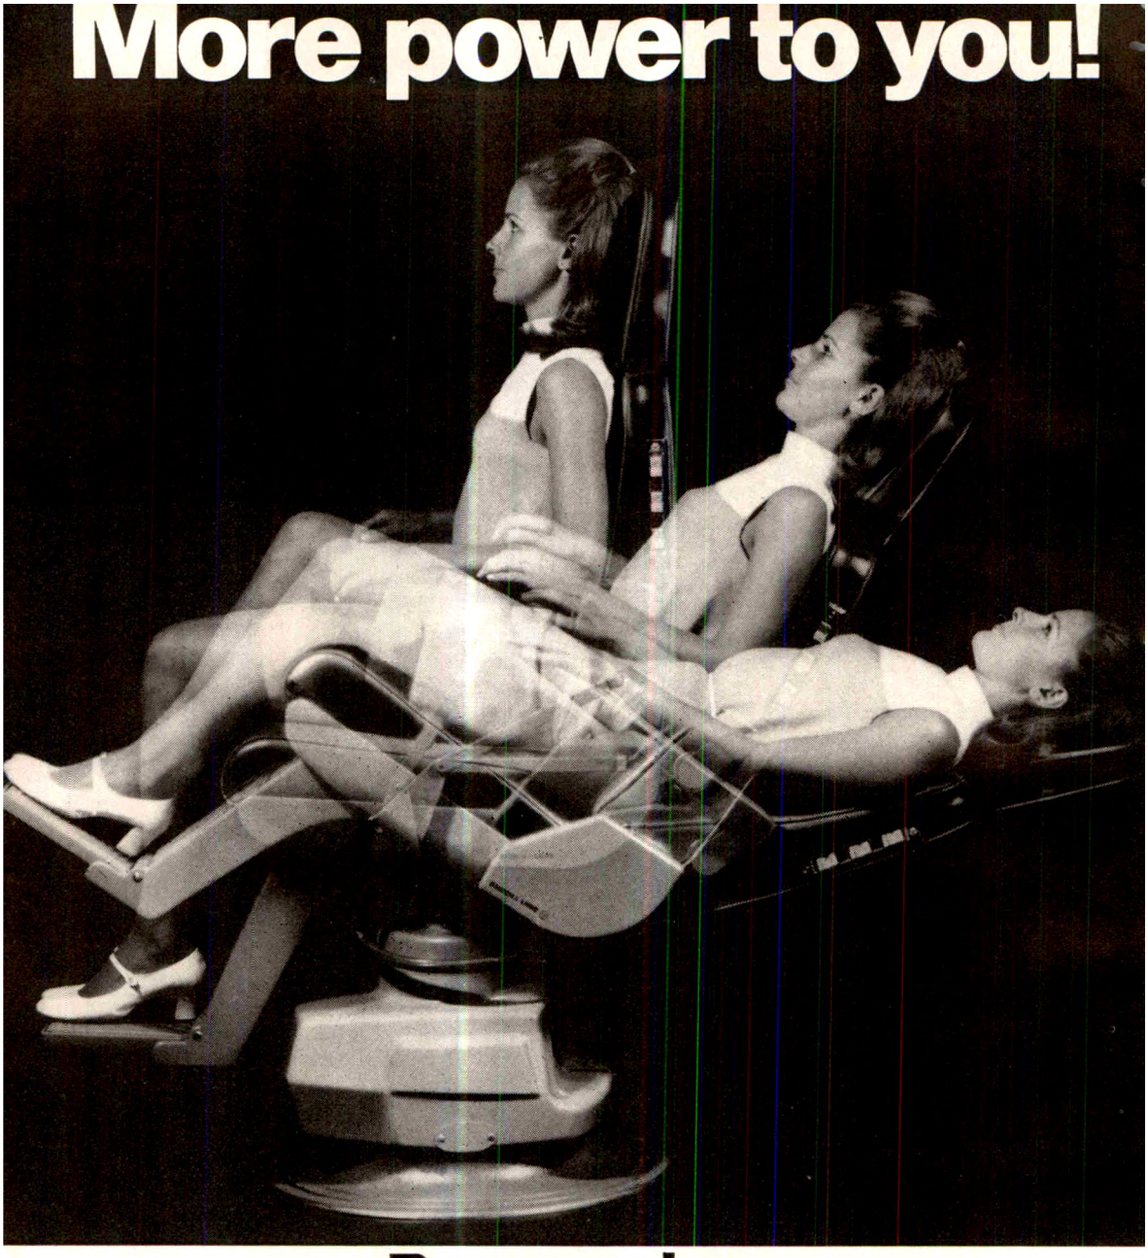
# THE 10 MOS
# QUESTIONS ABOU

## THE QUESTIONS

1. What makes PHOTOGRAY lenses work?
2. How fast do PHOTOGRAY lenses change?
3. Will the darkening-fading process wear out?
4. Do PHOTOGRAY lenses need breaking in?
5. Can PHOTOGRAY lenses be hardened or toughened?
6. How do PHOTOGRAY lenses work in a car?
7. In what types of lenses is PHOTOGRAY glass available?
8. Is the darkening-fading process comfortable to the wearer?
9. Do PHOTOGRAY glasses have a residual tint indoors?
10. Will PHOTOGRAY glass be available in a darker sunglass version?

**Note:** If you get asked other questions by your patients about PHOTOGRAY glasses that you think would be of broad interest, please send them to us. When we get enough new ones, we'll answer them in another ad.

If you'd like complete technical information on PHOTOGRAY lenses, just write to: Corning Optical Products Dept., Corning, New York 14830.



# )FTEN ASKED
# PHOTOGRAY® LENSES.

## THE ANSWERS

1. PHOTOGRAY lenses are photochromic: sensitive to ultraviolet light. When sunlight strikes them, invisible microcrystals of silver halide become darkened. When the light is removed, the crystals clear again.
2. Quite rapidly. In 60 seconds the lens is 75% darkened by sunlight and virtually fully darkened in 5 minutes. Removed from sunlight the lens clears half way in 5 minutes and 75% in 20 minutes. At their darkest, PHOTOGRAY lenses have a light transmittance of 45%. When clearest they have a light transmittance of 85%.
3. No. The photochromic reaction is locked into the composition of the glass and is completely reversible. It will keep performing for a lifetime without changing its characteristics.
4. Yes. Several complete darken-fade cycles are needed to bring PHOTOGRAY lenses up to their normal operating performance.
5. Yes, Most definitely. PHOTOGRAY lenses can be heat-treated or tempered. The tempering time is slightly different from that needed for clear lenses. Corning publishes heat-treating tables that give settings for the more popular units available.
6. Not too well. The window glass will screen out a lot of the ultraviolet light which activates the photochromic property of the lenses. This keeps the glass from darkening as fully as when it is exposed to direct sunlight.
7. PHOTOGRAY lenses come in a full range of sizes—in both single-vision and 1 piece multi-focal types.
8. Yes. The process, while quite rapid, is gradual enough to be imperceptible to the wearer. This, combined with the protection given by the darkened glass, is why PHOTOGRAY is known as the "comfort glass".
9. Yes. It's a very light, hardly noticeable tint.
10. Yes. Corning is currently in the final stages of developing a sunglass companion to PHOTOGRAY glass. Called PHOTOSUN™ glass, it's a true variable sunglass. PHOTOSUN lenses will be ready for introduction shortly.

# *Now* OCUTRON®

## *offers you visual fields*

...whenever you want
...as often as you want
without your being there

## *quickly... automatically!*

U.S. Patent Nos. 3,288,546
and 3,421,498

The Ocutron® Visual Field Tester, developed by a leading ophthalmologist, is a highly precise electronic instrument that automatically examines the visual field and records it permanently on the standard chart that you are accustomed to using and interpreting.

Without the presence of doctor or nurse, the patient tests himself by push-button response to stimuli of standard light targets as they appear within the white hemisphere. This response is electrically registered on the chart.

Difficult and time-consuming fields like the above glaucoma field are as easily and quickly tested as a simple normal field.

Background may be lighted or not, as desired, for light or dark adapted fields. Built-in check on patient fixation and patient reliability.

Particularly suitable for high volume performance. Simple enough for screening. Accurate enough for definitive, repeatable field study.

For further information write for new literature
or contact your ophthalmic distributor.

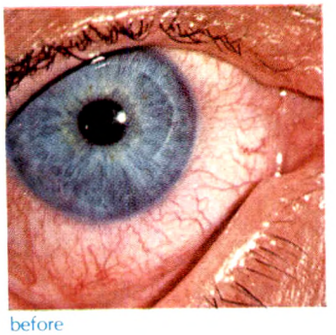
# A singular new antibiotic for the eye that works the way you think it should

## GARAMYCIN® brand of GENTAMICIN SULFATE OPHTHALMIC SOLUTION/OINTMENT

Each cc. or gram contains gentamicin sulfate equivalent to 3.0 mg. gentamicin.

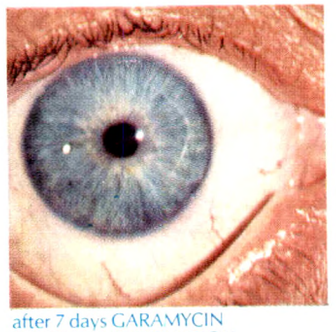
## You think it should have a wide antibacterial spectrum

GARAMYCIN's wide range of antibacterial action is equal to the spectrum commonly prescribed in the combinations of neomycin, polymyxin and bacitracin or gramicidin in the treatment of external eye infections due to susceptible organisms. It has activity against a wide variety of both gram-positive and gram-negative organisms, including the "difficult" ones—*Pseudomonas aeruginosa* strains and Proteus.



## You think it should be a single entity antibiotic

GARAMYCIN is a single entity antibiotic with a low incidence of sensitization or resistance*—can be used repeatedly with continued effectiveness, less concern about allergic potential (*Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.)



## You think it should be clinically effective

GARAMYCIN OPHTHALMIC has been described as appearing to be "...an antibiotic of choice for the initial treatment of external ocular infections."[1] It has "proved highly effective...for a wide variety of common bacterial eye infections..."[2] (due to susceptible organisms).
(1. Gordon, D.M.: Amer. J. Ophthal. 69:300 [Feb.] 1970. 2. Magnuson, R. H., and Suie, T.: JAMA 199:427 [Feb. 6] 1967.)

# New GARAMYCIN® ophthalmic

brand of GENTAMICIN SULFATE

SOLUTION/OINTMENT

†Photographs courtesy of D. Gordon, M.D., N.Y., N.Y. ††Photographs courtesy of S. Fox, M.D., Baltimore, Md.

# You think it should have flexibility in dosage forms

GARAMYCIN OPHTHALMIC SOLUTION, sterile, isotonic, and buffered to pH of tears, does not blur vision, is well suited to daytime use—supplied in an unbreakable, easy-to-handle dispenser.

GARAMYCIN OPHTHALMIC OINTMENT provides gentle emollient action and keeps medication in contact with tissues for longer periods. It is particularly advantageous for nighttime use or in non-ambulatory patients—supplied in easy-to-use ophthalmic tube.

## Clinical Considerations

**Description:** GARAMYCIN is an antibiotic of the aminoglycoside group active against a wide variety of pathogenic gram-negative and gram-positive bacteria.

GARAMYCIN Ophthalmic Solution is a sterile aqueous solution buffered to approximately pH 6.7 for use in the eye. Each cc. contains gentamicin sulfate (equivalent to 3.0 mg. gentamicin), disodium phosphate, monosodium phosphate, sodium chloride, and benzalkonium chloride as a preservative.

GARAMYCIN Ophthalmic Ointment contains, in each gram of ointment, gentamicin sulfate (equivalent to 3.0 mg. gentamicin), and methylparaben and propylparaben as preservatives in a bland base of clear petrolatum.

Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.

**Indications:** GARAMYCIN Ophthalmic Solution and Ointment are indicated in the topical treatment of infections of the external eye and its adnexa caused by susceptible bacteria. Such infections embrace conjunctivitis, keratitis and keratoconjunctivitis, corneal ulcers, blepharitis and blepharoconjunctivitis, acute meibomianitis, and dacryocystitis.

**Contraindications:** GARAMYCIN Ophthalmic Solution and Ointment are contraindicated in patients with known hypersensitivity to any of the components of these preparations.

**Precautions:** Prolonged use of topical antibiotics may give rise to overgrowth of nonsusceptible organisms such as fungi. Should this occur, or if irritation or hypersensitivity to any component of the drug develops, discontinue use of the preparation and institute appropriate therapy.

**Dosage and Administration:** GARAMYCIN Ophthalmic Solution: One or two drops every four hours. In severe infections, dosage may be increased to as much as two drops once hourly.

GARAMYCIN Ophthalmic Ointment: Apply a small amount to the affected eye two to three times daily.

**How Supplied:** GARAMYCIN Ophthalmic Solution, 5 cc. plastic dropper bottle, sterile, box of 1. GARAMYCIN Ophthalmic Ointment, 1/8 ounce tube, box of 1.

Note: Store away from heat.

E-6699 ■ $1495

**STORZ INSTRUMENT COMPANY, 3365 Tree Court Industrial Blvd., St. Louis, Mo. 63122**

*New York Showroom: 629 Park Avenue*

**Composition:**

**Inflamase**

*Prednisolone Sodium Phosphate .....0.125%
(Equivalent to Prednisolone 0.1%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

**Inflamase Forte**

*Prednisolone Sodium Phosphate 1.0%
(Equivalent to Prednisolone 0.8%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

Prednisolone Sodium Phosphate is a water soluble inorganic ester of prednisolone. It is approximately 2,000 times as soluble in water at 25°C. as is hydrocortisone.

*Licensed under patent #3,134,718.

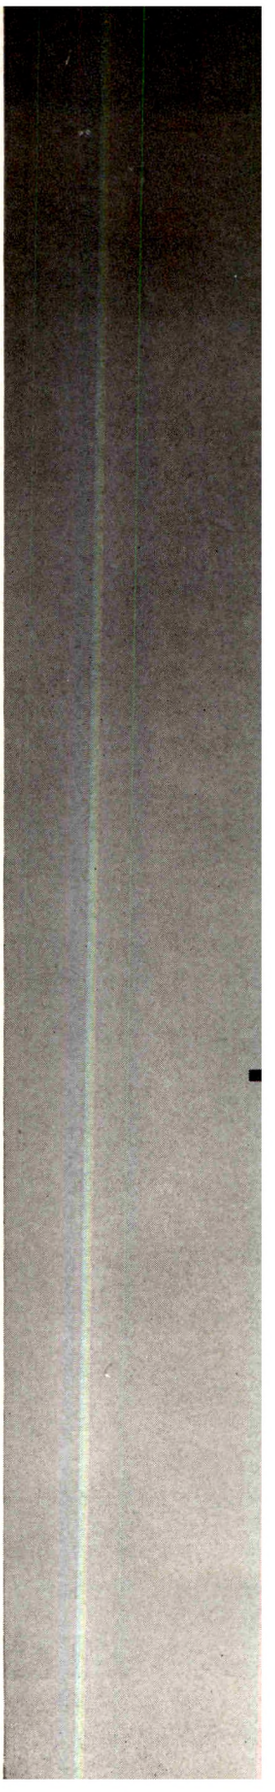
**Indications:** Inflamase and Inflamase Forte ophthalmic solutions may be used effectively in the following conditions of the anterior segment of the eye: superficial keratitis, including punctate epithelial lesions (Thygeson type), phlyctenular keratoconjunctivitis, and Sjogren's keratoconjunctivitis (with systemic steroids); deep keratitis, including interstitial or parenchymatous keratitis, acne rosacea, sclerosing keratitis; herpes zoster opthalmicus (do not use in herpes simplex); non-purulent conjunctivitis, including vernal, allergic, catarrhal; iridocyclitis; acute iritis; recurrent marginal ulceration, whether endogenous or due to atopic or contact allergies, or microbial allergy; corneal injuries, such as aseptic thermal, radiation, or chemical burns and corneal injuries following surgery or the penetration of foreign bodies; lid allergy; and non-purulent blepheritis, including catarrhal and allergic.

Inflamase and Inflamase Forte ophthalmic solutions have their principal effect on the anterior segment of the eye (cornea and the anterior uvea), with acute disorders responding more favorably than chronic disorders. Inflamase Forte 1% solution is recommended for moderate to severe inflammations particularly when rapid control is desired. In stubborn cases of anterior segment eye disease, systemic adrenocortical hormone therapy may be required. When the deeper ocular structures are involved, systemic therapy is necessary.

**Dosage:** Initially, 1 or 2 drops placed in conjunctival sac every hour during day and every 2 hours during night until improvement occurs. Thereafter, 1 or 2 drops 2 to 4 times daily.

**Contraindications:** Contraindicated in acute herpes simplex, ocular tuberculosis, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva; fungal diseases of the eye. Purulent conjunctivitis, purulent blepharitis, and infectious conditions are contraindications to the use of steroids.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.



**Warning:** If irritation persists or develops, patient should be advised to discontinue use and consult prescribing physician.

**How Supplied:** 5 cc plastic squeeze bottle with dropper tip. These products are sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area, or other areas with the dropper tip of the bottle. Keep bottle tightly closed when not in use.

Store in cool place. Protect from light.

**Caution:** Federal law prohibits dispensing without prescription.

Nikon, the name synonymous with the world's finest optics, now adds a new applanation tonometer to their ophthalmic instrument line. Its ease of operation during routine biomicroscopic examination will amaze you.

When not in use, it simply swings to one side of the microscope.

First displayed at the Academy of Ophthalmology meeting in Las Vegas in September, it joins these other important new Nikon ophthalmic products.

- The Nikon Retinapan 45° Fundus Camera
- Hand Ophthalmoscope
- Binocular indirect ophthalmoscope with an erect, unreversed image
- Stereo photo adapter for the slit lamp microscope
- 30D Aspheric Ophthalmoscopic lens

For complete information on these superb additions to the Nikon Ophthalmic line write or call: Nikon Inc., a subsidiary of Ehrenreich Photo-Optical Industries, Inc., 623 Stewart Avenue, Garden City, N.Y. 11530 (516) 248-5200.

## Only Glazcote lets the plastic eyeglass wearer see what he's missing.

Just one dot of Glazcote® on each side of a plastic or hard resin lens fills hair line scratches and helps protect the lenses against future possible scratches. This unique product was developed for the Space Program, for use on spacecraft windows, and to clean, polish and protect astronauts' plastic face shields. And continuous use of optically clear Glazcote helps keep the lenses clean, static free, and polished as well as filling hair line scratches. ALLERGAN Irvine, Calif.; Montreal, Canada

# Recommend Glazcote...just a dot does it.

THINK
TWICE

The Phaco Emulsifier enables the surgeon to emulsify and simultaneously aspirate many senile cataracts. It is also a sophisticated aspiration device for congenital and traumatic cataracts which are soft and require minimal or no emulsification.

Prompt rehabilitation of the patient is achieved because the limbal incision is limited to 2mm compared to the 19mm standard incision.

HOW IT WORKS. Emulsification of the cataract is achieved by the .0015 inch forward and backward excursion of a titanium tip 40,000 times a second. Emulsified lens material is simultaneously aspirated through the center of the hollow tip. Sterile isotonic fluid is introduced into the anterior chamber of the eye to replace the aspirated lens material and fluid. A constant fluid pressure within the anterior chamber is maintained by a flow control system.

COMMERCIAL AVAILABILITY of the Phaco Emulsifier is the culmination of more than six years' research and product refinement by Cavitron and the surgeon[1] who originated the technique.

A COMPREHENSIVE PROGRAM has been established and includes surgeon and operator training classes, a per operation charge plan for use of the system, and regular factory servicing and inspection.

SYSTEM USAGE Twenty-two surgeons at six medical institutions have performed over 450 extractions using the Phaco Emulsifier.

## for significantly faster cataract convalescence

# Born free

Like trend-setting CM-II, the new Mentor* CM-III Portable Operating Microscope gives total freedom to the surgeon—freedom to swing the microscope in when he wants it, out when he doesn't, freedom to turn away momentarily, freedom to carry it anywhere and set it up quickly, freedom from wearing or holding any equipment.

What's new is CM-III's steadiness. We have entirely redesigned the arm, pivot, and clamp for firmer, smoother action. When you swing it back in you return to the same focus, same angle, and same field of view without readjustment. (It's parafocal.) The maneuvering handles are sterilizable.

And the coaxial light source. The neat pool of light makes finding the subject much easier, then illuminates it at an intensity of 600 foot-candles. The optics present a bright, wide, flat field at your choice of magnification—7X, 10.5X, or 14X.

The price of the CM-III, complete with attractive, lightweight carrying case, is only $1060. Let us send you complete information. Mentor Division, Codman & Shurtleff, Inc., Randolph, Mass. 02368.

available as sterile ophthalmic drops and sterile ointment...

Alcon *dedicated to advances in ophthalmic therapy*

DESCRIPTION: *DROPS*—Sterile suspension containing: *Active:* Dexamethasone 0.1%, Neomycin (present as sulfate) 3.5mg/cc, Polymyxin B Sulfate 6000 units/cc; Vehicle: Hydroxypropyl Methylcellulose 0.5%; *Inactive:* Sodium Chloride, Polysorbate 20, Hydrochloric Acid and/or Sodium Hydroxide (to adjust pH), Purified Water; Preservative: Benzalkonium Chloride 0.004%. *OINTMENT—Active:* Dexamethasone 0.1%, Neomycin Sulfate equivalent to 3.5mg/gm Neomycin; Polymyxin B Sulfate 6000 units/gm; *Inactive:* White Petrolatum, Anhydrous Liquid Lanolin; Preservatives: Methylparaben 0.05%, Propylparaben 0.01%. CONTRAINDICATIONS: This drug is contraindicated in tuberculous, fungal, and most viral lesions of the eye (herpes simplex/dendritic keratitis); vaccinia, varicella; acute purulent conjunctivitis and acute purulent blepharitis, and in those persons who have shown hypersensitivity to any of its components. PRECAUTIONS: Extended use may cause increased intraocular pressure which should be checked frequently and may result in overgrowth of nonsusceptible organisms. Perforation can occur in diseases causing thinning of the cornea. Discontinue use if sensitivity occurs. Not recommended for long-term use in pregnant patients.

# REACTIONS FOLLOWING INTRAVENOUS FLUORESCEIN

MERVYN R. STEIN, M.D.
*San Francisco, California*

AND

CHARLES W. PARKER, M.D.
*St. Louis, Missouri*

Intravenous fluorescein is an important diagnostic and research tool in ophthalmology. The most common side effects have been nausea and vomiting. One manufacturer (Smith, Miller & Patch) warns physicians of no other adverse reactions. There are several reports[1-15] of more serious reactions, however, with some culminating in shock or cardiac arrest (Table 1). Toxic reactions have been reported,[15] and in addition, many reactions of an allergic type have been described. If these reactions were indeed allergic, identification of the responsible allergen would be important, as well as development of effective test procedures for the identification of susceptible individuals, as has been done in the case of penicillin allergy.[16]

This paper reports nine patients who sustained systemic reactions to intravenously administered fluorescein (Table 1). Intradermal skin testing for allergic reactivity was performed in the first three, using both sodium fluorescein 5% (Fluorescite) and fluorescein-conjugated human serum albumin (F-HSA). Hemagglutination and hemagglutination-inhibition studies were carried out on sera from these three patients in an attempt to demonstrate circulating antibodies to fluorescein. Additionally, hemagglutination studies were performed on the sera obtained before and after intravenous fluorescein administration from eight control patients.

From the Departments of Ophthalmology (Dr. Stein) and Medicine (Dr. Parker), Washington University School of Medicine, St. Louis, Missouri. This study was supported in part by Public Health Service Research Grant EY-00336.

## CASE REPORTS

*Case* 1—This 61-year-old white woman had had multiple admissions for hypertension, atherosclerotic heart disease, atrial fibrillation, diabetes mellitus, and gout. She had a history of allergy to sulfonamides characterized by the development of urticaria. In 1964, an infranasal choroidal mass was discovered in the right eye. She was lost to follow-up until July, 1968, when the mass had enlarged to a size of 5-6 disk diameters. A fluorescein (Fluorescite) angiogram was attempted one month later. Ten ml (500 mg) of sodium fluorescein was injected into the antecubital vein. About 30 seconds later she became nauseated, then developed labored breathing with wheezing, followed by cyanosis and apnea. The femoral pulse was weak. An airway was inserted, and 0.5 ml of 1/1000 epinephrine was injected subcutaneously. Respiratory movements returned spontaneously; at first her breathing was shallow, and later it became deeper. The electrocardiogram revealed atrial fibrillation with multifocal premature ventricular contractions (PVC). The blood pressure stabilized at 220/120, and the PVC decreased in frequency. She was observed in the cardiac care unit for 48 hours and recovered uneventfully. The right eye was enucleated in April, 1969; pathologic diagnosis was malignant melanoma of the choroid.

*Case* 2—This 42-year-old black physician was seen in January, 1969, with central serous retinopathy in the left eye. He had a history of serum sickness following a tetanus antitoxin injection several years before, and he reported urticaria after the ingestion of oranges. There was a family history of

asthma. His general health was otherwise unremarkable. A diagnostic fluorescein (Fluorescite) angiogram was performed. Sixty seconds after a 10 ml injection he became nauseated. His vital signs were within normal limits, and his lungs remained clear, but in another 60 seconds, transient urticaria appeared on the left thigh.

*Case* 3—This was a 43-year-old exiled Cuban physician, referred to Dr. Alan Kolker because of central serous retinopathy. At the time of his examination (April 15, 1969), he was taking a corticosteroid (Prednisone) in a dosage of 40 mg daily. He had had allergic rhinitis during the previous year. A papillary reaction occurred on the tongue following penicillin therapy. The patient developed generalized urticaria with facial edema within five minutes of the intravenous injection of 10 ml of sodium fluorescein (Fluorescite). There was no laryngeal edema. The urticaria quickly subsided.

In addition to these cases of drug reactions to intravenous fluorescein, there were two cases of pruritus, two cases of urticaria, one case of urticaria with hypotension, and one case of dizziness with hypotension seen at Washington University School of Medicine in the period of January, 1968, to June, 1971.

## Experimental procedures

*Skin testing*—Skin testing was performed

in two steps, using sodium fluorescein (Fluorescite) and F-HSA at a maximal concentration of 7.7 mg/ml. The latter was obtained by conjugating fluorescein isothiocyanate with human serum albumin in a bicarbonate buffer and purifying the material by prolonged dialysis.[17] The extent of the conjugation was determined with a spectrophotometer on the basis of absorbance at 280 and 490 mμ. It was estimated that there was an average of 13 fluorescein groups per molecule of albumin.

The patients were scratch-tested with 1:100 and 1:10 dilutions of sodium fluorescein and F-HSA. Since the scratch tests were negative at both concentrations in the three patients tested, intradermal injections were employed. The first two patients were skin tested by the authors. The third patient (a physician) was unable to return so the solutions were sent to him and he was skin-tested by a medical colleague. He was no longer taking systemic corticosteroids at the time of skin testing. The skin test solutions were tested in normal subjects for their ability to produce nonspecific irritation, and there were no reactions at any concentration.

*Human sera sources*—Blood was obtained from all three patients who had experienced the drug reactions; in the first patient, it was taken one month later, in the second, it was taken two days afterward, and in the third, two months after the reaction. A control group of eight patients undergoing fluorescein angiography was also studied. There were five with diabetic retinopathy, one with pseudoxanthoma elasticum, one with macular degeneration, and one with retinal detachment. Blood specimens were obtained prior to and 10 to 14 days after the fluorescein study. A nonspecific control serum was collected from a laboratory technician.

*Rabbit sera*—New Zealand rabbits were immunized with one mg of F-HSA in complete Freund's adjuvant injected into the footpads, and serum was obtained four to six weeks later. On the basis of quantitative precipitin analysis, the serum was found to contain 200 μg/ml of antibody. Rabbit antiserum to human gamma globulin was obtained by the method of Thiel and associates.[16]

*Hemagglutination technique*—A modification of the technique employed by Thiel and associates[16] for the detection of hemagglutinating antibodies to penicillin and its derivatives was used. In this procedure fluorescein isothiocyanate is covalently bound to human red blood cells and the cells are agglutinated by sera containing anti-fluorescein antibodies.

Sensitization of human red blood cells with fluorescein was accomplished in the following manner. Washed Group O, Rh-negative human red blood cells were obtained from a single donor and mixed with an equal volume of Alsever's solution. The cells were washed three times with a solution containing 0.15 M NaCl, 0.008 M $K_2HPO_4$ and 0.002 M Na $H_2PO_4$,pH 7.4 (phosphate-saline). An equal volume of 0.15 M NaCl solution was then added to the packed red blood cell volume to produce a 50% suspension. One volume of the suspension was added to a solution containing 30 volumes of a 0.15 N sodium barbital buffer, pH 9.8, and 0.3 volume of a suspension of fluorescein isothiocyanate in acetone containing 5 mg/ml. The resulting mixture was incubated for one hour at 37°C, washed three times with a wash solution (20.5 g dextrose, 20 g EDTA disodium salt, and 4.2 g NaCl in one liter of distilled water, with 2 g of bovine serum albumin added just before use) and the blood cells were finally diluted to a 1% suspension in this medium.

Serial four-fold dilutions (from 1:4 to 1:256) of human and rabbit sera were made up in duplicate using phosphate-saline. Half of the tubes received $2.5 \times 10^{-4}$ M sodium fluorecein in phosphate-saline. An equal volume of the 1% fluorescein-treated red blood cell suspension was added to all the tubes. They were shaken thoroughly and then examined for hemagglutination and hemagglutination inhibition at 30 and 90 minutes. An identical set of tubes was made up and used in carrying out a subsequent indirect Coombs test.

A 2-plus hemagglutination reaction[18] was consistently obtained in this experiment with rabbit anti-fluorescein sera at the 1:256 dilution. Furthermore, the reaction was consistently inhibited by unbound sodium fluorescein at a concentration of $10^{-3}$ or less. Fluorescein-treated red blood cells incubated with phosphate-saline alone did not agglutinate.

*Indirect Coombs procedure*—The Coombs procedure was employed to accentuate the hemagglutination response. Rabbit anti-human gamma globulin was absorbed with the cells preincubated with sera, and observed for agglutination at 30 and 90 minutes.

## Results

*Skin testing*—The scratch tests were negative to both sodium fluorescein and F-HSA at both the 1:10 and 1:100 dilutions in all three patients. The third patient had a positive intradermal response to F-HSA at the 1:10 dilution, but showed no reaction to sodium fluorescein. Unfortunately, we did not conduct, nor did we witness the skin testing, and the role of albumin in the skin reaction was not elucidated. Therefore, the signifiance of this positive result is questionable. The other two patients had negative intradermal reactions.

*Hemagglutination reaction*—The sera from the three patients who manifested idiosyncratic reactions to intravenous fluorescein, as well as the sera obtained before and after fluorescein injection in eight control patients, produced negative hemagglution reactions. The nonspecific control serum was weakly positive at the 1:4 dilution, and its reaction with antigen-coated red cells was inhibited by sodium fluorescein.

Testing with the Coombs reagent produced a weakly reactive response at the 1:4 dilution in the pre-angiographic serum of one of the control patients with diabetic retinopathy, but was negative in the post angiographic serum from the same patient. Among the three patients being studied, the first had a moderate reaction at the 1:4 dilution. Both responses were inhibited by sodium fluorescein. Frequently, false-positive results are obtained with the hemagglutination test at the lowest titer (i.e., 1:4). Therefore, we cannot place a great deal of confidence in these elevations, especially since the nonspecific control had a 1:4 titer.

## Discussion

We have collected 55 cases of reactions to intravenous fluorescein in 54 patients (Table 1), including several of our own cases.[1-15] The majority of the reactions (67.3%) were of an allergic type (Table 2), and most of these were characterized only by urticaria. About 29% (16) of the reactions were of a severe nature, and 11 presented a shock-like picture. Seven of the 16 severe reactions appeared to be allergic in type and these consisted of two cases of shock, two cases of respiratory obstruction, a case of respiratory arrest, a case of hypotension, and a case of hypotension with loss of consciousness. Cardiac arrest, shock, loss of consciousness and myocardial infarction were the main diagnoses in the non-allergic group. In most cases, recovery was uneventful, but one patient developed a myocardial infarction several hours after the procedure and died.[3] Of the cases in which the sex was stated, half were male. The age range was from 24 to 75 years with a mean of 48.2 years.

For each institution, the prevalence rate was calculated from the total number of reactions versus the number of fluorescein studies, where this information could be obtained. It varied from 0.1 to 1.14%. The prevalence rate for severe reactions was even lower, ranging from 0.06% to 1.00%. We cannot be sure whether the differences between institutions were significant, as the number of drug reactions and angiographic studies in some series were small. Nevertheless, with this limitation in mind, the mean rate for all types of reactions in this review was 0.60% (six reactions per 1000 angiographic studies performed) and for severe reactions it was 0.41% (four reactions per 1000 angiographic studies performed). This incidence is worthy of consideration, especially for institutions performing large number of studies. In

TABLE 2

TYPES OF REACTIONS FOLLLOWING INTRAVENOUS ADMINISTRATION OF FLUORESCEIN

| Degree | Allergic Type | Non-allergic Type |
|---|---|---|
| Mild | 30 | 9 |
| Severe | 7 | 9 |
| Total | 37 | 18 |

the light of the seriousness of some of the reactions, as well as the sporadic nature of their occurrence, certain safety precautions should be taken. It would seem desirable to perform the study in a room large enough to allow for comfortable treatment of the patient.[3] Administration of the fluorescein through a small indwelling catheter[3] has value, since the vein can be kept open in the event that a severe reaction should develop. An emergency tray should be available.[3,4,10] It should contain epinephrine HCl solution 1:1000, diphenylhydramine HCl (Benadryl) parenteral, aminophylline, metaraminal bitartrate (Aramine), hydrocortisone sodium succinate (Solu-Cortef), parenteral fluid with intravenous adapters, syringes, needles, an airway, and oxygen.[19,20] Finally, one should be prepared to act in a rapid and efficient manner, with maximum utilization of ancillary staff.

Drug allergies of the immediate hypersensitivity type are thought to be the result of an immunologic response of the host to a hapten (drug)-protein combination. Nearly all drugs attach themselves by reversible bonds to proteins, especially albumin, but this combination does not appear to be antigenic. Apparently antigenicity is determined by the ability of the drug to produce a stable or covalent bond with the protein.[21,22]

In the case of many drugs, the allergic reaction is probably the result of the conjugation of serum protein with degradation products of the drug. Support for this concept is provided by experiments on penicillin allergy. Several penicillin derivatives, notably the penicilloyl group,[16] have been found to be the important antigenic determinants. These derivatives conjugate covalently with protein; however, penicillin and several other derivatives, which are poor sensitizers, are bound reversibly to serum albumin.[21]

Fluorescein, when injected intravenously, is adsorbed in large part (50-84%) to plasma proteins (mainly the albumin fraction),[23] and also to red blood cells (15-17%).[24] The resulting bond is weak.[25,26] Webb and associates[27] have shown through paper chromatography studies in rats that fluorescein is not degraded in animal tissues, but is excreted mainly in the urine, unchanged, and partly by way of the liver after conjugation with glucuronide. It is also rapidly excreted in the urine in man.[28]

Do these drug reactions have an immunologic basis, and, if so, is fluorescein the responsible allergen? Since fluorescein does not bind covalently to the plasma proteins it would not appear to be an important sensitizer, and this is supported by the available experimental results. Antibodies to fluorescein were not conclusively demonstrated in any of our own or our collected cases. One of our three patients (Case 3) manifested a positive intradermal test to F-HSA at a 1:10 dilution. This may have been an immunologic reaction to conjugated fluorescein, but we did not perform the test, nor did we observe the reaction. Furthermore, testing with albumin would have been useful to strengthen the case for allergy to fluorescein itself. The Prausnitz-Küstner test was performed in two reported cases,[4,10] and skin testing was employed in two others.[1,2] All results were negative. In addition, we were unable to demonstrate the development of circulating antibodies to fluorescein by the hemagglutination technique in the eight control patients, or in the three cases of drug reactions. The argument that the fluorescein-tagged red blood cells were insufficiently sensitized with fluorescein does not seem valid, since rabbit antisera to fluorescein at high dilutions gave strongly positive agglutination reactions. Although Case 1 and one of the control patients had positive responses at the 1:4 dilution in

the indirect Coombs test, the significance of a 1:4 titer is questionable. Insofar as fluorescein has not been found to be degraded metabolically,[27] the formation of small quantities of breakdown products has not been excluded, and these could act as sensitizers.

It is possible that the inciting haptene was a contaminant. According to their weekly recall list (May 8, 1970), metallic and ionic mercury have been detected in fluorescein vials by the Food and Drug Administration. Mercury has resulted in hypersensitivity reactions.[29] However, it cannot be implicated as the primary cause of these allergic reactions, since several cases of urticaria were noted subsequent to the second release of the mercury-free fluorescein.[7,13]

Finally, the reactions may have been caused by nonallergic mechanisms. A vasovagal type response is a distinct possibility in several cases (i.e., Case 9). Since many drugs cause histamine release in vitro in the absence of an antigen-antibody reaction,[30] histamine should be considered as a possible causal factor. There is little evidence, however, that drug reactions of the type described in this review are mediated by this pathway. An embolic effect from the rapid injection of a bolus of dye, with transient ischemia of vital organs, must be raised as a possible mechanism. Several cases appear to be the result of a direct toxic effect—a probable contaminant resulted in a series of pyrexic reactions at the Bascom Palmer Eye Institute.[15] Inorganic mercury can result in an acute toxic reaction,[31] however, the concentration of mercury administered in the cases cited in this study was probably too low to be toxic.

If some of these reactions were due to an allergy to fluorescein, how were these patients sensitized? The topical route would be a likely source of sensitization, as many of the patients in this review had received topical fluorescein previously. However, Theodore and Schlossman[32] state that topical fluorescein "is rarely, if ever, a sensitizer." Sensitization from a previous intravenous injection might be considered, but we uncovered only two cases in which previous angiographic studies had been performed. One patient had a reaction to the second, but not to the first injection;[3] in the other patient, urticarial reactions occurred after both studies.[13] If the intravenous route is an important pathway for sensitization, the incidence of adverse reactions might be expected to increase as more and more patients are exposed to repeat angiograms. Sensitization by another route is possible since fluorescein is a widely distributed substance in our environment.

Since there is an increased risk of drug allergies in atopic individuals,[33] it is important to probe for a history of allergy where this is possible. A positive history was obtained in seven of 14 cases where it was specifically sought, and in three of these there was a history of drug allergy. In three other cases, a history of a drug reaction was obtained, but it was not typically allergic in nature. We have no information regarding allergy among the other cases depicted in Table 1.

## Summary

Nine cases of reactions following intravenously administered fluorescein are reported with a review of the literature. Skin testing was performed in three of the nine patients, using commercial fluorescein and fluorescein isothiocyanate conjugated with human serum albumin (F-HSA). A positive response to F-HSA at the 1:10 concentration occurred in one of them, but the reaction was not witnessed by the authors. Hemagglutination and hemagglutination inhibition studies were conducted on sera from these three patients and from eight control subjects who had undergone fluorescein angiography. Significant antibody levels to fluorescein could not be detected in patients or controls. Reactions to intravenous fluorescein are reported to occur in 0.6% of patients undergoing angiography. The majority of the reactions were of an allergic type (67.3%), but a significant percent (29.1%) were severe in na-

ture. Therefore, an emergency tray and oxygen should be readily available when angiography is performed. The possible mechanisms underlying these reactions are multiple.

ACKNOWLEDGMENTS

# JOHANNES KEPLER ON THE EYE AND VISION

HARRY H. MARK, M.D.
*New Haven, Connecticut*

This year the scientific world celebrates the quadricentennial birthday of Johannes Kepler (Fig. 1), and it appears fitting on this occasion to touch on some aspects of his work concerning ophthalmology. It seemed desirable on two accounts:

1. The pertinent Latin books are not available in English, and only fragments have been translated into German. This inaccessibility of original sources may explain errors published repeatedly by various authors. It is hence a purpose of this communication to present Kepler's views as he himself stated them.

2. The short comments on these views are aimed at providing a degree of perspective. Studying the work of great scientists of the past affords insight into the general art of scientific investigation.[1] It serves to remind us that the intellectual effort required for scientific progress has not been changed or lessened by the more sophisticated tools available today. The ontogenesis of each individual scientist historically follows the phylogenesis of science at large.

Concerning ourselves with ophthalmology alone hampers a complete portrayal of Kepler's genius. He is best known for his three laws of planetary motion which paved the road to Newton's celestial mechanics and modern space trips. His elucidation of refraction through lenses—the Dioptrice—ranks second only to Euclid's classical Catoptrics. In this field, Kepler explained the workings of Galileo's terrestrial telescope and proposed the astronomical one, also known as the Keplerian telescope, variations of which were incorporated into numerous other optical instruments such as the microscope. His work in astronomy and optics required a good deal of mathematical knowledge; in this area, too, Kepler added new knowledge on logarithms and infinitesimals.

Reprint requests to Harry H. Mark, M.D., 2 Church Street South, New Haven, Connecticut 06519.

## SOURCES

The material of ophthalmic interest is contained in two books. The first, commonly referred to as *ad Vitellionem,* or *Astronomiae pars optica* (Fig. 2), was published in 1604, and its title translates: *Supplements to Witelo, in connection with the optical part of astronomy, especially on the proper observations and estimations of the waning diameters of the sun and moon, with examples of significant eclipses. In this book the reader is offered, among many other new subjects, a most lucid treatise on the mode of vision, and the use of the ocular humors, contrary to views held by opticians and anatomists.*

The second and much shorter book (Fig. 3) was published in 1611, and essentially complements and supplements the first. Its

full title translates: *Dioptrics, or, demonstration of the effects which the newly invented telescope has on vision and the visible.* In this second book, Kepler's theory of accommodation is of particular interest to us.

## Anatomy

Kepler's main endeavor is in astronomy, but, as he says, "astronomical observations depend ultimately on the human eye. Therefore, in order to avoid inaccuracies and deceptions, it is necessary to study the eye, and to begin with its anatomy." Since, however, Kepler had no first-hand knowledge of the subject, he accepted "the torch from authorities in anatomy in order to illuminate with it the physical problems."

The anatomy of the eye depicted in Figure 4 was drawn by Kepler mainly from Felix Palter,[2] in conjunction with works of John Jessen[3] and Fabricius ab Aquapendente.[4] Figure 4 conforms accurately to the eye depicted in Vesalius' *Fabrica,*[5] and is not far removed from ancient Galenic concepts.

## Kepler's concepts

*The orbit*—This is the bony shield of the eye. The eye protrudes out somewhat in order to attain a wider visual field. The orbital axes are directed downwards and temporally to facilitate social intercourse and also to see better the feet and mouth, needed for locomotion and nourishment. To this end, too, the face between the nose and the cheek is depressed. The forehead protrudes above the eyes to shield them from overhead lights.

The nose between the orbits forms a dam to prevent one eye from seeing the other, which would impair vision by reflections. That part of vision, however, which is thus obscured for one eye, is complemented by the other, for with two eyes Nature achieved complete vision.

*The eyelids*—These protect the eyes by keeping them moist and by wiping off foreign matter and discharge. In order to function properly as occluders and wipers they

Fig. 3 (Mark). Title page of Kepler's Dioptrics, 1611.

must remain in contact with the globe in all positions and with their entire surface; this can be achieved only by hemispherical shutters anchored on each side of a sphere, as the eyelids are. The eye brows and lashes shield the eye from excessive light and from foreign bodies. Upon blinking, the lashes also work as fans, blowing approaching dust away.

*The globe*—This has a spherical form for easy rotation on all axes, essential for complete vision. The center of rotation is also the center of the sclera, uvea, and retina. The lens is slightly in front of this center.

The globe resembles an onion with its stalk in the brain. The hard membrane of the brain forms the sclera and cornea, the soft membrane of the brain forms the sclera and cornea, the soft membrane forms the choroid posteriorly and the uvea anteriorly, and the brain itself forms the optic nerve and retina.

*The conjunctiva*—This springs from the periosteum of the orbital rim. It contains nutritive vessels and also helps retain the globe in the orbit.

*The cornea*—The cornea is avascular. Its radius of curvature is smaller than that of the sclera, and indeed may not be spherical at all but rather spheroidal in order to counteract spherical aberrations.

*The sclera*—This is white in order to reflect light away, for its absorption by a dark color would generate injurious heat.

*The iris*—This is variously colored to accentuate it from the white sclera and black pupil. In this manner, we can tell immediately when someone is looking at us. The stiff and smooth body of the iris occasionally emits sparks by internal friction, similar to those produced by stroking a cat or freshly cut hair.

*The pupil*—The pupil dilates in the dark up to three times its normal size in order to admit more light to the lens. It constricts in bright light and on looking at near objects.

*The choroid*—This is half as thick as the iris, and is attached to the sclera by fibers.

*The ciliary processes*—These originate in the uvea (not in the retina) and are anchored to the lens, which they nourish. With the lens they form a septum between the aqueous and vitreous humors. The processes are all black, swell in bright light, and shrink in the dark. The purpose of the whole uvea is to provide darkness inside the eye.

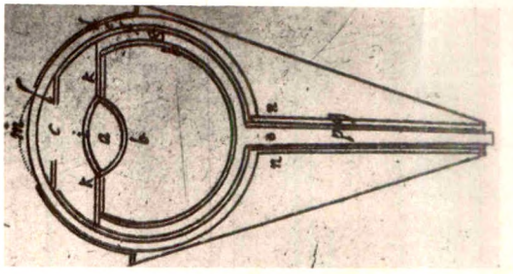

Fig. 4 (Mark). The human eye.

*The aqueous humor*—This is in direct contact with the cornea, iris, lens, hyaloid, and ciliary processes. It has no membrane. Its function is to fill the chambers and to maintain a uniform refractive index between the cornea and lens.

*The crystalline lens*—This is located only a little in front of the center of the globe. It is encapsulated by a membrane to prevent penetration of aqueous humor. The crystalline is an optical lens with a spherical, convex front surface parallel to the corneal surface, and a hyperbolic posterior surface. As a biconvex lens, it reduces and inverts the image of a distant object when the receptive screen is farther behind the lens than the length of its radius.

*The vitreous humor*—This is covered by the hyaloid membrane which separates it from the aqueous humor and the retina. Its refractive index is lower than that of the lens, for otherwise light would not emerge convergent from the lens. The vitreous holds the retina taut against the uvea.

*The retina*—This originates in the optic nerve and spreads forward to end in front of the ciliary processes. Its form is thus larger than the hemisphere and correspondingly, our visual field is wider than 180°. Kepler states: "That this is so I have proven to my-

self, for I often saw the sun and my shadow simultaneously; one does not miss by much to see one's own ears, particularly if they are large."

*The optic nerve*—This is located diametrically opposite the pupil and lens, and is therefore the site of best vision. It possesses a twisted channel connected to the brain. No optical image can be transmitted through the nerve, only the visual impressions from the retina. The two nerves unite and cross in order to connect the brain equally to both eyes; when one side of the brain or nerve is damaged, the eye will thus maintain its contact with the sensorial centers. The nerves do not cross in order to see singly with both eyes, for we can see double even with intact nerves.

## Comment

Kepler's anatomy of the eye bears heavily on his physiological optics. In general, we note his then common teleologic approach which assigned to structure an ulterior purpose. This intimate association sounds naive today, but is still held subconsciously at present, for one always tacitly assumes that any structure has a purpose, or, as von Bruecke put it, "teleology is a lady without whom no biologist can live; yet he is ashamed to show himself in public with her."

Kepler himself occasionally expressed conflicting teleologic views. At one point, for instance, he asserts that two eyes were not made in order to protect vision in case one is lost "for Nature designs nothing against loss"; at another point he explains that the purpose of the two optic tracts is to preserve vision in case one is damaged. Today we may simply accept two eyes as a fact, and then proceed to study the advantage of the situation extant. One wishing to explain why we have two eyes would look to the evolutionary development of symmetry in living organisms, rather than extrapolate their existence from the advantages of their function.

The structure of the crystalline lens was theoretically deduced by Kepler from its function. Since spherical lenses cause optical aberrations detrimental to a clear image on the retina, the lens (and cornea) had to be given a spheroidal shape. Similarly, the refractive index of the vitreous had to be higher than that of the lens to accommodate Kepler's theory which called for light from the lens to converge on the retina. Such deductions are commonplace in mathematics and physics, but may have dubious value in biology. Kepler's reasoning is thus amazing in its proximity to the actual facts as we now know them.

On the other hand, Kepler's visual theory suffered because of inaccurate anatomical data. Chief among them was the central position of the lens in the vitreous cavity. This location was assigned to it in antiquity, was formalized by Galen, and this belief continued until the 18th century when cataract extractions began. Fabricius ab Aquapendente correctly placed the lens right behind the pupil, but the idea did not prevail, so that, for instance, a notable anatomist and ocular surgeon such as William Cheselden in the 18th century wrote of the large space between the pupil and lens.

Interesting also is the description of the aqueous humor in direct contact with its surrounding tissues. A capsule containing the humor has been described as late as the 19th century, and a disease, aquocapsulitis, was then assigned to it.[6] Evidently even in anatomy newer knowledge is not necessarily tantamount to enlightenment.

## Vision

"I shall describe the process of vision as never before explained or comprehended to the same degree," Kepler states. "Vision ensues when the entire external hemisphere, and somewhat more, is brought into the concave surface of the retina. How this image on the retina becomes conscious to the soul I shall leave for others to explain."

He continues: "Each single point of the external object forms the apex to a cone of light which has its base on the anterior sur-

face of the crystalline lens. To this cone corresponds another one with the same base but with an apex on the retina. The anterior cone is somewhat refacted by the cornea, the posterior one by the posterior face of the lens. All cones from all points intersect at the pupil on their way to the lens. The divergent rays from the objective point become convergent by refraction at the cornea. Therefore, the larger circle of light formed on the cornea shrinks to fit the smaller aperture of the iris, and is still smaller when it reaches the lens. No refraction occurs on the anterior surface of the lens because the refracted rays from the cornea fall perpendicular to it. The rays do, however, become more convergent by refraction at the hyperbolic surface of the posterior lens, and they finally unite exactly at the center of the optic nerve head. Best vision is attained when all the rays from one objective point passing through the pupil are reunited after two refractions (at the cornea and posterior lens) at one point on the retina (Fig. 5).

"Another point of the object, to the right of the central one, will send an oblique cone of light to the pupil. It will cross the first cone at the pupil and will land upon the face of the lens to the left of the first one, similar to what happens in a camera obscura. The crystalline lens in the eye represents the posterior wall of the camera. Behind the lens no rays intersect; therefore, an object located between the pupil and the lens will appear inverted (Fig. 6). The image on the lens is still blurred because not all rays have yet intersected; only after refraction by the lens

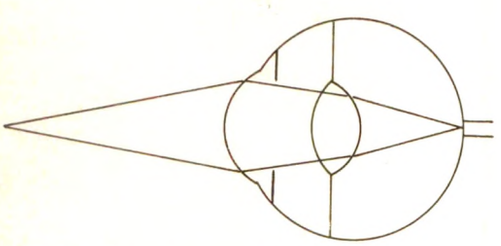

Fig. 5 (Mark). The course of light from a point-object through the eye (after Kepler's text).

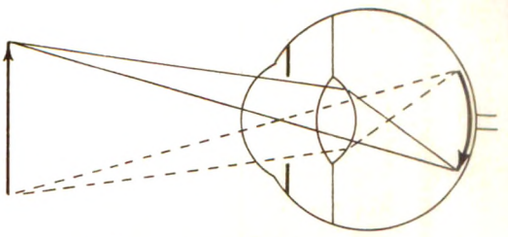

Fig. 6 (Mark). Image formed in the eye by an extended object (after Kepler's text).

do all rays unite perfectly on a point on the retina.

"According to optical principles, which I have elsewhere sufficiently proven by several demonstrations, the image on the retina is inverted in relation to the external object. To those who object, I say that vision is not an action, though illumination is one. Vision is a passive impression—a reaction to the action of light. Besides, the inverted image is still completely proportional in the relative position of its details. The eye also knows its own position, and when it sees something high it spontaneously turns upwards.

Rays from lateral points of the objects form oblique cones on the way to the eye. They are therefore refracted not only by the cornea and posterior lens face but also by the anterior lens. Furthermore, the entry pupil now is vertically oval. All this causes these rays to form an indistinct image on the retina. The retina itself has only a weak sensorial power at these peripheral areas. Hence peripheral vision does not satisfy the eye but merely invites it to turn toward it to form direct and distinct vision. The peripheral images flow as in a funnel toward the optic nerve, and contribute to the formation of a complete picture.

*Spherical aberration*—"Rays incident on a spherical lens at its periphery are more refracted than those which pass it centrally; in a convex lens they converge to a focus nearer the lens. In the eye this phenomenon is counteracted in three ways: First, the pupil excludes the peripheral parts of the crystalline lens. Second, the posterior face of this

lens is aspherical, and, finally, the peripheral parts of the retina are closer to the lens than the central parts. The image on the retina remains sharp even when the pupil is dilated since the other two factors are still operative.

"Very near objects always appear blurred because the focal point of their rays recedes into the head, leaving on the retina a diffuse circle instead of a sharp point.

*Physiologic diplopia*—"When both retinas are similarly affected, we see singly; when dissimilarly affected, we see two pictures of the same object. In Figure 7, the eyes (Band C) are looking at an object (F). Point D is projected on the retina of eye B at a different place from point F, whereas in eye C both points project to the same place. Therefore, point D appears double.

*After-imagery*—"Vision is a sensual perception by the brain of the stimulated retina. The visual spirits are either offered to the brain by the retina, or else the brain requests the information from the retina. Light and colors cause a change within the structure of the retina rather than merely paint a picture on it; this is analogous to the burning of paper by means of light concentrated upon it. The change in the retina is not contemporaneous with the stimulus, for the image may remain after the stimulus had subsided.

*Depth perception*—"Distant objects as well as small ones subtend a small angle at the eye—near or large ones, a larger angle. The distance of an object from the eye may be judged best by the use of both eyes, since these are separated from one another by a certain distance. As long as there is a noticeable ratio between the interocular distance and the distance of the viewed object, the latter distance may be perceived.

"A single eye may also judge distances by being moved from one vantage point to another. This in effect creates vision from two separate angles similar to simultaneous vision with the two eyes. Furthermore, the eye is capable of sensing the degree of refraction in its media and the degree of diminution in the intensity of light passing through its humors, and in this manner judge the distance of the object from which the light emanates.

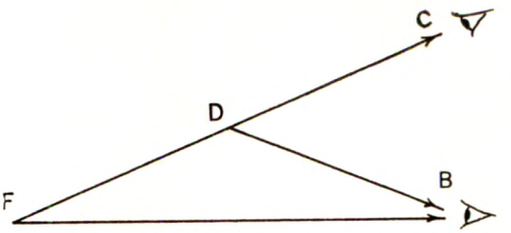

Fig. 7 (Mark). Physiological diplopia explained.

*Inhibition*—"Of objects of equal size, those which are brighter appear larger, and the less luminous ones appear smaller. A brightly illuminated area of the retina inhibits clear vision in the neighboring areas."

## Comment

Prior to Kepler, the commonly accepted theory of vision saw the lens as the perceptive organ. The notion originated with the ancient Greeks and was taken over by Alhazen in his book on optics. The book was written in Arabic in the 10th century and was translated into Latin by Witelo in the 13th. Even such a notable optical luminary and contemporary of Kepler as John Baptista Porta[7] accepted it.

Toward the end of the 16th century, a few observers noted that the crystalline lens, when removed from the eye, acted as any other optical lens. Among them was the obscure Franciscus Maurolycus[8] and the more widely known Felix Plater.[2] Lacking insight into physical optics, they understood the action of the crystalline lens to be one of mere magnification.

It was thus Kepler's brilliant accomplishment to confirm that the lens was indeed an optical instrument, and as such he documented its action within the eye. He did this by applying to the eye his thorough knowledge of physical optics in general and of lenses in particular. So convincing was his demonstration that the revolutionary idea of the inverted retinal image was accepted in the bargain. The experimental proof was

furnished by Christopher Scheiner a few years later.

Reducing the function of the eye to clearly comprehensible physical events had both immediate and delayed consequences. Once the veil of mystery had been lifted from the act of vision, man needed no more stand in awe of it. It became unnecessary to worry whether the images seen through spectacles and telescopes were real or merely a demoniac deception brought about by these heretic devices. It was sometimes argued that if God wanted man to see more, He would have given him the necessary eyes. But when Kepler showed that the eye functioned along the same lines as the artificial optical tools, the whole problem evaporated into thin air.

Similarly, once it had been understood how the crystalline lens functions, its removal could be contemplated in more rational terms. The first obstacle to cataract extraction was thus overcome. All that was lacking in Kepler's time was the proof that cataract was indeed an opacity of the lens. This proof came 100 years later.

The camera obscura, a name Kepler coined, was known since antiquity and commonly used in astronomy. This knowledge, together with the superficial resemblance of the eye to such a camera, must have prejudiced Kepler. He thus made incidental light intersect at the pupil in front of the lens, asigning the latter a secondary role—a role dictated perhaps also by the deep position of the lens within the globe.

On the other hand, his conflicting views concerning the dioptrics of the eye are biased in favor of the newly discovered lens. At one time he stated that the cone of light from the object is based at the lens; another time he stated its base to be the cornea, from which it converges onto the lens.

Today we know, of course, that the eye is mainly a dioptric apparatus which, contrary to a camera obscura, may still function without an iris diaphragm. Its nodal point (or points) is in the posterior part of the lens or behind it, the cornea being the main refracting surface. But all this is founded on what Kepler began, and came to us refined through the able minds of C. F. Gauss and H. L. Helmholtz in the last century.

Kepler's idea that the curvatures of the cornea and anterior lens were identical was taken from Alhazen. The latter required the concept since he believed that light was lost by refraction, and hence could not be accurately perceived. To Kepler's theory of vision it was irrelevant.

Among the many novel ideas expressed by Kepler we note: (1) The correspondence of the visual field to the area of the retina. (2) The varying visual angles at which objects of different size or distance subtend at the eye. (3) The inverted and reduced retinal image. (4) The proprioceptive consciousness of the position of the globe in space. (5) The difference between central and peripheral vision. (6) Inhibition processes within the retina. (7) Corresponding retinal points as prerequisite to single binocular vision. (8) The ability of the eye to sense the degree of refraction occurring in its media. This last idea is similar to his notion that a free-floating image may be perceived by the onlooking eye.

Of lasting value remain Kepler's elucidation of the refractive errors and of accommodation, which follow directly from his visual theory, based upon available anatomical and optical data.

## Refractive errors

Kepler states, "Those who see clearly at distance but indistinctly at near are helped by convex spectacles, and those who see poorly at distance but well at near are helped by concave spectacles. How amazing that while the practical use of this fact is so widespread, its scientific cause remained obscured.

"I myself believed, with Porta and others, that convex lenses help vision because they magnify. They do so indeed for all eyes, but render the object more distinct only for those who see well at distance. Similarly,

concave lenses reduce a distant object for all, but clarify it only for those who see it clearly at near; for those who see clearly at distance these lense may indeed blur the object.

"For those who see well only at distance, convex lenses modify the cone of light emanating from a near object to appear as if it arrived at the eye from distance—that is, parallel. The light is thus focused on the retina, and the near object is well perceived. Without these lenses, all light from a near object unites behind the retina, and upon it remains merely a blurred image by the overlapping circles.

"For those who see well at the near, the concave lenses modify the light from a distant object to appear as if it arrived from near (Fig. 8), and thus the object is well perceived. Without these lenses, the light from a distant object will unite before reaching the retina, and when it reaches it, will again be wider and confused. This I found confirmed by experience: I know two gentlemen of nobility one of whom can read the smallest print, but at such close distance that he cannot use both eyes together. With deeply concave lenses he sees perfectly well at distance, but these same lenses blur the distance pictur for me although I wear lenses that are concave—but weaker. Each myopic person needs his specific strength of lenses. The other gentleman had early acquired the ability to see perfectly well at great distance, but was almost blind for near objects. With convex spectacles he reads quite well.

"It is false that only old people see poorly at near and the young at distance. Both conditions may occur at all ages. With age, however, the power of changing the view from distance to near weakens, and hence those who had healthy eyes at youth see well only at distance. Furthermore, it is more natural and less tiring to hold the eyes parallel rather than convergent on near objects. Therefore, too, tired old eyes remain focused for distance. Those who do much close work in their youth become myopic."

## Comment

Spectacles were invented 300 years before Kepler wrote the paragraphs above, but many objected to their use for various reasons. To pious men, the use of man-made contrivances to improve on God's work seemed preposterous. Others feared damage to the eye by looking through them. Georg Bartisch,[9] the oculist, warned against their use for he could not conceive an eye seeing better with something in front of it than through empty space. His opinion reflects perhaps the imperfect art of lens manufacture.

The scientific foundation which Kepler gave to the function of spectacles did not help popularize their use. Those who were literate and rich enough to read scientific books such as Kepler's wanted no part in the mundane business of making and selling spectacles. Those who peddled spectacles did not read, nor could they understand the appropriate books if they did. The manufacture of optical lenses lacked standardization, marketing was haphazard, and above all, there was no way to arrive at one's need of spectacles except by trial and error.

Ocular astigmatism was described by

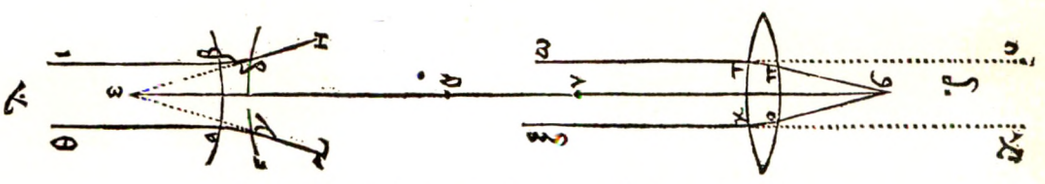

Fig. 8 (Mark). The action of concave and convex spectacles.

Thomas Young 200 years later, and the whole field was most lucidly summarized by Franz Donders[10] in 1864. It is only in the past 100 years that spectacles are applied, at least theoretically, in a truly rational manner.

### Accommodation

"It is impossible for the retina, which is immobile within the eye, to receive clear images simultaneously from near and far. Some see well at distance, some at near. Those who see everything confused have diseased eyes due to faulty structure. In those who see everything distinctly, either the retina or the lens must change its position relative to one another.

"It is probable that in young and healthy eyes the globe is alternately compressed and dilated at the equator when vision shifts to different distances. In this manner, the fundus moves farther or nearer to the lens. It also corresponds to the constriction and dilation of the pupil during this act. The ciliary processes, anchored centrally at the lens, function as a muscle: When they contract, the equator is pulled inward and the globe becomes elongated, removing the fundus backwards to focus the retina for near objects. The opposite occurs when the eye looks at the distance. This is also why the ocular humors (except the lens) are fluid and compressible."

### Comment

It would have required the wildest imagination of a physicist in 1600 to suppose that a lens, including the crystalline lens, could change its form and power; the compressible globe was much closer to observable and possible facts. In addition, the supposed origin of the ciliary processes from near the equator facilitated the notion that their contraction would act upon it. Even so, Kepler's theory of accommodation still holds true for a number of animal species. In man, the actual mechanism was ascertained 250 years later, when tools for observation became available and minds were ready for the observed data.

With the dynamic theory of accommodation, Kepler's work on vision reached its climax—a work which began by studying the effect of lenses upon light, and then applying the observed phenomena to the human eye. The endeavor followed a systematically chartered plan, from one object point to an extention of that point—from the cornea in front to the retina in back, from the optic nerve head centrally to the retinal periphery. And once the static conditions in the normal eye were known, the elucidation of pathologic deviations followed as a matter of course, and even dynamic changes could be conceived.

Kepler reaped a rich harvest by using a deductive method, for, as he told a friend, he was no empiricist concerned with the accumulation of observed data. As such he could hardly have published his work in a modern biological journal that insisted on "original data" and "documented facts." But, as Huxley wrote, "those who refuse to go beyond the facts rarely get as far."

### Summary

A rendition from primary sources of Johannes Kepler's work pertaining to ophthalmology is presented on the anniversary of his 400th birthday. This includes his ideas on ocular anatomy, the dioptrics of the eye, physiologic optics, the nature of the refractive errors, and the mechanism of accommodation.

Kepler's work affords us a good perspective of the state of knowledge about the eye and vision at a time when rational science was emerging from darkness. In addition, it accurately reflects the entire man: his successful struggle to rid himself of old modes of reasoning, the helplessness of his deductive method in face of faulty data, and finally the utter irrelevance of his momentous discoveries to the practice of ophthalmology then and for centuries thereafter.

OPHTHALMIC MINIATURE

Nothing you lack to make your outward eye
Totally blind, for what is seen by all
To be a stone you seek to glorify,
A senseless piece of stone that you would call
A god! Put out your hand and let it fall
Upon it, touch it, taste it! You will find
Your hand says "Stone!" although your eyes are blind.

# ELECTRON MICROSCOPY OF POSTERIOR POLYMORPHOUS DEGENERATION

S. ARTHUR BORUCHOFF, M.D., AND TOICHIRO KUWABARA, M.D.
*Boston, Massachusetts*

Posterior polymorphous degeneration is clinically characterized by peculiar opacification of the posterior limiting layers of the cornea. Both sporadic[1] and familial[2] cases have been reported, and most authors state that the disease is nonprogressive.[2]

This report concerns the case of a patient with a strong family history of posterior polymorphous degeneration, who showed a progressive course and anomalies of the angle. The surprising feature was the presence of cells on the posterior surface of the cornea having the characteristics of epithelium.

## CASE REPORT

*Case* 1—A 35-year-old white man was first seen at the age of 15 years by Dr. D. G. Cogan, who made a diagnosis of "peculiar dystrophy of the posterior corneal surface." Over the course of years, the corneal opacities gradually increased (Fig. 1). At the age of 33 years, the patient developed painful bullous keratopathy in the left eye. Gonioscopy revealed that extensive areas of the trabeculum were covered by broad synechiae. However, the intraocular pressure was normal. The rest of the examination was normal except for the presence of a Marcus Gunn jaw-winking phenomenon on the left side. There had never been injury or surgery to the eyes.

The family pedigree is noted in Figure 2. Of particular interest is the patient's brother, who also showed broad peripheral synechiae and progressive disease resulting in decompensation of the posterior limiting layers of the cornea and epithelial edema. Because of painful bullous keratopathy, a penetrating keratoplasty was carried out in the left eye. The excised corneal button was studied histologically and electron microscopically.

*Histopathologic findings*—One-half of the button was fixed in 10% formalin and embedded in paraffin for histological study. Paraffin sections stained with hematoxylin-eosin and with periodic acid Schiff reaction revealed that the cornea had a loosely attached epithelium, edematous stroma and a thickened Descemet's membrane. The thick Descemet's membrane consisted of a thin layer of strongly PAS-positive membranes anteriorly and a thick layer of lamellated substance posteriorly. The endothelium was uneven in thickness (Fig. 3). No wart was found in the Descemet's membrane. No scar tissue or inflammatory cells were found in the corneal button. Cresyl violet staining showed normal metachromasia in the stroma. No abnormal substance was deposited in the stroma.

*Electron microscopic findings*—The other piece of the button was fixed in 4% glutaraldehyde solution in phosphate buffer (pH 7.2) for 20 minutes at room temperature. The tissue was cut into smaller pieces and postfixed in 10% osmium tetroxide for 90 minutes at a cold temperature. The tissue was dehydrated in ethyl alcohol, treated with propylene oxide and embedded in an epoxy resin. Thin sections were stained with uranyl acetate and lead citrate and examined with an electron microscope.

A surprising abnormality was found by electron microscopy. Cells covering the posterior surface of the cornea were found to have all the characteristics of epithelium instead of endothelium.

The cells were extremely flat and formed a layer two to three cells thick (Figs. 4 and 5). At several areas, cells formed clumps of four to five cell thickness. The cells had elongated nuclei and thin cytoplasm. At the basal zone, the cells were flat and had occasional basal infoldings and hemidesmosomes. The apical surfaces of the cells which faced the anterior chamber had massive microvilli (Figs. 6 and

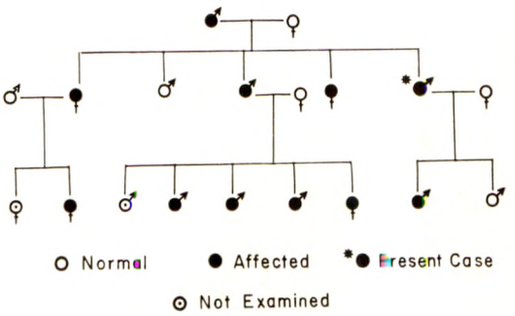

Fig. 2 (Boruchoff and Kuwabara). Pedigree of the family of the case.

7). The microvilli were taller than the plicae of the normal superficial epithelium of the cornea and were irregular in size. Lateral cell membranes were joined by numerous desmosomes which had prominent tonofibril attachments (Fig. 7). No tight junctions were found at the apical ends. The cytoplasm had a relatively electron dense matrix in which keratofibrils were seen abundantly. The fibrils formed bundles of varying sizes. Microorganelles were extremely sparse. Mitochondria, endoplasmic reticulum and Golgi apparatus were rare or entirely missing from the cytoplasm. Only a small number of glycogen particles was seen among the keratofibrils. Occasional cells, especially in the area of the clumpings, were larger and contained inclusion bodies, which presumably were phagocytized debris (Fig. 8).

A thick Descemet's membrane measuring about 30μ had formed between the lining cell of the anterior chamber and the stroma (Fig. 5). This consisted of a thin (3μ) portion which was highly PAS-positive light microscopically at the anterior limit and a thick (15-25μ) layer of abnormal collagen fibers with a minimal mucoprotein content in the posterior region. The thin portion of the Descemet's membrane was uniform in thickness and consisted of coarse granular substances which formed 100 nm spacings in several locations (Fig. 9). The fine structural appearance of the membrane was identical to that of the anterior portion of the Descemet's membrane of an adult cornea. The abnormal collagen layer consisted of irregular layers of fine fibrils, short collagen fibers and basal lamina substance (Figs. 5 and 9). A thick basement membrane was formed beneath the cells. The fibrillar substance formed two kinds of banded structures. One was made of aggregated short fibrils with a banding of 100 nm spaces, and the other was formed of longer (1-3μ) fibrils with 70 mm spacings. These components were scattered throughout the tissue without any specific pattern of distribution (Fig. 9). No cell, fibroblastic or otherwise, was found in this layer.

The swollen stroma showed a less distinct lamellar arrangement of collagen fibers. Spaces between collagen fibers were widened. Fine fibrillar substance was abundantly found between the collagen fibers and between the lamellae. The stroma cells were rounded and contained sparse microorganelles. Basal laminar substance was found abundantly accumulating around the stroma cells (Fig. 10).

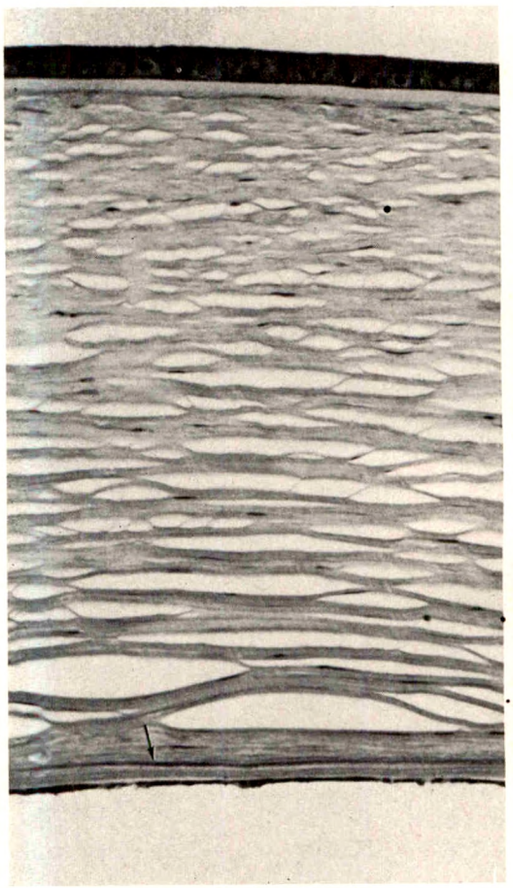

Fig. 3 (Boruchoff and Kuwabara). The central portion of the corneal button. The stroma is edematous. A thin PAS-positive layer (arrow) and thick PAS-negative layer form the Descemet's membrane (paraffin section, PAS and hematoxylin stain, ×80).

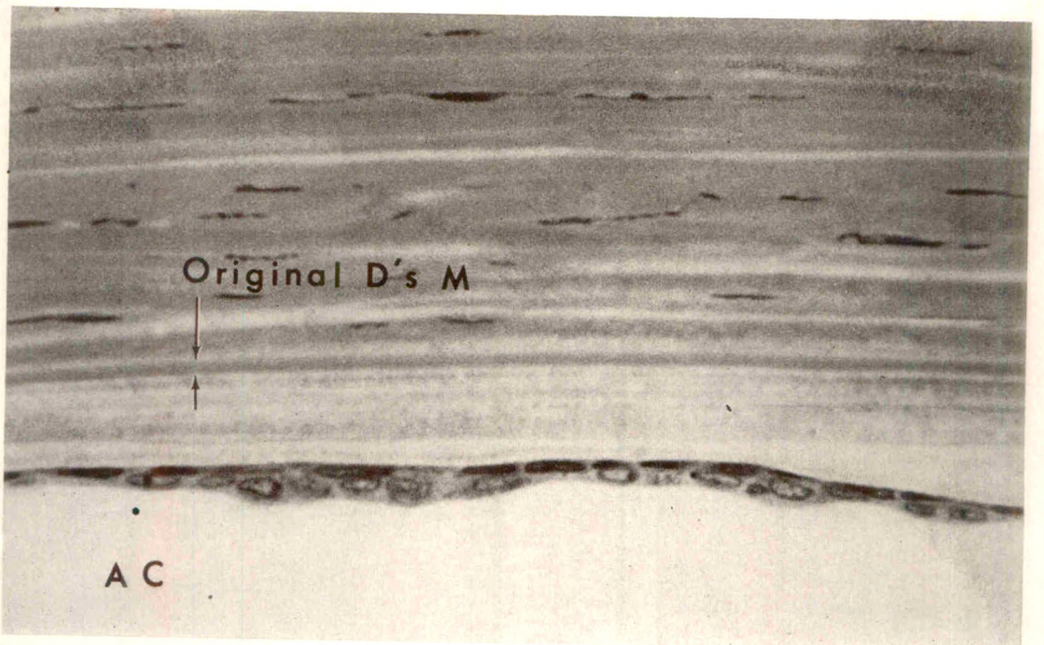
Fig. 5 (Boruchoff and Kuwabara). Low magnification electron micrograph of the posterior portion of the cornea. The surface cells are of an epithelial type. An abnormal membrane is formed between the cell layer and the original Descemet's membrane. This anterior portion of the Descemet's membrane is uniform in thickness and appearance (×4400).



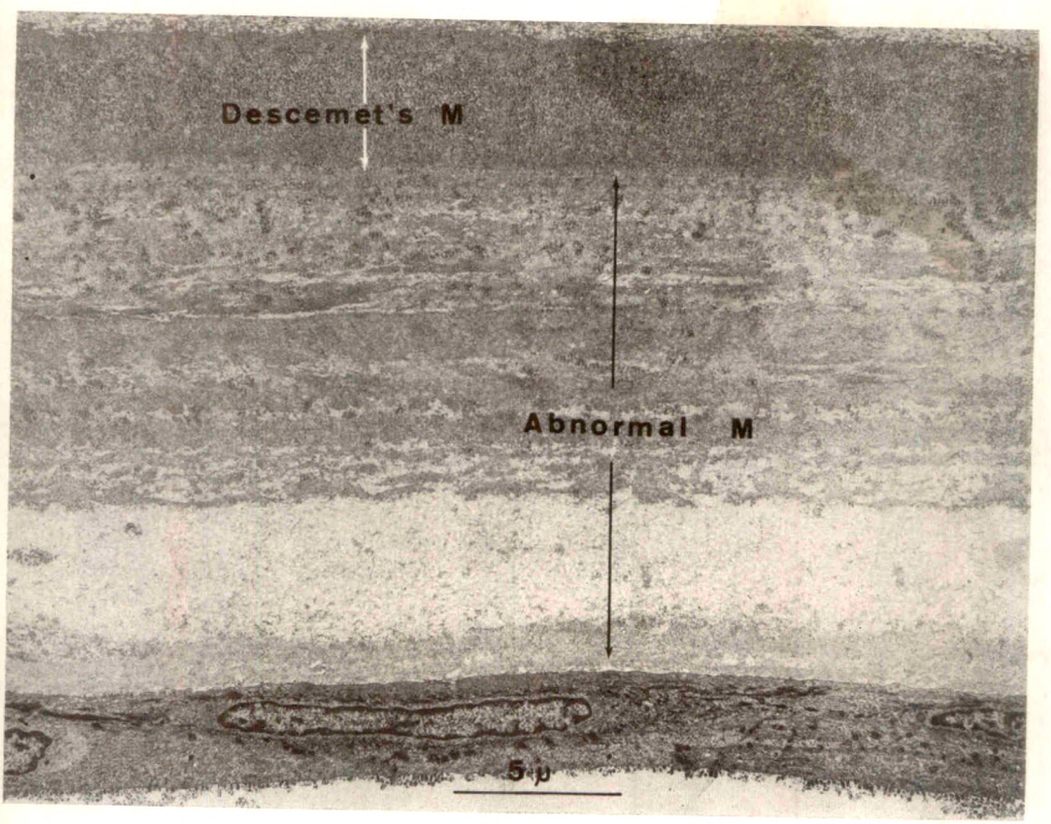


Fig. 4 (Boruchoff and Kuwabara). The cells covering the posterior surface of the cornea form a layer two to three cells thick. A thick acellular layer is formed between the thin Descemet's membrane and the posterior surface cells. Epoxy section, 0.5μ thick (toluidine blue, ×400).

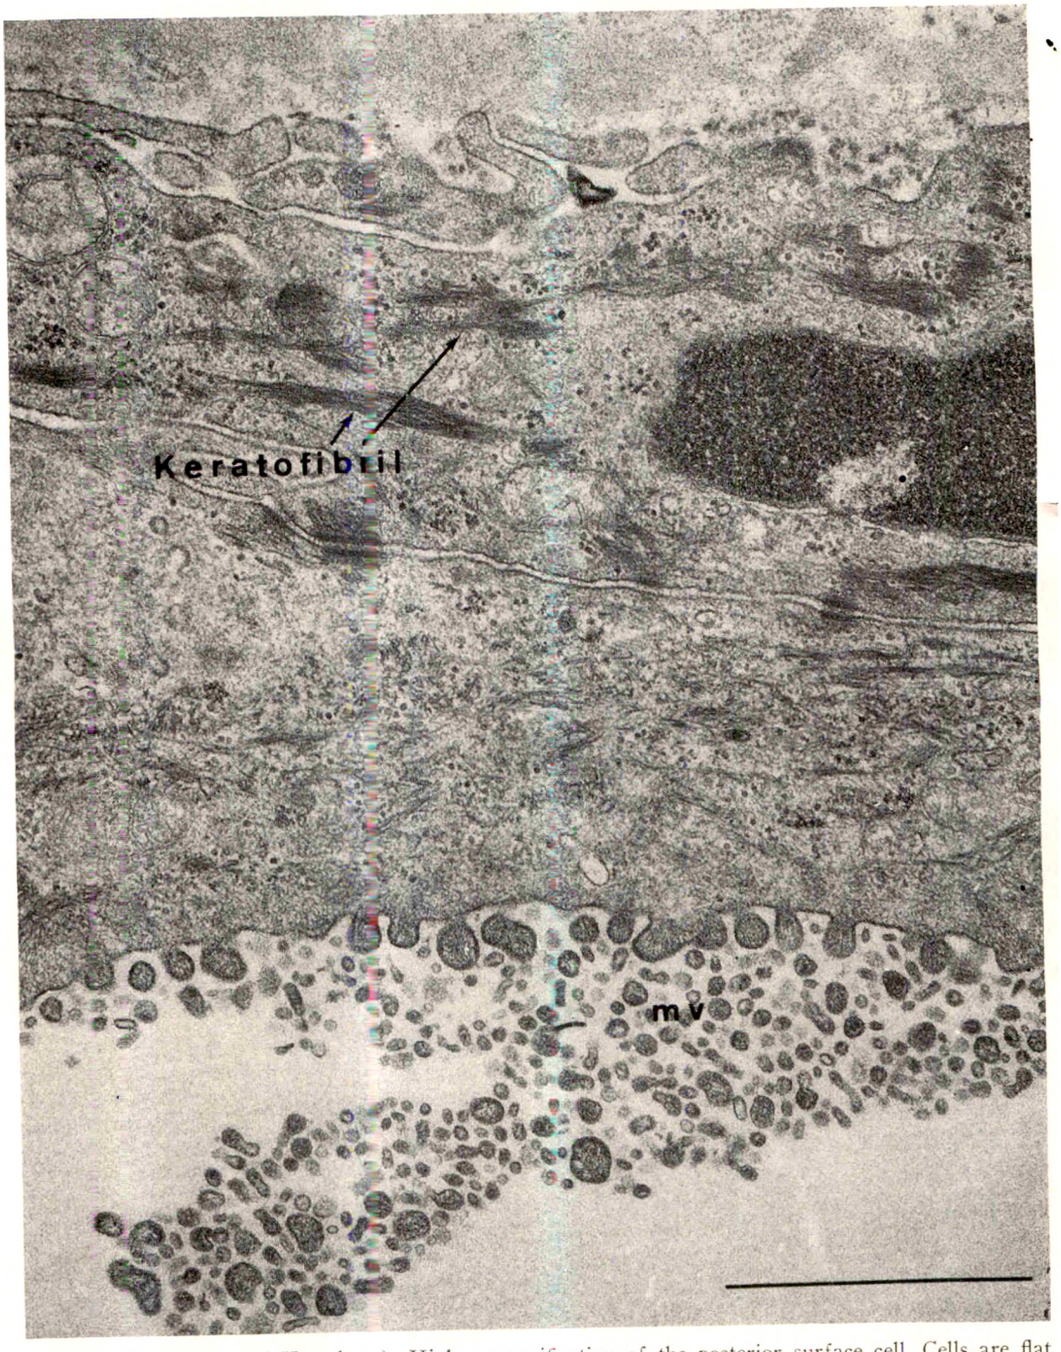

Fig. 6 (Boruchoff and Kuwabara). Higher magnification of the posterior surface cell. Cells are flat and joined by numerous desmosomes. Microvilli are seen abundantly at the apical end. The base of the cell is infolded. Hemidesmosomes are infrequent. The cytoplasm contains keratofibrils (×40,000).

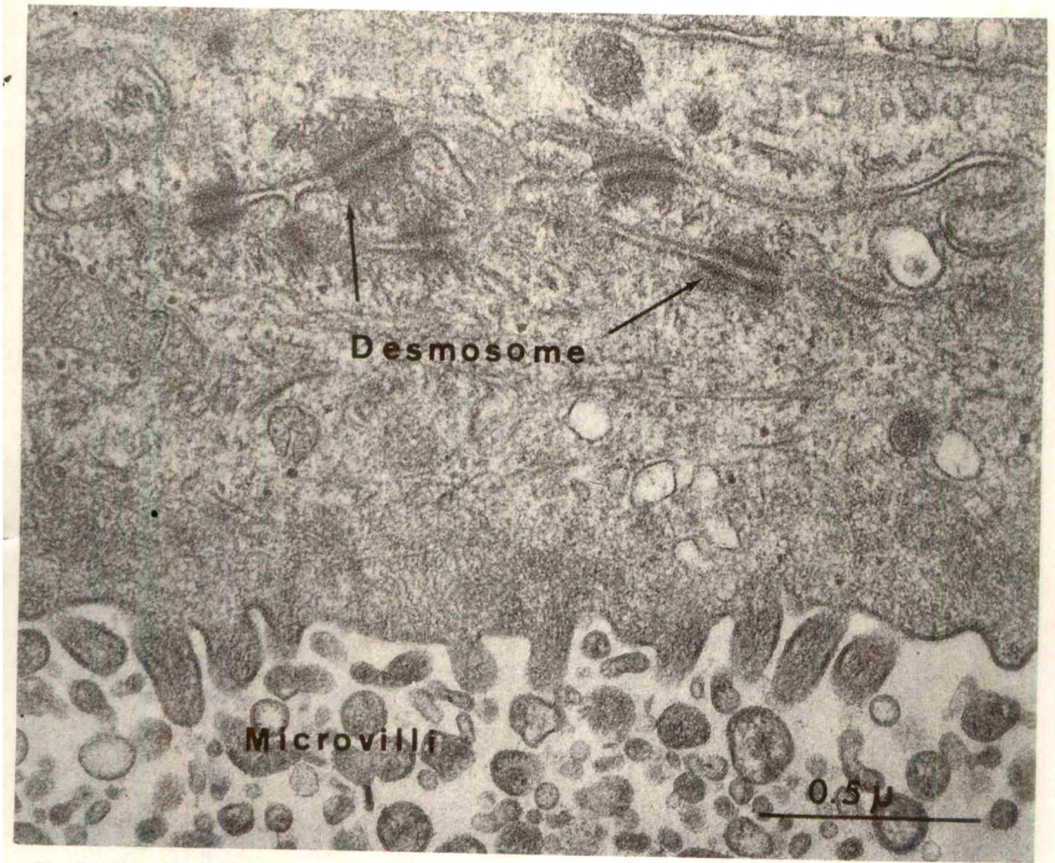

Fig. 7 (Boruchoff and Kuwabara). Higher magnification of the apical portion of the posterior surface cell. Microvilli are in varying sizes. Desmosomes between the adjacent cells are conspicuous. The cytoplasm contains tonofibrils, vacuoles and a little glycogen. Metabolically active microorganelles are sparse (×60,000).

The epithelium at the anterior corneal surface was loosely attached to the underlying connective tissue. The basal cells had markedly infolded cytoplasm at the base and the basement membrane was incomplete. The cytoplasm of the basal cells was electron lucent and contained sparse microorganelles. The wing and superficial cells appeared to be normal.

## Discussion

Since the patient had no history of ocular injury or surgery, the presence of epithelial cells on the posterior surface of the cornea was unexpected. The cytoplasmic appearance of these cells definitely indicated that they were cells of the epithelium: microvilli, abundant keratofibrils, desmosomes and sparse microorganelles. Characteristic structures of the endothelium, such as rich microorganelles, apical tight junctions and flat apical surfaces, were totally absent.

The origin of the epithelium on the posterior surface of the cornea has not been demonstrated in the present study and is subject to speculation. The most likely possibility is an embryonal displacement of the epithelial cells into the anterior chamber. Intraocular displacement of the ectodermal cell can occur when the optic cup is formed at the earliest stage of the development of the eye. Since the case presented here has a strong familial dominancy and has other abnormalities in the anterior chamber, an unspecified developmental disorder may have taken place in the earliest stage of formation of the eye.

Members of the family also showed vari-

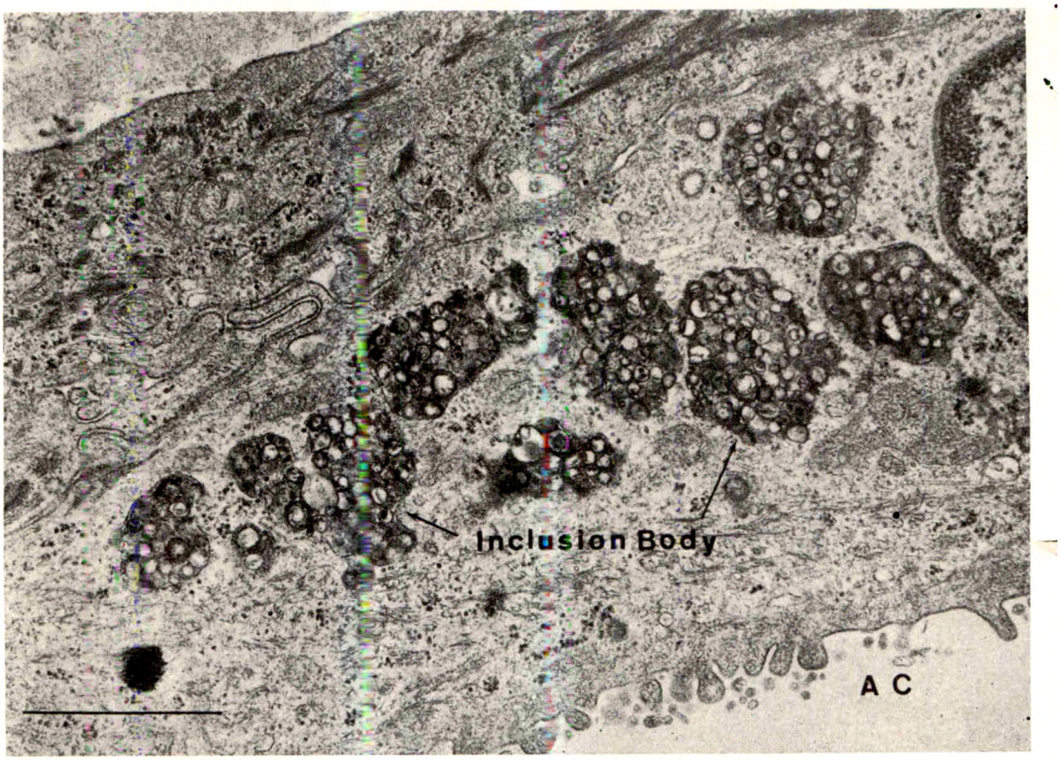

Fig. 8 (Boruchoff and Kuwabara). Some epithelial cells contain inclusion bodies, which appear to be degenerating cell debris (×27,000).

ous degrees of congenital abnormalities, ranging from rare scattered vesicles to widespread opacification of the posterior cornea. The presence of broad synechiae in the patient and other members of his family suggests some variation of the "faulty cleavage syndrome."[3] The presence of synechiae associated with posterior polymorphous dystrophy has been mentioned in the literature,[1] and seen by us in other patients with this disease not related to the family herein reported. There may be a spectrum of diseases with the common denominator related to the formation of the posterior surface of the cornea. The displacement of the ectodermal cell may be one of these embryonal abnormalities. There are other conditions—e.g., Rieger's anomaly (primary mesodermal dysgenesis of the iris), which has a high incidence of central corneal involvement (62 of 170 eyes)[4]; Peter's anomaly (mesodermal dysgenesis of the cornea), which shows a high incidence of synechiae between cornea and iris, and often correctopia and iris hypoplasia; and Chandler's syndrome (cornea guttata, iris atrophy and glaucoma)—perhaps all of these are varying manifestations of a developmental fault. It would prove most interesting to study the posterior limiting layers of these conditions.

Another possibility is a transformation of the endothelial cells into the epithelium. Yet endothelium and epithelium have no close developmental relationship, and pathologic endothelial cells in various clinicopathological and experimental conditions examined by us have never shown any suggestion of such a transformation.

The epithelial cells at the posterior corneal surface of the present case appear similar to

that of the downgrowth of epithelium in the anterior chamber following cataract surgery. With the clinical course and the history of the patient, this possibility can be ruled out. The downgrowth of corneal epithelium has a relatively rapid growth rate and the cells contain more metabolically active microorganelles. The cytologic findings of the epithelium in the posterior cornea of the present case suggest that these cells are metabolically inactive. The cytoplasm contains almost no active microorganelles. This may explain the slow clinical course in this patient.

The presence of the thin Descemet's membrane suggests that the cornea was formed by normal endothelial cells in the early developmental stage. Judging from the thickness and uniformity of the Descemet's membrane, the function of the endothelium ceased and was replaced by epithelium in an early infantile period. Since the structure of the whole thickness of the thin Descemet's membrane is identical to that of the anterior half of an adult membrane, the membrane appears to have aged without adding new normal substance. After the replacement of

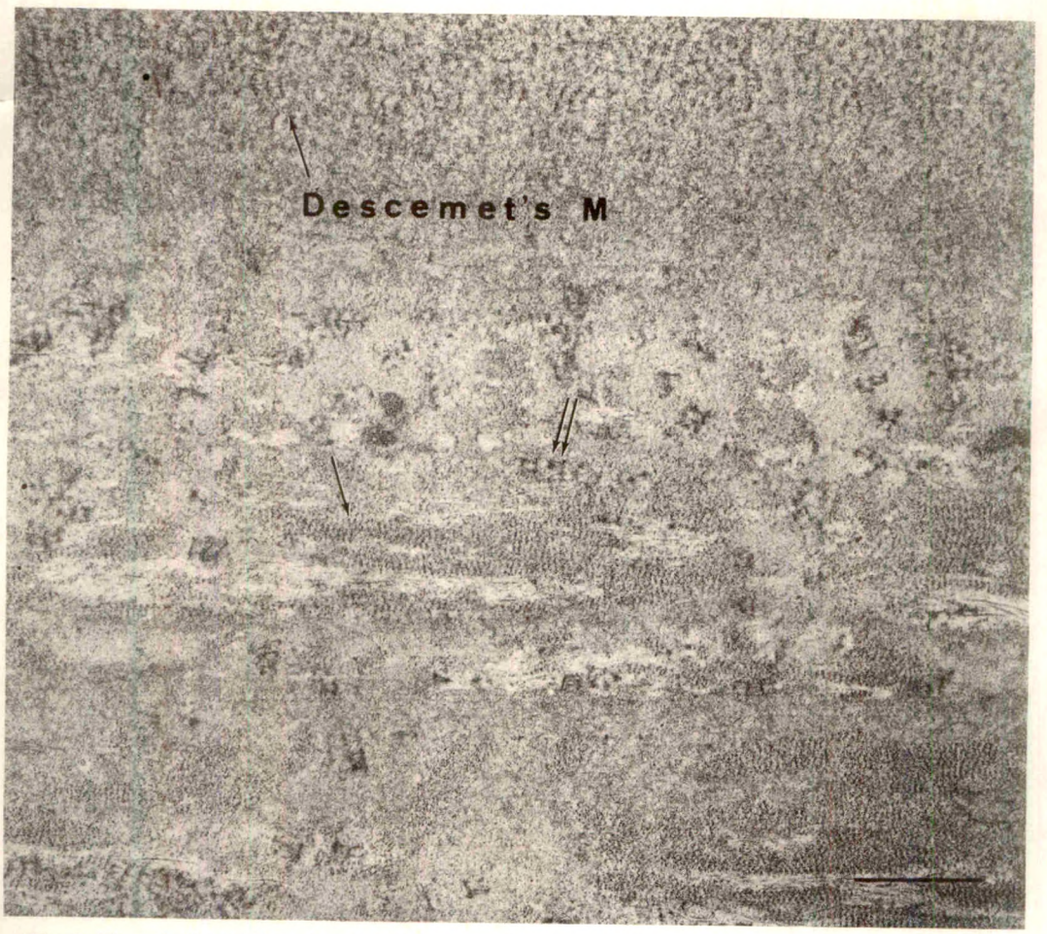

Fig. 9 (Boruchoff and Kuwabara). Higher magnification of the abnormal collagen membrane and the Descemet's membrane. The Descemet's membrane consists of coarse granular substances which are forming 100 nm spacings. The abnormal membrane is made of a mixture of fibrils, collagen fibers and basal lamina substance. Fibril materials are forming 100 nm spacings (double arrow) and 30 nm bandings (single arrow). Whitish portions are mainly collagen fibers (×17,000).

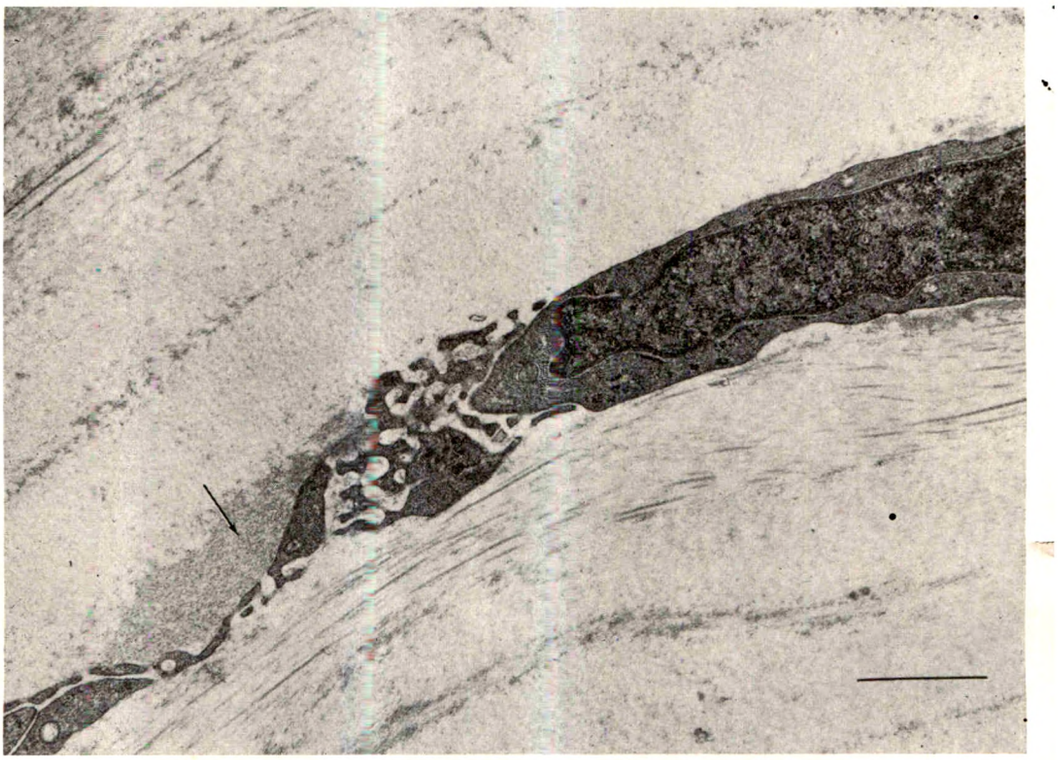

Fig. 10 (Boruchoff and Kuwabara). Stroma of the edematous cornea. Lamellar arrangements of collagen fibers are irregular. Stroma cell is rounded. Basal laminar substance (arrow) is seen abundantly around the cell (×17,000).

the endothelium by the epithelium, a thick pathologic portion appears to have formed posterior to the original Descemet's membrane. The appearance of this layer is similar to that of a nonspecific subepithelial or posterior accessory membrane. Abnormal collagen fibers and fibrillar substances form aggregations and bandings in various shapes. However, these structures may not have any specific correlation to the cause of this disease. A similar pathologic membrane in the posterior cornea was demonstrated recently in a case of hereditary corneal edema.[5]

It must be emphasized that the pathologic findings of the posterior zone of the cornea of the present case differ from those of the common endothelial dystrophy. Pathologic endothelium produces a thickened or multilayered Descemet's membrane instead of being buried as a thin layer.

It should be pointed out that the abnormal membrane contains no cells other than the epithelium at the posterior surface. This suggests that the abnormal collagen fibers have been produced by the aberrant epithelium. Analogous production of collagen fibers by the epithelium has been shown in developing avian corneas.[6] Pathologic findings in the present case support the theory of an epithelial origin for collagen formation.

## Summary

A corneal button from a case of hereditary posterior polymorphous degeneration was studied electron microscopically. The abnormal cells at the posterior surface of the cornea were found to have the characteristics of epithelial cells.

The pathogenetic origin of the cell may be

due to displacement of the ectodermal cells occurring at the earliest stage of the optic cup formation. This disease may be a part of a large spectrum of malformations of the anterior portion of the eye in the early developmental stage.

Electron microscopic study suggests that the accessory collagen membrane has been produced by the aberrant epithelial cells.

ACKNOWLEDGMENT

The authors thank Dr. David G. Cogan for his constant interest and criticism on this investigation.

OPHTHALMIC MINIATURE

Dirty lenses affect vision and they can upset a driver's judgement. An illustration of this was given by Paul Frere, the Belgian racing driver. He found he was lapping a circuit two seconds slower than normal, which does not sound much until you realize that races of 50 or 60 laps are often won or lost by a single second. Paul Frere could find no reason for his reduced speed until he examined the goggles he was wearing. They were scratched. He changed to an unscratched pair and his times went back to normal. The scratching had upset his judgement and therefore reduced his speed.

# HISTOPATHOLOGIC FINDINGS IN CORNEAS FOLLOWING LENS EXTRACTION AND RESULTS OF KERATOPLASTY FOR APHAKIC BULLOUS KERATOPATHY

GEORGE H. KURZ, M.D.

*Flemington, New Jersey*

Although in the vast majority of lens extractions the results of surgery are gratifying both to patient and surgeon, in a small number of cases, postoperative corneal problems leave the patient with severely impaired vision. Even in corneas that were clear, Miller and Dohlman[1] reported a demonstrable increase in corneal thickness following lens extraction in 76% of 50 unilaterally aphakic patients whom they studied. In this paper the histopathologic findings in a series of corneal specimens obtained from aphakic eyes are presented, together with the results of corneal transplant surgery.

## MATERIALS AND METHODS

Twenty-eight consecutive corneal buttons received in the ophthalmic pathology laboratory at New York University from eyes which had had previous lens extraction were studied. The specimens were submitted by several different contributors, and often the cataract surgery had been performed by a surgeon other than the one from whom the subsequent corneal specimen was obtained. Thus, histories relating to the original cataract surgery were not considered sufficiently reliable to permit a reasonable estimation of complications at the time of surgery.

The corneal buttons were fixed in Formalin. All were bisected (except for a 2-mm diameter specimen which was removed at the time of prosthokeratoplasty) and embedded in paraffin. Microscopic cross-sections were stained with hematoxylin and eosin, periodic acid Schiff, and special stains when indicated. The results of corneal transplant surgery were ascertained in all cases.

## RESULTS

Table 1 lists the principal histopathologic finding in each of the 22 full-thickness and six lamellar specimens. Bullous keratopathy secondary to endothelial degeneration was by far the most common abnormality. It was the only category large enough to provide significant follow-up data. There were seven other categories with only a small number in each.

*Bullous keratopathy secondary to endothelial degeneration*—Seventeen of the corneal specimens were obtained at the time of full-thickness keratoplasty for bullous keratopathy (Fig. 1). In each of these, in addition to bullous separation of epithelium from Bowman's membrane, the most striking finding was severe degeneration or virtual absence of corneal endothelium (Fig. 2). In all but two cases this was true in the presence of a normal Descemet's membrane without posterior excrescences. In one of

those two cases (Fig. 3), part of Descemet's membrane had been torn away. This is presumed to have happened at the time of lens extraction. The possibility of its occurrence during the keratoplasty was ruled out by an accumulation of pigment on the back of the exposed part of the stroma. The other had a laminated Descemet's membrane.

In some instances the epithelium was missing in the histologic sections and there was a diffuse infiltrate of acute inflammatory cells in the stroma—an acute keratitis secondary to ruptured epithelial blebs.

Two of the specimens in which the primary histologic finding was bullous keratopathy were lamellar specimens. Although the endothelium was, of course, not seen, similar degeneration might reasonably be expected.

The results of the transplant surgery in these 19 cases are summarized in Table 2. Despite the severely degenerated host endothelium, which might lead one to expect poor visual results, eight of the 17 penetrating grafts remained clear during a follow-up period ranging from six months to four years. Median age and duration of follow-up (Table 3) were similar for patients with clear grafts and with failures. Of the eight which were clear, the fellow eye in six cases was noted to have a normal cornea while two had cornea guttata. Of those which failed, the fellow eye had a normal cornea in three instances and an abnormal cornea in six. The abnormality in four instances was cornea guttata; one had an opaque cornea; another

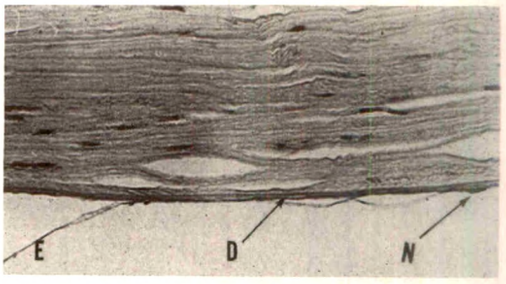

Fig. 2 (Kurz). Severe degeneration of corneal endothelium in a 65-year-old woman with bullous keratopathy nine months following lens extraction. was an aphakic eye which had had a keratoplasty.

Of the nine grafts which failed six were described simply as "opaque," two had epithelial edema, and one, which developed a pneumococcal ulcer three weeks postoperatively, became opaque and vascularized. None had better than 20/400 vision.

As one might expect, neither of the two lamellar grafts for aphakic bullous keratopathy remained clear. The first was performed in preparation for a prosthokeratoplasty. The second was done for relief of pain and structural improvement of a cornea on which a previous Salleras cauterization of Bowman's membrane had been done. The latter graft, initially clear, had developed epithelial edema seven months postoperatively. The cautery punctures in the excised speci-

men (Fig. 4) extended considerably deeper than Bowman's membrane.

## COMMENT

Dohlman and Boruchoff[2] state that in most cases of persistent corneal edema after cataract extraction some element of endothelial dystrophy was present as evidenced by guttate changes on the posterior corneal surfaces of both corneas. In the present series, less than half of the cases were said to exhibit cornea guttata in the fellow eye and none of the pathologic specimens had the posterior excrescences of Descemet's membrane characteristic of endothelial dystrophy.

The satisfactory results of penetrating keratoplasty in nearly half of these cases of aphakic bullous keratopathy despite the very poor condition of the host endothelium is similar to results recently reported by Foster and Fine.[3] In the eyes with aphakia and corneal edema, 46 out of 94 penetrating keratoplasties were transparent.

Stocker and Irish[4] reported the long-term results of 12 initially successful corneal grafts for Fuchs' endothelial dystrophy. One case after another eventually developed edema; all were cloudy nine years postoperatively. Their conclusion was that "the endothelium of the graft had probably exhausted its lifetime and diseased endothelium of the recipient was not able to replace the dying endothelium of the graft by normal cells." A similar eventual outcome might well be expected in the cases reported here because of the similarity of the basic problem of diseased host endothelium.

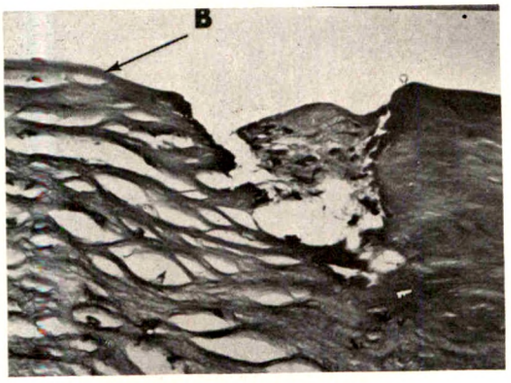

Fig. 4 (Kurz). One of numerous cautery puncture sites in cornea of 67-year-old man three years following lens extraction. Cauterization of Bowman's membrane was performed for bullous keratopathy two months prior to the lamellar keratoplasty from which this specimen was obtained. Epithelium is absent. Puncture extends well beyond Bowman's membrane (B) and into stroma. There is early fibrous connective tissue healing of this cautery site (hematoxylin and eosin, ×192).

It would have been most interesting to correlate the age of the donors with the successes and failures of grafts in this group. Unfortunately, under the circumstances of this study, this information is rarely available. Considering the poor condition of the host endothelium, I suspect that the condition of the donor endothelium may play a more important role in grafts of this type than in grafts not replacing corneas with degenerated endothelium.

Foster and Fine[3] found no significant differences in results between penetrating grafts done with donors of four different age groups. Their study included 398 grafts

TABLE 3

RESULTS OF PENETRATING GRAFTS IN BULLOUS KERATOPATHY

| Status | | Median Age | Mean Duration of Follow-up |
|---|---|---|---|
| Clear grafts | 8 | 67 | 18 months |
| Failures | 9 | 71 | 21 months |

in three prognostic categories followed for at least six months. But among their aphakic bullous keratopathy cases, 54.2% were clear in the 72 cases with donors under age 70 years, while 31.8% were clear in the 22 cases with donors over 70 years of age.

It would seem important for persons doing corneal surgery, especially of this type, to keep records of the age of donors.

*Pannus*—Degenerative pannus was the principal finding in one full-thickness and one lamellar specimen. In three additional cases a slight pannus was noted, and was regarded as an incidental finding.

In one case, because of a corneal lesion suspected clinically of being Bowen's disease, a lamellar keratoplasty was performed on a 65-year-old white man 12 years following lens extraction (Fig. 5). Histologic sections (Fig. 6), however, show a thick fibrous connective tissue pannus between Bowman's membrane and a degenerated epithelium. Nodules of epithelium were trapped within the pannus.

Pannus may be related to bullous keratopathy in some instances. Edema fluid elevating the epithelium probably precedes the growth of connective tissue between epithelium and Bowman's membrane.

Both grafts in which pannus was the principal finding failed. Two in which pannus

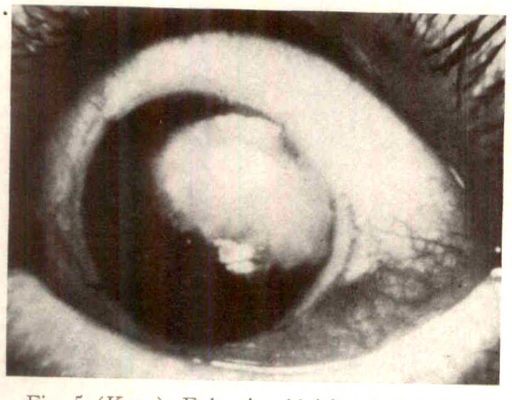

Fig. 5 (Kurz). Enlarging bluish raised lesion on cornea of aphakic patient. Vessels entered the lesion from the upper temporal periphery. Finger-like projections were present on its lower aspect. Clinical diagnosis was Bowen's disease.

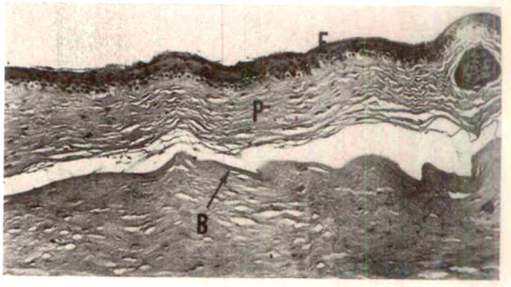

Fig. 6 (Kurz). Thick fibrous connective tissue pannus (P) between epithelium (E) and Bowman's membrane (B). Nodule of epithelium is trapped within the pannus (hematoxylin and eosin, ×75).

was regarded as an incidental finding were included among the unsuccessful penetrating grafts for aphakic bullous keratopathy secondary to endothelial degeneration. The third specimen with an incidental pannus was a lamellar specimen from an eye with band keratopathy. The graft was described as moderately clear four months postoperatively.

*Hypertrophic scar*—A 65-year-old black man developed a large opaque corneal mass with some vascularization involving the temporal two-thirds of the cornea (Fig. 7). At the time of cataract surgery three years prior

Fig. 7 (Kurz). Lamellar keratoplasty specimen, 9.5 mm in diameter, removed from a 65-year-old black man three years following lens extraction. A 6.7-mm diameter round, elevated, vascularized lesion was eccentrically located on the anterior surface.

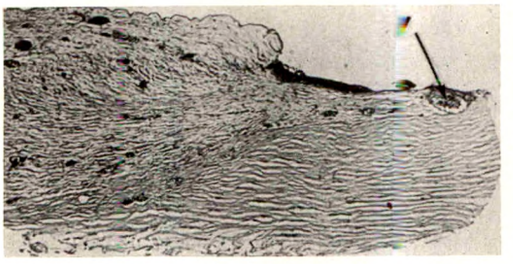

Fig. 8 (Kurz). Vascularized lesion occupies nearly full thickness of lamellar specimen. Large vessel (V) enters vascularized scar anterior to Bowman's membrane (hematoxylin and eosin, ×39).

to keratoplasty there had been vitreous loss. Postoperative vitreous touch followed by corneal edema preceded the growth of the mass.

Histologic findings (Fig. 8) showed an elevated vascularized scar occupying virtually the full thickness of the lamellar specimen. Vessels entered the periphery anterior to Bowman's membrane, suggesting that the lesion began as a pannus, and then branched out to fill the entire vascularized scarred area.

*Stromal overgrowth*—A 49-year-old white man was seen with advanced total bullous keratopathy almost two years following lens extraction. The clinical appearance (Fig. 9) resembled the cases of bullous keratopathy secondary to endothelial degeneration. Microscopic sections, however, showed a thin fibrous connective tissue membrane posterior to Descemet's membrane (Fig. 10) in addition to bullous keratopathy. This layer of stromal overgrowth stained with blue with Masson trichrome.

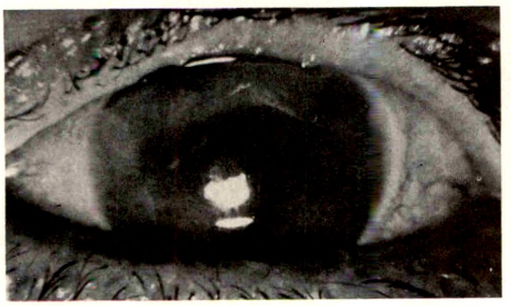

Fig. 9 (Kurz). Hazy cornea from advanced bullous keratopathy in a 49-year-old white man nearly two years following cataract surgery.

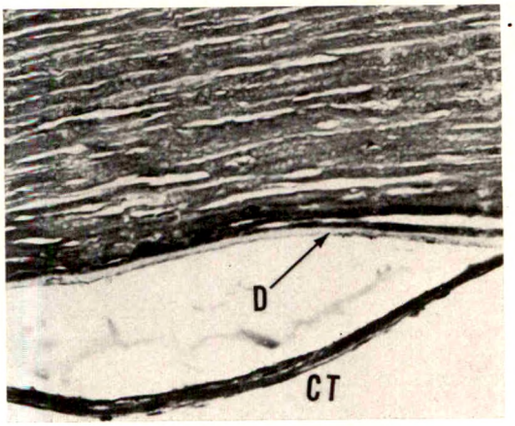
The second specimen exhibiting stromal overgrowth as its principal finding was a 2-mm diameter corneal button removed at the time of prosthokeratoplasty. The patient was an 80-year-old white man with a history of wound rupture, delayed reformation of the anterior chamber, glaucoma, keratitis and corneal opacification. In this one specimen (Fig. 11) there were scarring and vascularization, stromal overgrowth, and epithelial downgrowth.

In one other case, stromal overgrowth was an incidental finding associated with an epithelial cyst.

The subject of corneal stromal overgrowth, well known following penetrating keratoplasty, but infrequently recognized as a complication of lens extraction, was reviewed by Friedman and Henkind.[5] They mentioned the hypothesis that formed vitreous in contact with the wound might provoke a chronic inflammatory reaction and thus fibroplasia. Perhaps of greater importance is the fact that formed vitreous prevents endothelialization of the posterior aspect of the wound, leaving stromal fibroblasts free to proliferate in the tissue culture-like aqueous (Kurz and D'Amico[6]).



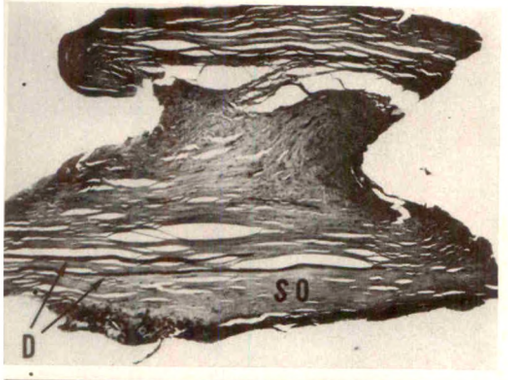


Fig. 10 (Kurz). Thin layer of fibrous connective tissue (CT) lines posterior aspect of Descemet's membrane (D). Areas of separation are probably artifactitious (Masson, ×192).

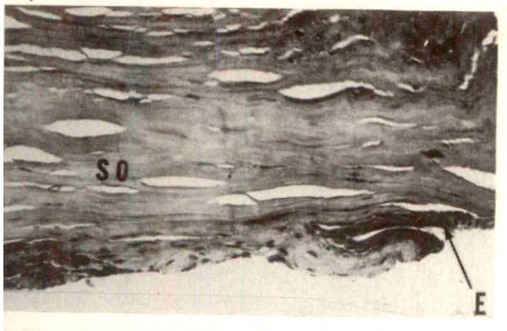
*Epithelial downgrowth*—A 74-year-old white man whose vision became diminished from bullous keratopathy one year after lens extraction with peripheral iridectomy was noted to have a large iris cyst superiorly. A penetrating keratoplasty was performed three years following the cataract surgery. Microscopic examination (Fig. 12) showed surface epithelium lining a portion of the posterior corneal surface. Descemet's membrane was thickened and laminated, endothelium was largely absent, and an incidental stromal overgrowth was present. A thicker layer of surface epithelium covered much of the atrophic iris which was excised at the same time.

This was the only specimen in the series exhibiting epithelial downgrowth as the principal histologic finding. In one other case, epithelial downgrowth was present. Although any epithelial downgrowth assumes major significance clinically, in the histologic sections of this case it was overshadowed by stromal overgrowth.



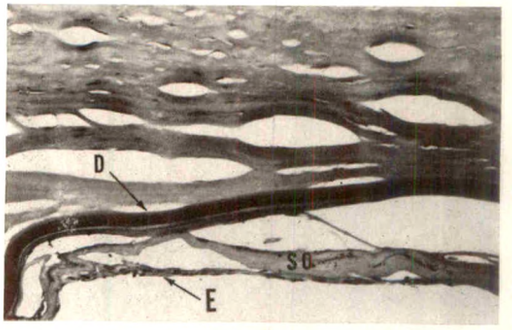


Fig. 11 (Kurz). Top: Corneal button removed at time of prosthokeratoplasty. Appearance of two Descemet's membranes (D) may be due to folding. Fibrous connective tissue extends around end of Descemet's membrane to form plaque of stromal overgrowth (SO) (Pas, ×39). Bottom: Surface epithelium (E) is adherent to posterior aspect of stromal overgrowth (PAS, ×192).

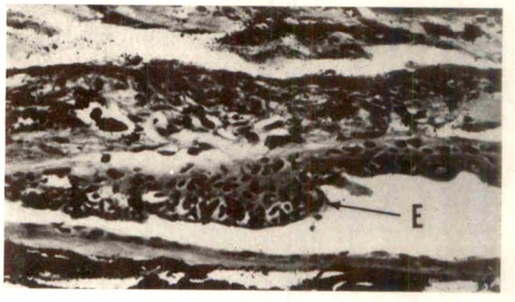

Fig. 12 (Kurz). Top: Epithelial downgrowth (E) and stromal overgrowth (SO) on posterior aspect of Descemet's membrane (D) one year after cataract surgery (PAS, ×192). Bottom: Thicker layer of epithelium lines portion of folded iris (PAS, ×192).

*Intracorneal hematoma and descemetocele*—An extraordinary case was that of a 72-year-old white man who was said to have undergone an uneventful cataract extraction with an uncomplicated course in the immediate postoperative period. Shortly thereafter, however, he complained of progressive loss of vision with occasional irritation of the eye. Three and one-half months after surgery a blood-stained cornea and central descemetocele were evident clinically (Fig. 13).

Hemoglobin globules scattered in the stroma and positive staining for iron in keratocytes bore out the clinical diagnosis of blood-stained cornea. In addition, surrounding the central descemetocele there was a striking intracorneal hematoma between the

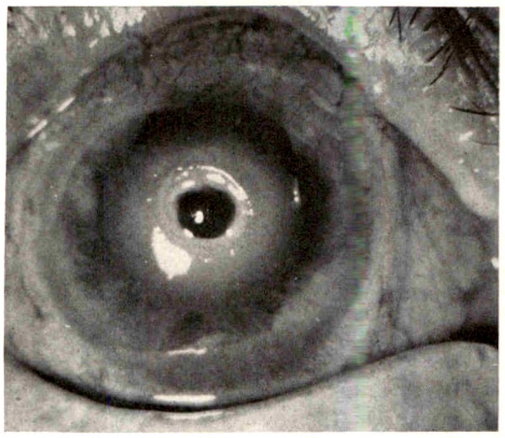

Fig. 13 (Kurz). Central descemetocele and blood staining of cornea three and one-half months after lens extraction.

deepest layers of stroma and Descemet's membrane (Fig. 14).

## Comment

The pathogenesis of the hematoma is unclear. In the eye pathology laboratory at New York University, however, there is one other case (an evisceration specimen and therefore not included in this series) with a hematoma between Descemet's membrane and corneal stroma in an aphakic eye which had also had an iridencleisis and two electrodialyses of an iris cyst. Another (an enucleated aphakic eye) has blood vessels between Descemet's membrane and the deep stroma. Vascularization such as this may have been the source of the hematoma illustrated in Figure 14. Bardy[7] states that deep corneal hematomas, which are much rarer than superficial ones, are usually due to rupture of a deep vessel as in old interstitial keratitis. According to Duke-Elder,[8] these new vessels immediately in front of Descemet's membrane arise from the iris in interstitial keratitis associated with uveitis. No evidence of old interstitial keratitis was seen in the cornea of the fellow eye of the case reported in this series.

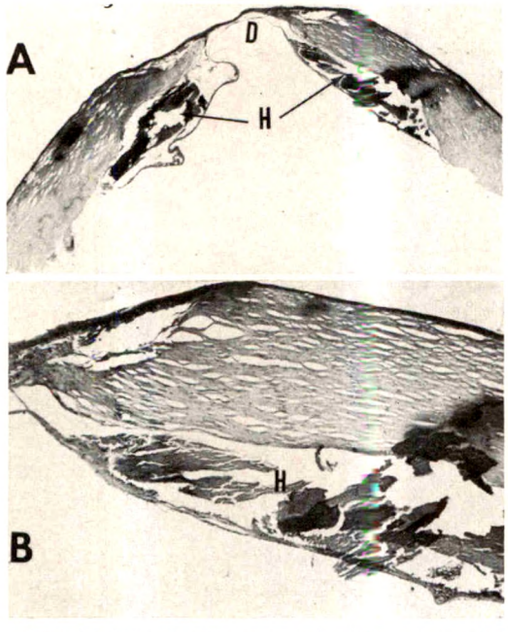

Fig. 14 (Kurz). Descemetocele (D), surrounded by deep intracorneal hematoma (H) (hematoxylin and eosin; top: ×15, bottom: ×48).

*Mooren's ulcer*—The only eye of a 75-year-old white woman slowly developed a marginal degeneration after lens extraction. In one year following surgery she had an advanced Mooren's ulcer encircling the cornea (Fig. 15), and vision was reduced to hand movements. An 11-mm lamellar keratoplasty was performed which became cloudy. The histopathology was characteristic of Mooren's ulcer with an overhanging central edge and epithelium from the periphery lining the necrotic ulcer bed (Fig. 16).

*Band keratopathy*—Nine years following lens extraction, a 62-year-old white woman

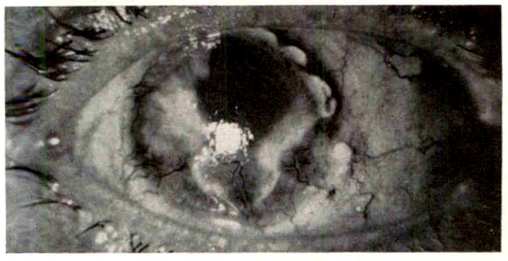

Fig. 15 (Kurz). Mooren's ulcer one year following lens extraction.

had a lamellar graft for band keratopathy (Fig. 17). Ten years prior to cataract surgery she had had a thyroidectomy followed by tetany. She had been maintained on calcium gluconate and vitamin D, but was found to be hypercalcemic 10 months prior to the corneal graft. Calcium levels improved after the calcium gluconate was discontinued.

Microscopic sections demonstrated large deposits of calcium beneath a thin epithelium (Fig. 18). In addition, there was a degenerative pannus in front of Bowman's membrane. This suggests that a factor of dystrophic calcification (deposition of lime in dead or degenerating tissues not dependent on increase in blood calcium) was present in addition to that of metastatic calcification[9] (precipitation of calcium salts in previously undamaged tissues due to an excess in circulating blood). Calcification was not present in the fellow eye which was also aphakic. The graft was moderately clear with no evidence of calcification four months postoperatively.

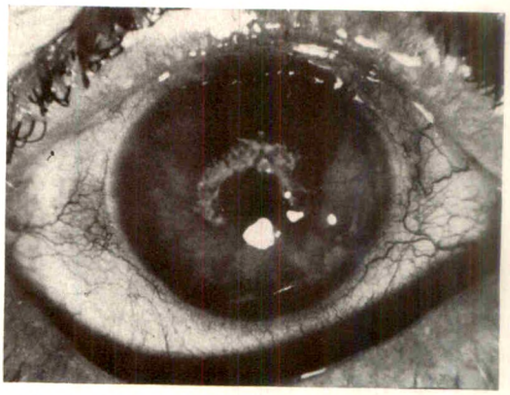

Fig. 17 (Kurz). Band keratopathy in 62-year-old aphakic patient who developed hypercalcemia. Note semicircular pattern of corneal deposits.

## Summary

Nine of 28 corneal graft specimens obtained following lens extraction exhibited a variety of unusual pathologic findings. The remaining 19, however, showed bullous keratopathy as the principal histopathologic finding. This was believed to be secondary to endothelial degeneration, demonstrable in all but the two lamellar specimens. Posterior excrescences on Descemet's membrane characteristic of endothelial dystrophy were absent.

Penetrating keratoplasty performed on 17 eyes with aphakic bullous keratopathy yielded satisfactory results in nearly half the cases during a follow-up period ranging from six months to four years. Considering the condition of the host endothelium, these

operative results are better than one might have expected.

A plea is made for persons doing corneal surgery to keep records of the ages of the donors.

ACKNOWLEDGMENTS

I thank Robert A. D'Amico, M.D., and Donald A. Morris, M.D., for their helpful suggestions in revising this manuscript, and Mrs. Marianne Bracco for her typing.

OPHTHALMIC MINIATURE

"This is a very singular knife," said Holmes, lifting it up and examining it minutely. "I presume, as I see blood-stains upon it, that it is the one which was found in the dead man's grasp. Watson, this knife is surely in your line?"

"It is what we call a cataract knife," said I.

"I thought so. A very delicate blade devised for very delicate work."

"The tip was guarded by a disc of cork which we found beside his body," said the inspector. "His wife tells us that the knife had lain upon the dressing-table, and that he had picked it up as he left the room. It was a poor weapon, but perhaps the best that he could lay his hands on at the moment." . . .

. . . A knife which certainly no sane man would use for a weapon. It was, as Dr. Watson told us, a form of knife which is used for the most delicate operations known in surgery.

# INFLUENCE OF VARIOUS AGENTS ON CORNEAL PERMEABILITY

KEITH GREEN, PH.D., AND ASBJORN TONJUM, M.D.
*Baltimore, Maryland*

There are some reports of the effect of a surfactant on corneal irritability[1,2] and enhancement of drug penetration into the eye,[3,4] but there is a paucity of detailed reports on the influence of agents on corneal permeability. The present study was undertaken to examine the effects of several agents on the permeability of the cornea to fluorescein, using an in vitro system.

## MATERIALS AND METHODS

Adult albino rabbits (2-3 kg) were killed with an overdose of sodium pentobarbital. Eyes were proptosed, the corneas removed and transferred immediately to a Petri dish containing Krebs-bicarbonate Ringer's solution (pH 7.2) at 23-24° C. Corneas were mounted in chambers described previously,[5] except that no simulated intraocular pressure was used. The inside volume (endothelial solution) of each chamber was 5 ml and corneas were always bathed with Ringer's solution on this surface.

Following mounting, the epithelium of a cornea was bathed with one of the following solutions for two minutes: $10^{-5}$ M histamine; 2% laboratory-prepared pilocarpine (JHHP); 2% commercially available pilocarpine HCl in half-strength Ringer's solution; 2 mM cetyl pyridinium chloride (CPC); 0.02%, 0.01% or 0.005% benzalconium chloride (BAC); 0.5% proxymetacaine (Ophthaine); 2% 1-norepinephrine; or $10^{-3}$ M ouabain. In addition to the two-minute exposure to $10^{-3}$ M ouabain, some corneas remained in ouabain for 30 minutes and some for two hours. One series of experiments was made using JHHP pilocarpine for two minutes followed by immersion in norepinephrine for two minutes before immersion in fluorescein for four minutes. All solutions, other than commercially available compounds, were made up in Ringer's solution, except as noted.

In order to bathe an exposed epithelium, the whole chamber was immersed in a large beaker containing sufficient solution to cover it. After the two-minute (or longer) exposure to a drug, the chamber was transferred to a beaker containing sufficient 5% sodium fluorescein (Fluorescite) to cover the exposed epithelium. After four minutes in fluorescein, the chamber was removed and carefully rinsed with distilled water to remove the excess fluorescein on the external chamber surface. Care was taken not to wash the top surface of the chamber or the epithelium. The chamber was then placed in a beaker containing sufficient Ringer's solution to cover the epithelium completely. Paired corneas were used in over 35% of all experiments. Both corneas in a pair were bathed in fluorescein and then immersed in Ringer's solution, but only one was previously treated with a drug.

After the epithelial surface was bathed in Ringer's solution the entire endothelial solution was removed and replaced at 30 and 60 minutes and finally removed at 120 minutes. These solutions were analyzed for fluorescein using an Aminco-Bowman spectrophotofluorometer. A linear relationship was found between the fluorescein concentration in Ringer's solution and the relative intensity (scale reading x sensitivity) below 0.1 mg%. Samples with a concentration close to this or

higher were diluted with Ringer's solution before analysis. The apparatus was checked with known concentrations of fluorescein made in Ringer's solution before each determination was made of the samples. The analyses were thus made in essentially the same manner as described previously.[6]

A high pressure (80 cm water) applied to the posterior surface of the cornea causes a splitting of the superficial wing cells from the columnar basal cells which remain attached to the basement membrane.[7] To determine if the wing cell layer became more permeable, corneas were set up as previously described[7] with an 80 cm head of water on the posterior surface for one hour, except that the endothelium remained attached in the present experiments. At this time, the pressure was removed and the epithelial surface exposed to fluorescein for four minutes; the procedure then followed that described above for sampling of the endothelial solution.

Some corneas were mounted in other chambers[8] where small volumes of fluid bathed each corneal surface. The endothelium was always bathed in Ringer's solution. The epithelium was initially bathed in one of the following solutions for two minutes—0.2 or 2 mM lauryl sulfate (SLS) or 0.2 or 5 mM ethylenediaminetetraacetate (EDTA). The epithelial chamber was then flushed with 50 ml Ringer's solution and replaced with Ringer's containing $^{14}$C-mannitol. The endothelial bathing solution was sampled (total volume 3 ml; samples 20µl) every 30 minutes for two hours, and the epithelial solution was sampled at the beginning and end of the two-hour experimental period. The samples were counted using an end-window G-M tube. One cornea of each pair was treated as above while the other received no agent, but was treated identically, including flushing of the epithelial solution.

A few corneas were taken immediately after treatment with some agents, the exposed 6 mm diameter portion trephined out of the whole cornea and fixed in osmium for electron microscopy. The tissue was embedded in Araldite and sections were cut which were mounted on copper grids. The sections were stained with lead citrate and uranyl acetate and examined in an RCA electron microscope.

## Results

The amount of fluorescein passing the cornea per sampling period and the total amount in two hours is shown in Table 1. Although many experiments were made on paired corneas, the differences were so consistent that any permeability increase was readily obvious, thus all data are given in the respective groups.

Pressure applied to the posterior surface caused an increase in permeability; the epithelium is known to split longitudinally between the superficial and basal cells under high pressures,[7] and it is not surprising that it also produces some separation of the superficial epithelial cells where the principal resistance lies to the passage of water.[7] Figure 1 illustrates a normal epithelium from an untreated cornea. Figure 2 shows the effect of high pressure, where the principal effect is that of a widening of the intercellular spaces.

Corneas treated with ouabain ($10^{-3}$ M), were compared at two and 30 minutes when no increased permeability was found and at two hours, since an increase in corneal thickness occurs after two to three hours when ouabain is applied to the epithelial surface.[9,10] A 50-fold increase in dye penetration was found with two-hour ouabain. The intercellular spaces have become distended (Fig. 3) while the cells appear fairly normal. After 30-minute treatment with ouabain, the ultrastructure of the epithelium appeared normal.

Proxymetacaine, pilocarpine (JHHP), and the combination of pilocarpine (JHHP) and norepinephrine, all produced increased corneal permeability. Norepinephrine alone had no effect, nor did pilocarpine in Ringer's solution, eliminating these compounds from the possible agents causing increased permeability. The pH of the JHHP pilocarpine solu-

tion was pH 6.1 while that of the Ringer-pilocarpine solution was pH 6.4. All other solutions had a pH of 6.8-7.4, thus pH was without influence on corneal fluorescein permeability. Of all the components of the JHHP pilocarpine solution ($Na_2HPO_4$, $NaH_2PO_4$, NaCl, and BAC) and of the ophthalmic solution (Ophthaine) the only common compound was BAC. The concentration of BAC in proxymetacaine is 0.01% and in JHHP pilocarpine is 0.02%. BAC alone, at 0.02%, caused a 25-fold increase in permeability,

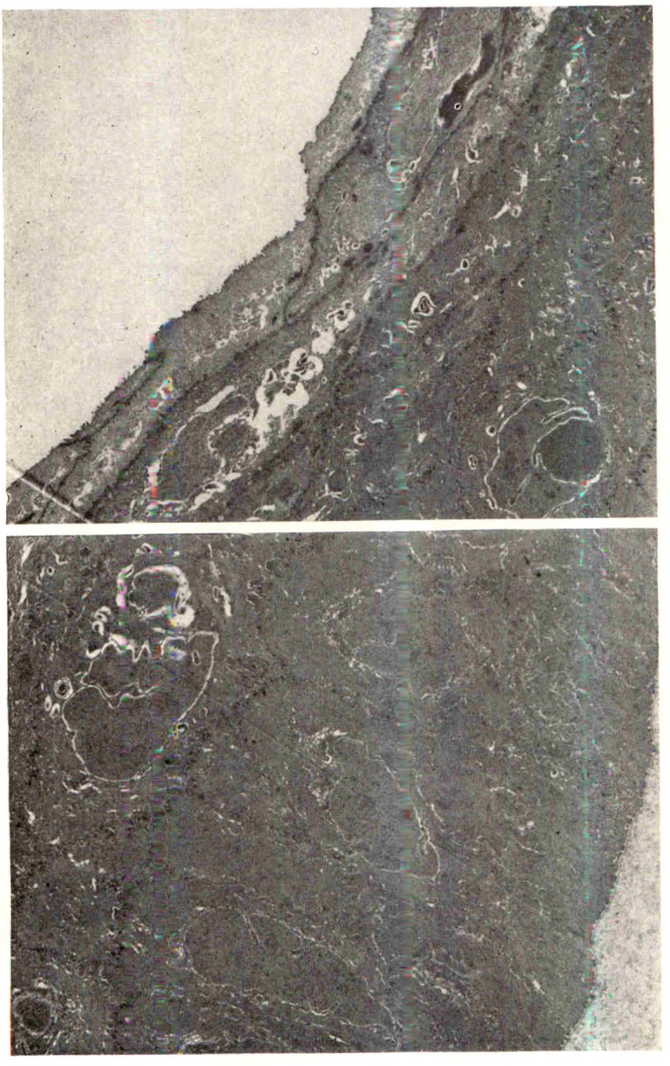

Fig. 1 (Green and Tonjum). Electron micrograph of epithelium from an untreated (control) cornea (×2640).

thus BAC alone had a greater effect than the equivalent concentration in a commercial preparation. Figure 4 shows the effect of 0.02% BAC; the superficial cells are disrupted and an increase in intercellular space is seen in the outer two or three cell layers.

The combination of JHHP pilocarpine followed by norepinephrine each applied for two minutes gives a three-fold permeability increase. The lower effect of this combination compared to the effect of JHHP pilocarpine alone may be caused by washing off the JHHP pilocarpine in the norepinephrine solution prior to immersion in fluorescein. The comparison between JHHP pilocarpine, the combined JHHP pilocarpine and norepinephrine, and BAC alone emphasized that BAC is the inducer of increased permeability.

Both BAC and CPC are cationic surfactants and they increased corneal fluorescein permeability; CPC (2 mM) caused a 30-fold increase. The superficial epithelium shows an increase in the width of the intercellular spaces after CPC treatment and the cell cytoplasm is slightly disrupted (Fig. 5). Increased intercellular spaces are found only in the superficial layers, with the basal cells showing a normal tight configuration. The anionic surfactant sodium lauryl sulfate

(SLS) had no effect on the permeability of the cornea to $^{14}$C-mannitol; neither did EDTA. No mannitol passed through the cornea under either control or experimental conditions.

Any agent which produced a permeability increase caused more fluorescein to pass out of the cornea in the 30-60 minute time period; the 0-30 minute sample was slightly lower (Table 1). The 60-120 minute sample generally showed a reduction in fluorescein transfer into the endothelial solution. When the total amount of fluorescein was very low, transfer was essentially the same for all time periods. This is expected since only a limited amount of fluorescein would enter the cornea and most of this would slowly diffuse into the endothelial solution.

## Discussion

Only $10^{-3}$ M ouabain (two-hours incubation), BAC, CPC, and high, posteriorly-applied hydrostatic pressure produced an increase in corneal permeability to fluorescein or mannitol. Both Ophthaine and JHHP pilocarpine increased permeability, but it was shown that BAC is the only common inducer of increased permeability in each solution. BAC in Ringer's solution produced a larger increase in permeability than the same con-

Fig. 2 (Green and Tonjum). Electron micrograph of superficial epithelium following high posteriorly applied pressure to the whole cornea. Notice the enlarged intercellular spaces (×30,044).

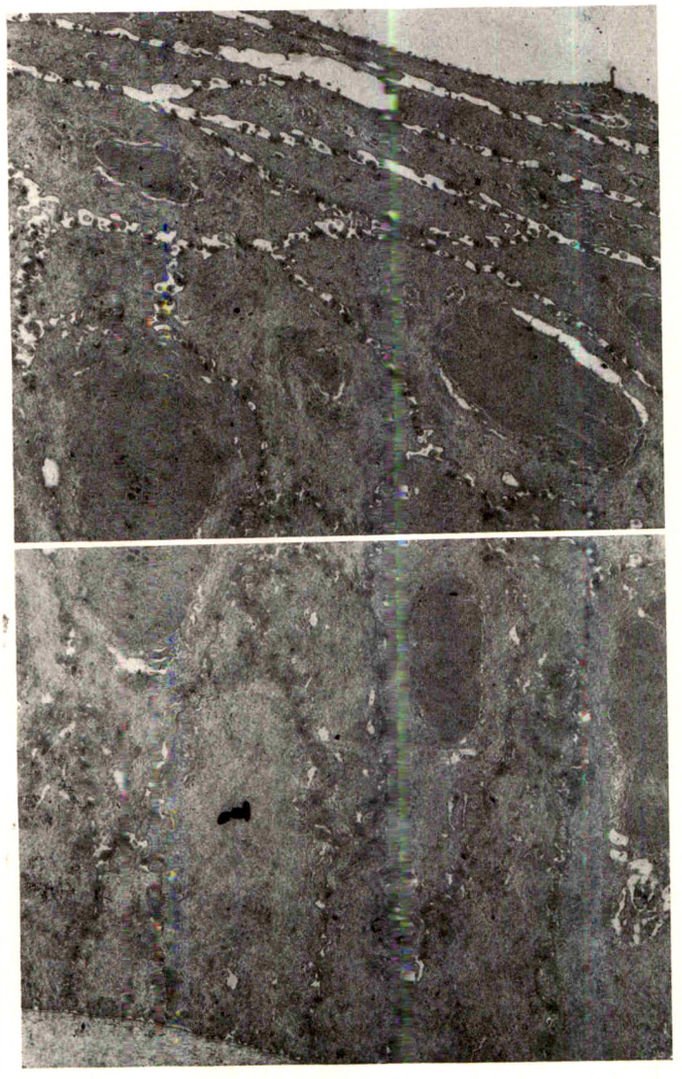

Fig. 3 (Green and Tonjum). Epithelium of a cornea treated with $10^{-3}$ M ouabain for two hours on the epithelial surface. Enlargement of intercellular spaces through the whole epithelium is obvious, with larger spaces in the superficial layers. Some intracellular disturbance is evident (×2640).

centration in commercial products. The differences seen here between BAC in Ringer's solution and BAC in commercial products (at the same percent of concentration) may reflect either differences in molecular weight, or differences between batches of the commercial products.

Ouabain inhibits cellular active transport systems[11] and causes increased corneal thickness when perfused over the epithelial surface.[9,10,12] It has been reported that two-hour incubation in ouabain at $10^{-3}$ M has no effect on the permeability of the corneal endothelium to urea or sucrose.[13] Here, a highly significant increase in epithelial fluorescein permeability is seen after two-hour incubation.

Electron microscope findings show that posteriorly applied pressure produced a breakdown in the cohesion of the epithelium (Fig. 2) by increasing the width of the intercellular space. Ouabain (Fig. 3), BAC (Fig. 4, and CPC (Fig. 5) all produced some disruption of the cell cytoplasm presumably either by actions on the plasma cell membrane per se (BAC and CPC) or on the intracellular metabolism (ouabain). The cationic surfactants, BAC and CPC, together with ouabain, produced an increase in the width of the intercellular space of the superficial epi-

thelial cells, indicating that they affect not only the cell membrane but also the intercellular route. The effects on the intercellular space are more pronounced in the region of the superficial epithelium when compared to the basal epithelial cells; only in the case of high, posteriorly applied pressure[7] and ouabain treatment does the widening of the intercellular spaces extend to the basal cell layers.[14]

BAC has been shown to be an effective antiseptic at concentrations of lower than 1 in 2,000 (0.05%)[15-17] and it is widely used in different concentrations (0.02% to 0.004%) as a germicide in topical ophthalmic solutions. Swan[1] and O'Brien and Swan[18] reported that BAC concentrations of 0.04-0.05% produced punctate epithelial disturbances which recover spontaneously when the drug is discontinued: BAC concentrations of 0.02-0.03% had no effect on the epithelium. Further, it has been shown that instillation of a 0.025% solution of BAC into the eye every day for 10 days produced no gross injury or thickening of the anterior epithelium.[19] Topically applied BAC (0.005 M), however, produced a loosening in adhesion between the corneal epithelium and

Fig. 4 (Green and Tonjum). Effect of 0.02% BAC on the corneal epithelium. Note the enlarged intercellular spaces between the superficial cells. Note also the cytoplasmic disruption in the most superficial cell layer (×2640).

Fig. 5 (Green and Tonjum). Effect of CPC on the superficial corneal epithelium. There is a much greater disruption of the cytoplasm than seen after BAC. An increase in the width of the intercellular space is seen when compared to the normal (Fig. 1); note that the areas where desmosomes are present remain closely apposed (×16,650).

stroma.[20] BAC is known to increase the permeability of another epithelial membrane, namely frog skin,[21] and the effect of related compounds (such as CPC and SLS) was shown to be on the passive permeability of the membrane.[22]

Neither histamine nor norepinephrine caused increased permeability, although it has been reported that these agents cause a loosening of the epithelium.[14] The incubation time in these latter experiments, however, was 20 hours so it is not surprising that two-minute incubation was ineffective.

The wide use of benzalconium chloride (Zephiran) as an antiseptic might suggest that it is an inactive compound regarding permeability, but the present results, together with previous investigations,[3,4,18,23] show that BAC can increase corneal permeability. Since most drugs penetrate the cornea only very slowly, the inclusion of an agent such as BAC, which produces a permeability increase, would be advantageous. Indeed, when describing the intraocular effect of topically applied drugs (in particular, water soluble ones), it may well be that the same drug in different preparations (with different concentrations of BAC) produces different effects and it would appear to be worthwhile to take into account the BAC

concentration of the solution, since higher concentrations would increase drug penetration.

Marsh and Maurice[24] recently reported on the effects of non-ionic detergents on human corneal permeability to fluorescein and concluded that there was a narrow margin between increased permeability and the creation of discomfort and epithelial disturbance. Such a conclusion also appears applicable to BAC, as shown above. Swan[1] reported, however, that the minimal concentrations of wetting agents producing irritation in the conjunctival sac are greater than those that are effective therapeutically as germicides.

## Summary

Corneal fluorescein permeability has been measured following treatment with different agents. Ouabain ($10^{-3}$ M for two hours), proxymetacaine (Ophthaine), and commercial pilocarpine (two-minute incubation) increased fluorescein transfer; pilocarpine in Ringer's solution did not. The active component of the commercial products was benzalconium chloride (Zephiran); dilute solutions of benzalconium chloride (a cationic surfactant) in Ringer's solution increased fluorescein permeability. Another cationic surfactant, cetyl pyridinium chloride, was similarly effective. Posteriorly applied pressure, ouabain and the surfactants increased permeability due to widening of intercellular spaces.

# INCORPORATION OF RADIOACTIVE SULPHATE BY CORNEAL STROMA DURING CRYOPRESERVATION

FRANK M. POLACK, M.D., R. GILLES BERNIER, M.D., AND THOMAS E. SLAPPEY
*Gainesville, Florida*

Adequate cyropreservation of corneal tissue for penetrating keratoplasty requires the survival of corneal endothelium. Experimental[1-5] and clinical data[6-7] support the importance of this corneal layer in the success of full-thickness grafts. The ability of nonviable corneal stroma to become transparent when a semipermeable membrane is placed instead of the endothelium[8,9] demonstrates the relative importance of corneal connective tissue cells (or keratocytes) in corneal transparency. This was observed in a previous study in which grafts of cryopreserved rabbit corneas remained clear from the day of transplantation even though there was histologic and historadiographic evidence of lack of keratocyte survival.[3] There is clinical evidence also that lamellar grafts with nonviable tissue are clear before the graft is repopulated by keratocytes.

The incorporation of radiotagged sulfate ($^{35}S$) in connective tissue depends on the viability of its cell population and their ability to synthesize ground substance. Other factors, such as edema, may decrease the uptake, thus suggesting poor cell survival or cell death.[10] However, under controlled conditions this technique is valuable in assessing stromal cell viability.

In the experiments reported here, we investigated the feasibility of increasing the survival of corneal stromal cells during cryopreservation; this was determined by their ability, in vitro, to incorporate $^{35}S$-labeled sodium sulfate.

## MATERIALS AND METHODS

Adult albino rabbits were killed with intravenous pentobarbital and their eyes enucleated. The corneas were promptly removed and treated with a solution of dimethylsulfoxide (DMSO), sucrose, and rabbit serum following freezing procedures previously described.[6,11]

*Group 1*—Two corneas were placed in the controlled-rate freezer (CRF) which had been precooled to 4° C. The freezing cycle was initiated at a speed of 2°/minute. When the eutectic point (plateau) for this tissue and its preserving medium appeared (−10° C), the freezing rate was accelerated to 5°/minute until −80° C was reached. The corneas were then transferred to a liquid nitrogen storage tank at −180° C.

In order to determine the optimum freezing rate, we experimented with increasing the freezing rates after various temperatures had been reached at a rate of 2°/minute. For example, in Group 2, the rate of freezing was 2°/minute until −20° C was reached, at which point the rate was accelerated to 5°/minute. For the third group, the rate was increased from 2° to 5°/minute at −30° C. Acceleration was begun at −40°, −50°, and −60° C in Groups 4, 5, and 6, with two corneas used in each group. Tissues were stored for periods of one to six days.

Corneas were thawed by immersing their glass vial containers in a 65° C water bath for 50 seconds. To remove the dimethylsulfoxide, they were then transferred to a beaker containing calf serum, where they remained for two hours at room temperature.

*Incorporation of radiotagged sulphate*—Corneas from each freezing experiment, plus a fresh cornea, were incubated at 37° C for two hours in calf serum with 100 mc/ml sodium sulfate (sp. activity 100 mc/mM,

New England Nuclear Corp.). The solution was gently agitated every 15 minutes.

Following incubation, the corneas were washed in normal saline, incubated in a saturated solution of sodium sulfate at 37° C for two hours with frequent agitation. The solution was changed and the corneas refrigerated overnight at 4° C. After repeated agitations, the corneas were rinsed through several changes of distilled water and placed in a 50% alcohol solution for one hour for partial dehydration. The corneas were dried flat between strips of filter paper in an incubator at 37° C for 48 hours, and contact radioautographs were made on Kodak radioautographic plates (no screen) with an exposure time of 11•days. Plates were developed in Dektol 1/1.

## Results

*Evaluation of results*—Maximum incorporation of $^{35}S$ as shown in radioautographs was rated four plus (4+). Less uptake was rated from 3+ to 0, according to the density of the radioautographs. The results are summarized in Table 1. Maximum uptake of $^{35}S$ was observed in fresh corneas, while no uptake was shown in radioautographs of corneas frozen without DMSO. A small amount of uptake (1+ and 2+, respectively) was present in corneas with a freezing rate accelerated to 5°C/minute at −10° and −20° C. The isotope incorporation improved at −30° C when it was close to that of the fresh cornea (3+). Somewhat less uptake (2+) was present when acceleration began at −40° C, and little uptake occurred (1+) in corneas whose freezing rate was modified at −50° and −60° C.

TABLE 1

RATE OF $^{35}S$ UPTAKE AND STROMAL CELL SURVIVAL AT VARIOUS FREEZING SPEEDS

| Temperature at which Freezing Rate was Accelerated (in degrees C) | Rate of $^{35}S$ Uptake by Stromal Tissue | Rate of Stroma Survival |
|---|---|---|
| −10 | + | + |
| −20 | ++ | ++ |
| −30 | +++ | ++++ |
| −40 | ++ | ++ |
| −50 | + | + |
| −60 | + | + |

After autoradiography was completed, one cornea from each group was fixed in 10% Formalin and washed. Tangential frozen sections were made to study cell population in sections stained with hematoxylin-eosin. Cell-population was compared to that of sections of fresh corneas and rated from one to four plus. The decrease in number of stained stromal cells, or their complete absence, correlated well with diminished uptake of $^{35}S$.

## Comment

These experiments demonstrate that the survival of rabbit corneal stromal cells in tissue previously treated with a cryophylactic solution containing DMSO can be modified by altering the rate of freezing. Even though different cell populations may require different freezing rates for optimal survival, it is believed that most cells will preserve well with a freezing rate varying between 2° and 5° C/minute.[12] In the case of corneal endothelium, the best preservation is obtained with an initial rate of 2° C/minute, increased to 5° C/minute after the eutectic point is attained.[6,11] The corneal epithelium seems to survive at the same freezing rate, and the slight $^{35}S$ uptake shown by corneal stroma when this freezing rate is used suggests that some stromal cells immediately below the endothelium and epithelium may also survive.[3] Stromal cell survival was also noted in previous studies in which oxygen consumption was measured from the endothelium and the underlying stromal tissue of cryopreserved corneas.[13]

The improvement in stromal cell viability with a freezing rate of 2° C/minute past the eutectic point (to −30° C) suggests that a prolonged period of time is required for the central corneal layers to participate in the slower freezing rate. Unfortunately, we were unable to obtain radioautographs of

cross-sections of these corneas to substantiate this theory, since the whole-mount radioautographs indicate only total uptake.

Corneas not treated with a cryophylactic solution showed no uptake of sulfate, and no cells were seen in stained sections. Except in situations in which the host tissue has very poor regenerative ability (areas of necrosis or old corneal disease), corneas frozen without preservative become non-viable material adequate for lamellar keratoplasty or tectonic grafts for keratoprosthesis. It is possible that pretreatment with DMSO may permit survival of a large stromal cell population and improve the viability of corneas frozen in regular laboratory freezers for lamellar keratoplasty. Since cardiovascular and ear surgery often calls for vein homografts, the value of cryopreservation of connective tissue is not necessarily limited to the cornea. Our experiments suggest that freezing curves similar to those applied to corneal tissue can be correlated to segments of veins with the advantage of long-term tissue storage or true banking. Since previous studies have shown that the antigenicity of frozen (non-viable) or cryopreserved tissue does not depend on its viability,[14,15] a persistence of tissue antigenicity because of preservation of its cellular elements is most likely unimportant.

## Summary

Experiments were carried out to determine the optimal freezing rate for corneal stroma preservation. This was assayed by histology and by assay of the incorporation of radioactive sulfate in tissue samples frozen at various rates of speed. Rabbit corneas were treated with dimethylsulfoxide and frozen at rates of 2°/minute and this rate was accelerated to 5°/minute when various freezing points were reached. The best preservation was obtained by maintaining a rate of 2° C/minute until the temperature reached −30° C, when the freezing rate was increased to 5° C/minute until −80° C was reached. A similar freezing rate is suggested for vascular tissue.

# HISTOLOGIC AND ELECTRON MICROSCOPE STUDIES OF LIGNEOUS CONJUNCTIVITIS

A. KANAI, M.D., AND F. M. POLACK, M.D.
*Gainesville, Florida*

Repeated bacteriologic, histologic,[1] and electron microscopic[2,3] studies have failed to clarify the etiology of ligneous conjunctivitis. However, recent histochemical investigations by François and Victoria[4] demonstrated that, in ligneous conjunctivitis, acid mucopolysaccharides collect in great amounts around newly formed vessels.

Our histochemical and electron microscopic studies of a case of ligneous conjunctivitis demonstrates that areas with staining characteristics of acid mucopolysaccharides have the appearance of a multilayered basement membrane-like material. This material is located around new vessels and forms the bulk of the growth.

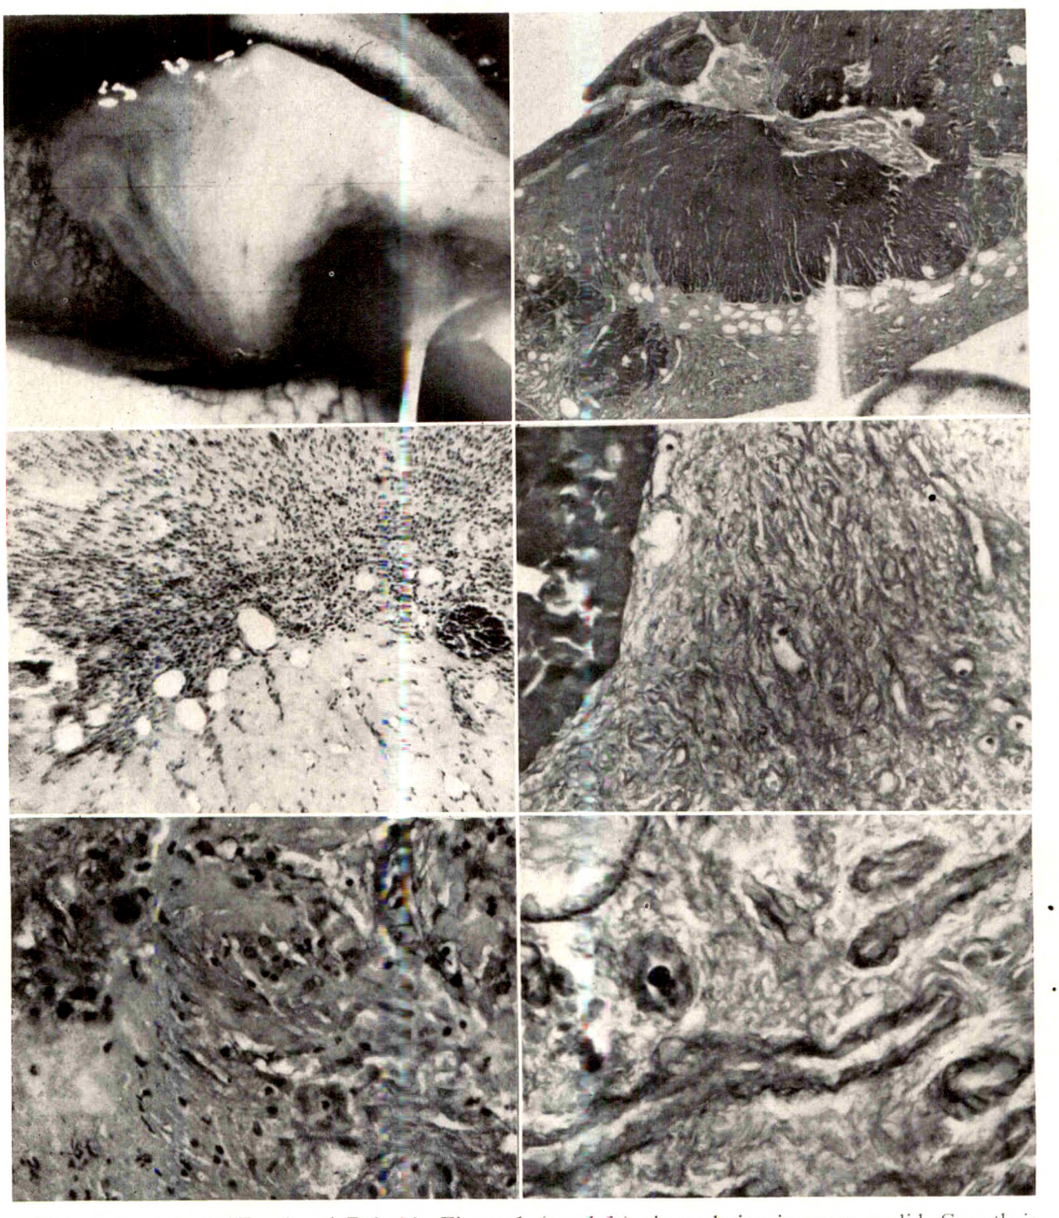
## CASE REPORT

An otherwise healthy 14-year-old boy was seen for the first time with a 10-month history of a small indurated mass under the right upper eyelid. This lesion was excised twice, but recurred to become as large or larger in size. His visual acuity was 20/20 in both eyes without correction.

On external examination, the right eye was normal except for a slight thickening of the temporal upper eyelid. There was abundant mucoid secretion in the right conjunctival cul-de-sac and mucous strands were present over the right cornea. The right lower eyelid was normal as were the cornea and tranparent media. Eversion of the upper eyelid showed a flattened, pedunculated mass with a whitish pseudomembrane (Fig. 1). The base of the growth was heavily vascularized and bled when touched lightly with a small forcep. The rest of the conjunctiva showed mild follicular reaction. Only the most superficial layers of the thick pseudomembrane could be removed without bleeding.

A biopsy excision of this growth was performed. Hyaluronidase drops (500 units/ml) and alpha-chymotrypsin (1/5,000) were prescribed every two hours, but neither these treatments nor subsequent hyaluronidase injections into the area of excision, and cryocauterization, served to inhibit the growth. Corticosteroid therapy, however, reduced the amount of secretion. For the past 12 months, the patient elected to discontinue these treatments. Peripheral corneal vascularization and upper corneal erosions developed, but were successfully treated with a hydrophilic contact lens.

## HISTOLOGY



A cross-section of the specimen stained with PAS showed a dense amorphous deposit covered by a pseudomembrane (Fig. 2). The amorphous mass stained deeply red with PAS stain and had a vascular core from which many fine capillaries advanced throughout the tissue. Sections stained with hematoxylin and eosin showed multiple areas of round cell infiltration around capillaries in the deep portion of the biopsy as well as some multinucleated cells (Fig. 3). Polymorphonuclear leukocytes and few eosinophiles were present in the external portion and in the pseudomembrane. Part of the tissue was relatively avascular, but in some areas there was a profuse bed of fine capillaries surrounded by PAS positive material (Fig. 4) and alcian-blue staining material (Fig. 5). Examination of PAS-stained sections under high power showed deposition of mucopolysaccharide material which was hyaluronidase-sensitive around and between capillaries (Fig. 6). Stains for reticulin demonstrated a net of argyrophillic fibers in these areas.

The portion corresponding to the pseudomembrane was weakly eosinophilic. A few epithelial cells, lymphocytes, and polymorphonuclear leukocytes were present within the fibrinous layer. Biopsies taken after treatment with hyaluronidase showed a similar structure.

Specimens for electron microscopy were immediately fixed. After two hours in cold 2% osmium tetroxide with phosphate buffer,

they were dehydrated through a series of ethyl alcohol treatments and embedded in Epon. Thick sections were stained with toluidine blue and studied with the light microscope for orientation in electron microscopy. Embedded tissue was cut with a Porter-Blum microtome and stained with uranyl acetate and lead citrate.

Electron microphotographs were taken with a Hitachi 11-C microscope. The amorphous substance which characterized the superficial portion of this tissue was partially covered by epithelial cells and contained leukocytes and fragmented cells (Fig. 7). Epithelial cells formed two to four layers, were usually rounded with many processes, and attached only by desmosomes. The epithelial cell membrane facing the stroma had multiple projections and showed a basement membrane; however, this was absent in some areas. Several layers of fibroblastic cells were located immediately under the epithelial cells.

Lymphocytes, plasma cells, monocytes, free red cells, fibroblasts, capillaries, and a few bundles of fibrillar material were present in the stromal portion of the specimen (Fig. 8). Fibroblasts showed distended endoplasmic reticulum containing a thinly dispersed flocculent material. Bundles of fine filaments were seen in the center or periphery of the cells with a well developed Golgi complex (Fig. 9). Fibrillar materials, with or without banding, were found in the

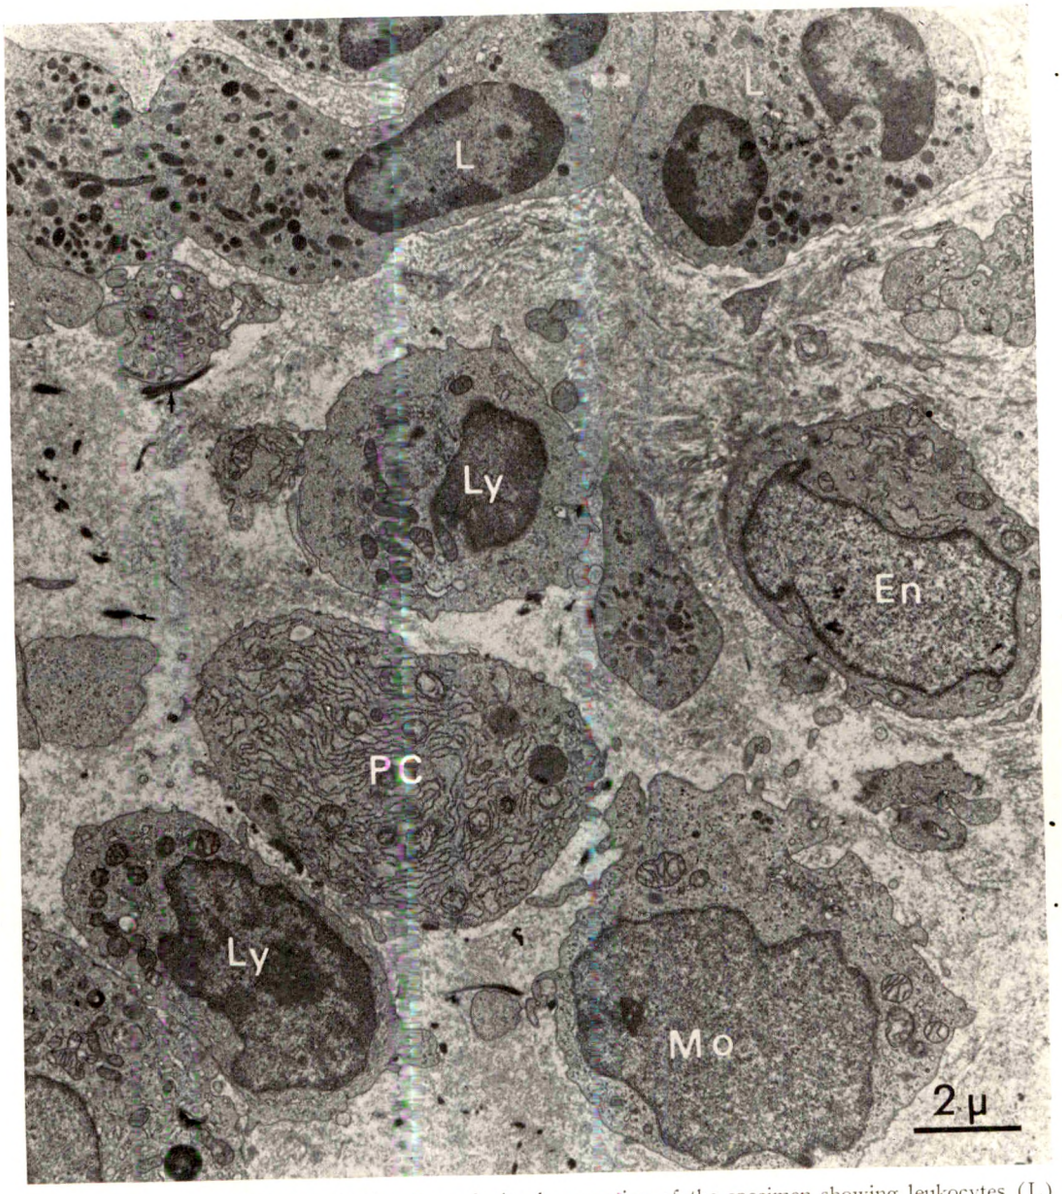

Fig. 8 (Kanai and Polack). Section through the deep portion of the specimen showing leukocytes (L) a free endothelial cell (En), a small bundle of fibrillar material (arrow) lymphocyte (Ly), monocyte (Mo), and plasma cell (Pl) (×7000).

stroma (20 nm). Occasionally, typical collagen fibers could be seen between these fibers.

Capillary endothelial cells had many cytoplasmic projections and were attached by tight junctions near the lumen. Vascular endothelial cells were usually wide around the nucleus; their cytoplasm contained mitochondria, distended endoplasmic reticulum, pinocytotic vesicles, and few inclusion bodies. Capillaries were surrounded by several lamellae of basement membrane-like material (Fig. 10) with a homogenous structure and irregular thickness (70-200 nm). Often, leukocytes were found within the layers of thick lamelliform formations (Fig. 11). Homogenous substances of higher density than the basement membrane formation were frequently found (Fig. 12).

## Discussion

Ligneous conjunctivitis is a rare disease of children and young adults which begins as a unilateral pseudomembranous conjunctivitis affecting one or both eyelids; this is eventually followed by an indurated growth. The disease runs a chronic course[5] and seems to be resistant to most kinds of treatment. François and Victoria[4] recently reported a favorable response to topical alpha chymotrypsin and hyaluronidase. The case presented here, however, did not respond to this treatment.

The most characteristic histologic findings are neovascularization, deposits of fibrillar material, and alcian-blue or PAS-positive staining materials around and between capillaries. Electron microscopic studies show a filamentous or homogenous material of irregular thickness arranged in multilayers around vessel walls. The density of PAS-positive areas forming the bulk of the specimen is similar to the perivascular homogenous material present around capillaries, suggesting a common vascular origin.

Thickening and reduplication of basement membranes occurs in diabetes mellitus and is found in retinal capillaries,[8] capillaries of subcutaneous tissue,[9] muscle,[10] kidney,[11] and

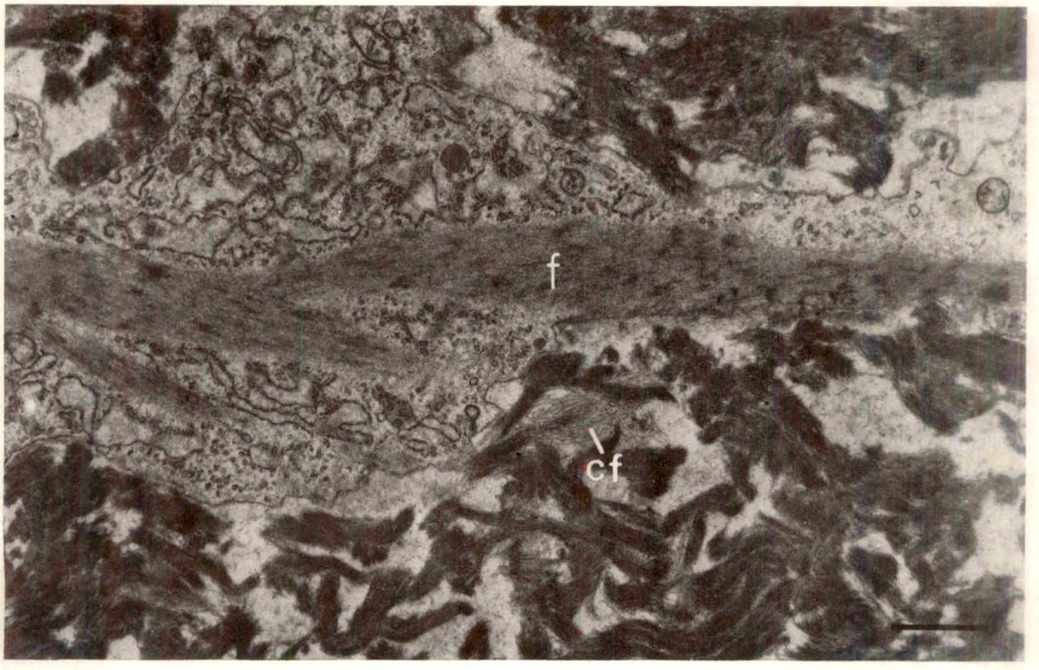

Fig. 9 (Kanai and Polack). Fibroclast (f) has sacs of distended endoplasmic reticulum. Bundles of fine filaments can be seen in the cytoplasm and outside the cell (×13,000).

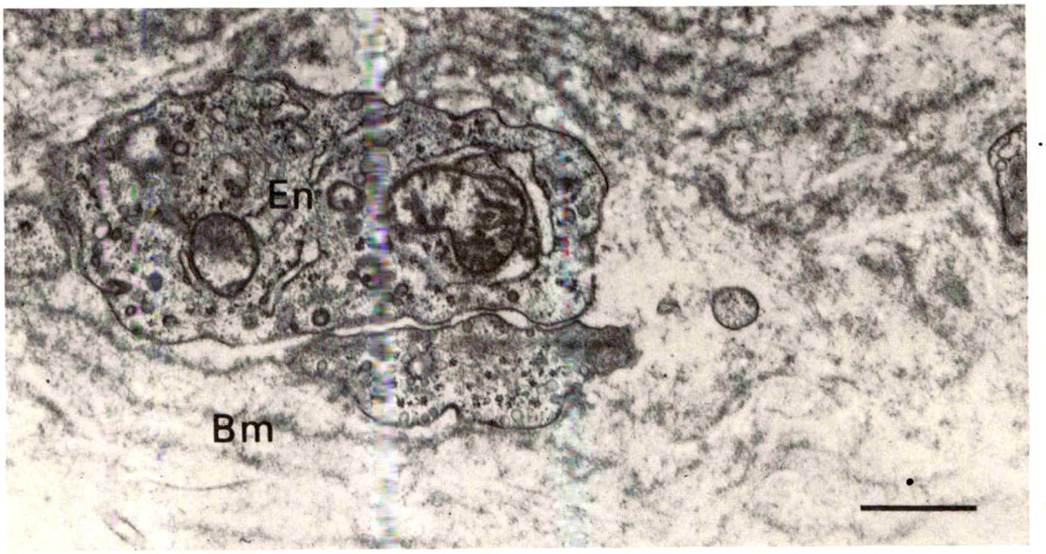

Fig. 10 (Kanai and Polack). Capillary with lamelliform basement membrane-like material (Bm) around its wall. En = endothelium (×16,000).

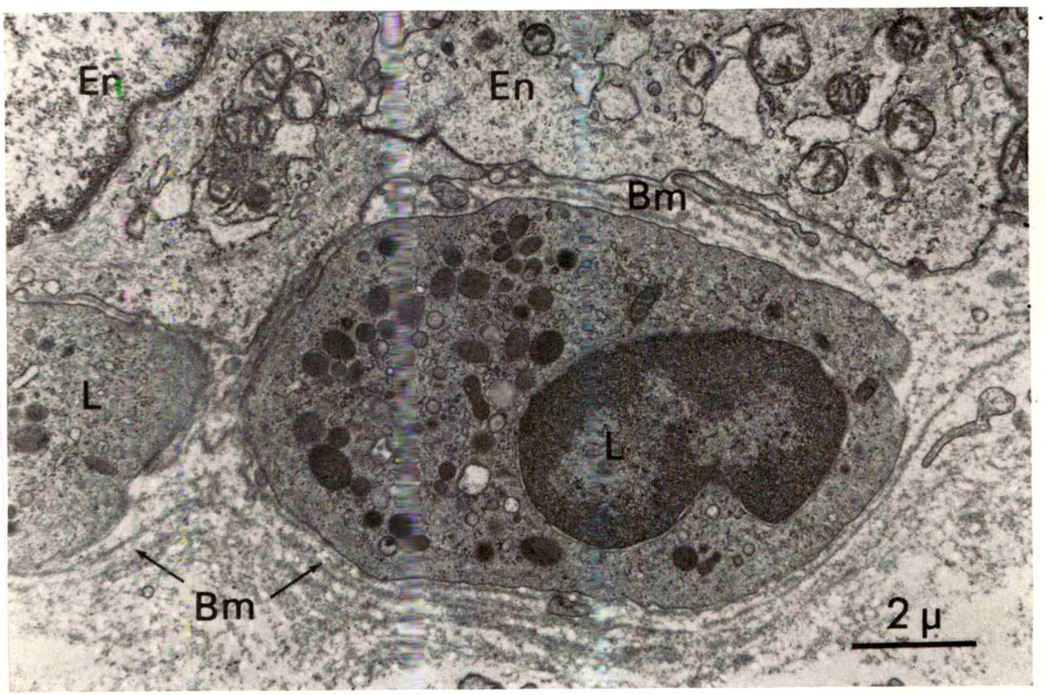

Fig. 11 (Kanai and Polack). Leukocytes (L) are seen surrounding the layers of the basement membrane-like materials (Bm) (×8200).

also in conjunctival capillaries.[12,13] This so-called lamelliform thickening of basement membrane is due to deposition of mucopolysaccharides and glycoproteins which stain with alcian-blue and PAS.[8] The basement membrane of normal vascular conjunctival endothelium consists of one or several layers, 50 to 100 nm thick, running nearly parallel to the outer contour of endothelial cells. Sometimes this membrane shows fenestrations.[14] The capillary endothelium observed in this case showed no fenestrations but had a lamelliform basement membrane-like formation. The relation between PAS or alcian-blue positive material and the basement membrane-like material was not previously described in ligneous conjunctivitis.

The lamelliform basement membrane-like material may derive either from the blood or be elaborated by the endothelial cell. The first possibility may be supported by the observations of Pappas and Tennyson,[15] who reported that marker particles passed from the lumen to the surrounding connective tissue of inflamed ciliary processes through thick capillary endothelium rather than through attenuated and fenestrated endothelial walls. In diabetes, Tamura[12] suggested that capillaries, because of an altered basement membrane, have an increased permeability to some materials. The second possibility may be supported by Curran's observations;[16] he reported that vascular endothelium produces mucopolysaccharides, and this activity is greatly increased in pathologic material such as in areas of wound healing or in stroma of tumors. It seems possible that in ligneous conjunctivitis, serofibrinous transudate may subsequently undergo coagulation, with the resultant formation of granulation tissue and hyaline material. With the electron microscope these hyaline deposits correspond to banded fibrils with a periodicity of 20 nm. Therefore, the hard ligneous consistency of this pathologic tissue may originate in direct outpouring of fibrin from neovessels and by passage of, or elaboration of, mucopolysaccharides by endothelial cells. In vitro studies with radiotagged sulfate ($^{35}S$) may elucidate whether these endothelial vessels are able to synthetize sulfated material.

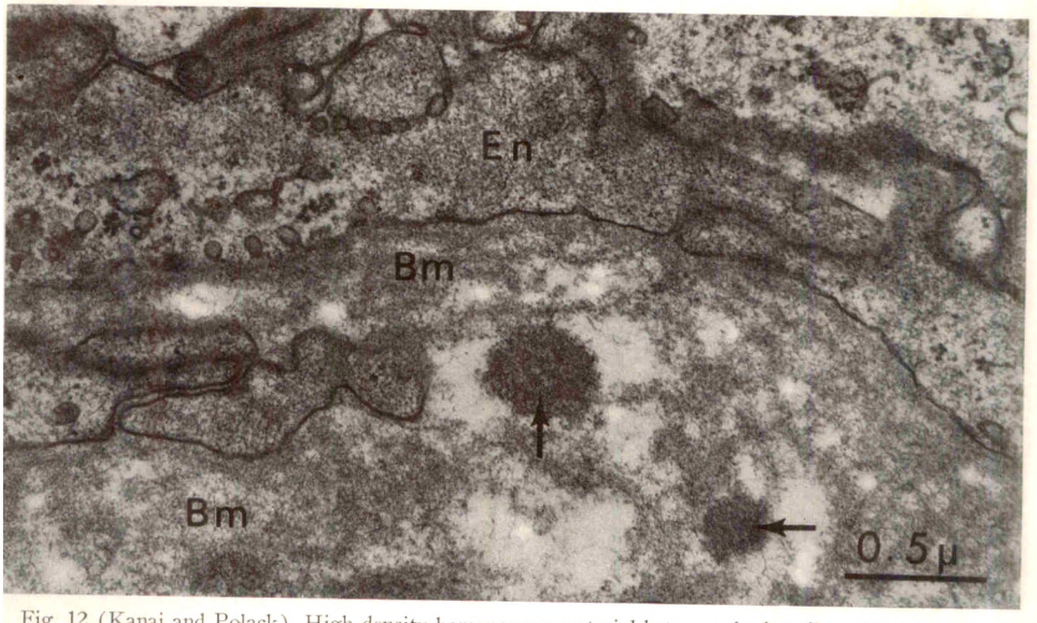

Fig. 12 (Kanai and Polack). High-density homogenous material between the lamellae of basement membrane-like material (arrows) (×38,000).

## Summary

Histochemical and histologic examination of a specimen of ligneous conjunctivitis revealed deposition of acid mucopolysaccharide, neovascularization, and round-cell infiltration. Areas of alcian blue-PAS positive deposits around capillary walls correspond to ultramicroscopic multilayered basement membrane-like material which forms the bulk of the growth. It is suggested that such material may be the result of increased capillary permeability, or it may be elaborated by endothelial cells, or both.

## Acknowledgments

We thank Dr. J. R. Brayton (Pensacola, Florida) for referring the patient to us and we thank Dr. C. F. McConnell (also of Pensacola), Drs. Ian Hood and J. Hazouri (Gainesville) for their collaboration in the study of this case.

# ATYPICAL BAND KERATOPATHY IN GLAUCOMATOUS PATIENTS

ROBERT E. KENNEDY, M.D., AND PRIMITIVO D. ROCA, M.D.
*Rochester, New York*

AND

PHILIP H. LANDERS, M.D.
*Binghamton, New York*

This report is to call attention to a keratopathy observed in well-controlled primary glaucoma patients, usually on long-term miotic therapy. Since 1963, 18 patients were observed who have manifested this clinical picture.

It is characterized by changes resembling band keratopathy, but having a different distribution pattern, usually paracentral in the interpalpebral area, over the lower central and nasal portion of the cornea, becoming less pronounced toward the periphery (Fig. 1). Clinically, fine, grayish, granular deposits can be seen in the paracentral areas in the subepithelial layers of the cornea. As the deposition increases, it tends to extend toward the limbus horizontally. Separate small areas may coalesce and progress in size and density rapidly, over a few months, or in a year or two. Rounded or irregular clear areas may develop in the opacified zone. Encroachment over the pupillary area may result in severe reduction in vision. Other symptoms may include photophobia, lacrimation, and irritation, because the overlying epithelium may become slightly roughened. The corneas have intact sensitivity and are not vascularized. Schirmer's tear function test was normal in the 10 patients who were studied.

The distribution of these corneal changes in our 18 patients has been diagrammed (Fig. 2). Ten of the patients were men and eight were women. They ranged in age from 64 to 87 years with the average age being 75 years.

The keratopathy appeared as a bilateral manifestation in 14, all of whom were being treated with miotics bilaterally. In three, only one eye was treated with miotics and the keratopathy developed only in that eye. In the one other patient, miotics were being used in both eyes, but the keratopathy developed in only one eye. It has been noted, however, that the changes in one eye may precede the other by as long as four years, so this patient may still develop bilateral involvement.

With two exceptions, duration of miotic therapy ranged from six to 16 years before the appearance of the keratopathy. In two patients, it occurred in less than one year (seven months in one and eight months in the other). Sixteen of the patients had wide-angle glaucoma, while two had a narrow-angle mechanism.

The incidence of this atypical band keratopathy must be low; its occurence is noted infrequently in the general glaucoma population, and in the practices of seven ophthal-

mologists, these 18 cases represent the total to have become manifest over the past eight years.

These patients have been evaluated medically and by laboratory studies to rule out any ocular process such as irridocyclitis, phthysis bulbi, absolute glaucoma, or any systemic-related cause for a band keratopathy (such as parathyroid adenoma, dysproteinemia, vitamin D intoxication, sarcoidosis, chronic renal insufficiency).[1-3] Laboratory studies included calcium and inorganic phosphorous in all 18 patients. Thirteen had additional studies, including alkaline phosphatase, cholesterol, glucose, urea nitrogen, uric acid, total protein, albumin and other tests. All tests were negative in all 18 patients.

The only common denominator in this group of well-controlled glaucoma patients appears to be the long-term miotic therapy. This seems to be more than coincidence; particularly so, since we have not observed this atypical band keratopathy in non-glaucomatous patients in the absence of systemic or local causes. If this disorder is iatrogenic, it leads to speculation regarding the possible role of the miotic agents or their vehicles as the etiologic factor, or factors, in the production of these changes. Whether an altered metabolism of the cornea can be attributed to the medication, resulting in focal deposition consistent with the appearance of calcium, is an intriguing consideration. The pattern of

⟹

the keratopathy should be recognized clinically so as to spare the patient the unnecessary effort and expense of detailed medical and laboratory investigation for other causes.

To date animal experimental work with various miotics and drugs used in the vehicles has not reproduced the lesion.

In 1966, Charney[4] reported a case described as idiopathic band keratopathy, treated by lamellar keratectomy and studied pathologically. There were no ocular or systemic findings, but his 62-year-old patient had been treated for eight years with miotics for glaucoma. The tissue specimen revealed calcium and iron in the deeper epithelium and Bowman's area. This case appears to be identical to those presented in this report. While this case seems to supply a pathologic evaluation of this atypical band keratopathy, lamellar keratectomy is not to be considered the method of choice for treatment. Treatment should be medical rather than surgical. Chelation was recommended by Grant,[5] and later, Breinin and DeVoe[6] pointed out that chelation "should be the primary treatment in cases of band keratopathy and may make future corneal surgery unnecessary." Chelation can be carried out as an office procedure. Prognosis is excellent.

Commercial ophthalmic preparations for chelation as such are not available. The disodium salt of a synthetic chemical, ethylenediamine tetra-acetic acid (EDTA), used in scleroderma, vascular, and other medical problems, is available in ampoules of 150 mg /ml, and it can be converted very simply to an ophthalmic solution[7] by withdrawing 5 ml of the stock solution by syringe and injecting it into 120 ml of a standard buffered ophthalmic irrigating solution. This prepares an 0.02 molar solution. Following topical anesthesia and denuding of the epithelium, this can be applied to the involved corneal area by continuous drip or constant stream for 15 minutes. This is simple and the results are dramatic, with good recovery of vision. Of our 18 patients, 11 have been so treated since 1965, with improved vision and relief of irritative symptoms. Three patients with incomplete removal have continued to deposit more opacity in the nontreated portion of the cornea. The others have had no recurrences in spite of continued miotic therapy, with the longest follow-up being six years. There is

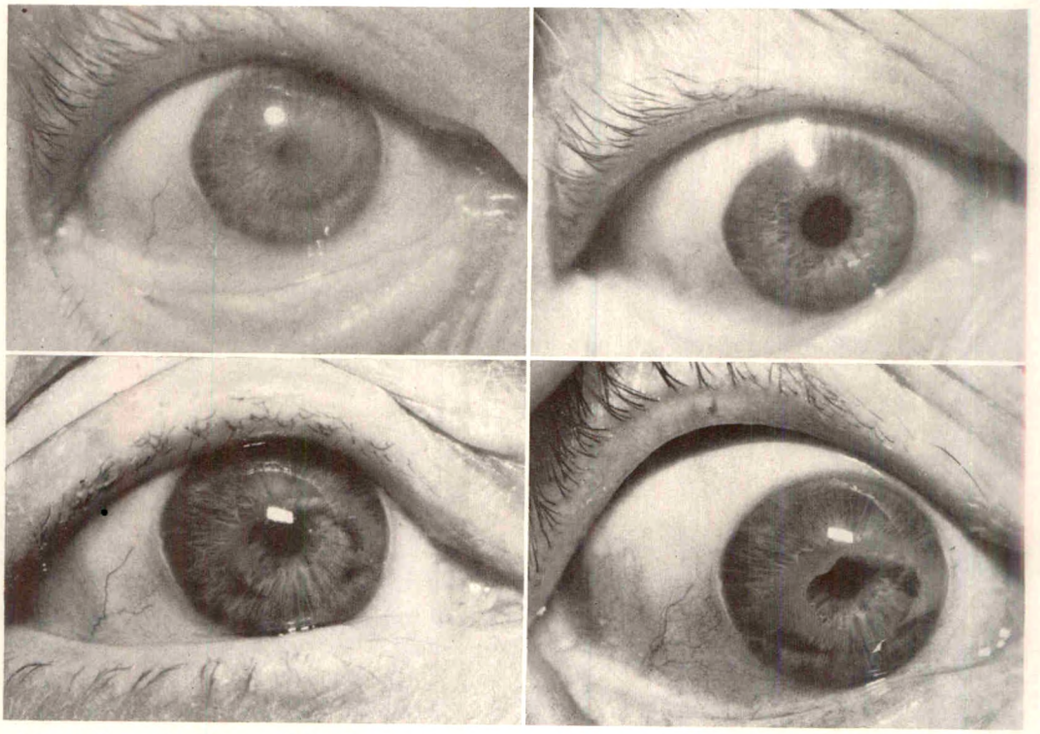

Fig. 6 (Kennedy, Roca, and Landers). Patient 4. Right eye. Top left: Vision 20/80 with keratopathy. Top right: Cornea clear, vision 20/20— one week after EDTA treatment. no reason why treatment could not be repeated.

Figures 3 through 7 show patients with the atypical band keratopathy before and after such treatment.

## Summary

An atypical band keratopathy was observed in 18 patients with well-controlled primary glaucoma, all of whom were receiving long-term miotic therapy. It is characterized by fine, gray granular deposition in the paracentral interpalpebral area of the

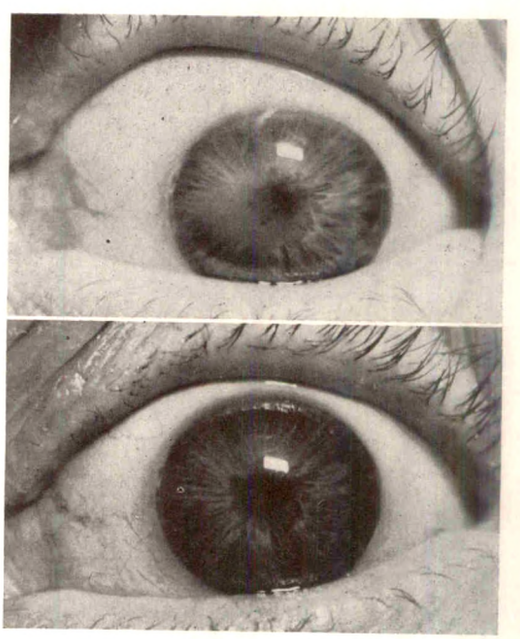

Fig. 7 (Kennedy, Roca, and Landers). Patient 4. Top: Left eye with keratopathy. Vision 20/30—. Bottom: Same eye with clear cornea after EDTA treatment. Vision 20/20.

cornea at the level of deep epithelium and Bowman's membrane and extends horizontally with progression.

The prognosis is excellent and satisfactory treatment by chelation with EDTA has proven the treatment of choice. Under topical anesthesia, this consists of irrigation with an 0.02 molar solution by continuous drip or constant stream for 15 minutes to the involved area of the cornea which has been denuded of epithelium. Eleven of 18 patients have been treated with improved vision and relief of irritation.

If this keratopathy is recognized, the patient can be spared detailed medical and laboratory investigation for other causes.

Etiologic factors have been considered, emphasizing the apparent role of the miotic agent, or more particularly their vehicles, in its production.

ACKNOWLEDGMENT

We thank Drs. John R. Fitzgerald, John F. Gipner, Harold J. Louis, and George A. Platt for allowing us to include their patients in this series.

# EFFECT OF OCULAR PIGMENTATION ON HYPOTENSIVE RESPONSE TO PILOCARPINE

LAURENCE S. HARRIS, M.D., AND MILES A. GALIN, M.D.
*New York, New York*

Ophthalmologists are aware that blue irides dilate much more promptly than do heavily pigmented, brown irides.[1-4] It is also generally accepted that cycloplegic agents are required in both greater quantity and concentration to obtain an adequate degree of cycloplegia in the latter category of patients.[5-7] One explanation for this is that the drug must penetrate through more dense pigment to reach receptor sites in darker eyes.[5-7]

The effect of ocular pigmentation on response to miotics, however, has not been well studied. If the hypothesis concerning mydriatics in pigmented eyes is correct, penetration of miotics to receptor sites should be impeded as well, and not only the pupillary, but also the hypotensive effects of these agents may be reduced. The present study was undertaken to see whether ocular pigmentation results in differences in the effects of miotics on intraocular pressure and outflow facility.

## METHODS

The study group was composed of 24 patients with open angle glaucoma, diagnosed by the criteria of elevated intraocular pressure, characteristic visual field loss, and cupping of the optic nerve heads. Patients were divided into three groups on the basis of ocular and systemic pigmentation. These were: a blue-eyed Caucasian group, a brown-eyed Caucasian group, and a group of Negro patients with heavily pigmented brown irides.

After obtaining initial baseline applanation intraocular pressures, tonography was performed with the Crescent unit and the outflow facilities calculated according to the Friedenwald tables. Patients were then given 1% pilocarpine to be used four times daily in the right eye only, with the unmedicated left eye serving as a control. At the conclusion of two weeks, applanation tonometry and tonography were repeated and the patients were started on 4% pilocarpine. During the final two-week period, 8% pilocarpine was utilized.

Statistical analysis for right eye/left eye differences within a group were done by mean pair differences, and those between groups were done according to the formula for grouped data. Student's t-test was used and p values of 0.05 or less were considered statistically significant.

## RESULTS

The initial right and left eye applanation intraocular pressures and outflow facilities for each group are given in Table 1. No statistically significant difference was noted.

Blue-eyed patients appeared to have a marked hypotensive response with 1% pilocarpine over that seen in the other two groups. A further, statistically significant decline in pressure was only reached in the latter patients with the 8% drug solution (Table 2). An adequate therapeutic effect was not really attained in the brown-eyed Caucasian patients until 4% drug concentration was employed, whereas 8% was necessary to elicit a comparable response in the black patients (Tables 1 and 2).

Initial improvements in outflow facility (C value) were seen with 1% drug concentration in all groups. Despite additional declines in intraocular pressure, no further statistically significant change in C value was noted (Table 1).

* Blue = blue-eyed Caucasian patients, Brown = brown-eyed Caucasian patients and Black = Negro patients.

No attempt was made to determine the degree of miosis in each group. Clinically, however, all patients had miotic pupils at the time of revisits during drug application.

## DISCUSSION

The data from the present study discloses that the ocular hypotensive response to pilocarpine is influenced by ocular pigmentation.

TABLE 2

P VALUES FOR STUDENT'S T-TEST FOR SIGNIFICANCE OF DIFFERENCE BETWEEN PILOCARPINE CONCENTRATION IN THE VARIOUS PATIENT GROUPS

| Solution Strength | Blue* | Brown* | Black* |
|---|---|---|---|
| Untreated and 1% | P<0.01 | P<0.05 | P<0.05 |
| 1% and 4% | P>0.05 | P<0.05 | P>0.05 |
| 1% and 8% | P<0.05 | P<0.01 | P<0.05 |
| 4% and 8% | P>0.05 | P>0.05 | P>0.05 |

* Blue = blue-eyed Caucasians, Brown = brown-eyed Caucasians, Black = Negro patients.

Blue eyes, which have the least amount of ocular pigmentation, had the greatest ocular hypotensive response to pilocarpine. In these eyes, the response to 1% drug solution was pronounced and, although additional declines in intraocular pressure were seen at 4% and 8%, these were not of great magnitude. By contrast, brown eyes of Caucasian patients had statistically significant changes in intraocular pressure with the 1% solution, but required an increase in dosage to 4% to produce therapeutically meaningful responses. Responses to pilocarpine in the black patients were not as good as either of the two preceding groups at any drug concentration. The resulting shift in the dose-response curve was such that, in these eyes, an 8% solution produced a response roughly equal to that seen with 4% in brown eyes. The correlation of outflow facility changes and ocular pigmentation paralleled those noted with intraocular pressures.

Statistically significant changes in intraocular pressure were noted during the course of the study without meaningful alterations in outflow facility. This lack of correlation between ocular hypotensive response and change in outflow facility was previously noted with pilocarpine, indicating that this drug may affect aqueous production as well as response to aqueous outflow.[8,9] Experimental data in several species confirmed this finding.[10,11] Furthermore, it has been shown that the dose-response curves for pilocarpine alone and for pilocarpine plus epinephrine are parallel, again implicating a duel mechanism of action for pilocarpine.[12]

One hypothesis to explain the observations of this study is that ocular pigment might bind topically administered drugs which would then fail to reach receptor sites in the iris and ciliary body. It is also possible that enzymatic differences exist coincidentally in pigmented ocular structures. Increased activity of iris dopa-oxydase has been postulated to explain the difference in response of albino and pigmented rabbit irides to adrenergic drugs.[13] This idea, however, appears a less likely explanation, since the degree of pigmentation influences the responsiveness to a wide variety of drugs (e.g., cycloplegics, mydriatics, and pilocarpine), thereby necessitating a vast number of enzymatic differences being called into play.[1-4]

From the present data, it would seem that the change in the dose-response curve should be borne in mind when using pilocarpine, particularly in black patients. In this instance, recourse to pilocarpine solutions in excess of 4% may be required. Also, studies with this drug should specify the distribution of ocular pigmentation in either patients or experimental animals in order to make interpretation of data more meaningful.

## Summary

Pilocarpine was administered in three strengths (1, 4, and 8%) to three groups of patients with open-angle glaucoma patients: Caucasians with blue irides, Caucasians with brown irides, and black patients with heavily pigmented, brown irides. It was found that blue eyes demonstrated near maximal ocular hypotensive responses with 1% pilocarpine. Black patients demonstrated a relative resistance to the ocular hypotensive response of this drug until the higher concentrations were reached. Brown-eyed Caucasian patients were intermediate in response between these two extremes. The results are consistent with the idea that ocular pigmentation hinders penetration of topically applied drugs to receptor sites. This shift in the dose-response curve should be considered when treating glaucomatous black patients.

# INTRAOCULAR PRESSURE CHANGES DURING HEMODIALYSIS

JOHN T. RAMSELL, M.D., PHILIP P. ELLIS, M.D., AND
CHRISTOPHER A. PATERSON, PH.D.
*Denver, Colorado*

Increased intraocular pressure (IOP) has been observed during hemodialysis in uremic dogs and in uremic patients.[1-6] It also has been suggested that since tonometry is effective in detecting IOP changes due to fluid transfer across the blood-aqueous barrier during dialysis, increases in IOP may parallel and thus predict fluid movement across the blood barrier as in the development of cerebral edema during dialysis.[1,3]

This study was undertaken to further evaluate changes in IOP with hemodialysis and to determine whether a correlation exists between hourly changes in serum osmolality and IOP.

## METHODS

Twenty patients receiving chronic intermittent hemodialysis were studied. All dyalyses were performed using the Kolff twin-coil unit with Ultra-flo 145 (Travenol Laboratories, Inc.) coils. The purpose of dialysis was to remove excess fluid weight as well as excess chemical constituents, such as urea nitrogen and creatinine. Intraocular pressures were measured with a Tonair applanation tonometer. This instrument was demonstrated to give comparable readings to the Goldmann applanation tonometer on 50 consecutive patients in the University of Colorado eye clinic. Measurements were made, with the patient in supine position, on both eyes of each patient before dialysis, every hour during dialysis and at the conclusion of dialysis. Since the readings for both eyes were similar in almost every instance the mean value of the two eyes was determined for data analysis. When IOP readings were 25 mm Hg or more, a series of readings were taken and the recorded values were based upon the higher readings as recommended by Posner and Inglima in their evaluation of the Tonair Applanometer.[7]

The duration of the dialysis was six hours in nine patients and five hours in 10 patients. In one patient, the dialysis had to be terminated at three hours following a convulsion; this patient was dropped from the study.

Arterial blood samples were collected for determination of serum osmolality (freezing point depression method, using an Advanced Osmometer) each time tonometry was performed. Specimens were allowed to clot, were centrifuged, and the individual serum samples stored at 4°C until osmolality determinations were performed.

After collection and analysis of the IOP and serum osmolality data it was suggested that tonographic data may be of use in the interpretation of the findings. Unfortunately, when the tonographic study was undertaken only three of the original group of subjects were available for study; the others were deceased, had moved from the area or were transplant recipients. Therefore, four additional subjects were admitted to the tonographic study. Tonographic recordings (and Tonair measurements) were made just before dialysis and at the four-hour stage during dialysis. The mean value of tonographic data from the two eyes was used for analysis.

## RESULTS

All patients in this study exhibited a decrease in body weight at the conclusion of dialysis.

The mean initial serum osmolality was 311

TABLE 1

INITIAL AND FINAL VALUES OF IOP AND SERUM OSMOLALITY

| | Five-Hour Group (10 patients) | Six-Hour Group (9 patients) | Combined Groups |
|---|---|---|---|
| Osmolality (mOsm/L): | | | |
| Initial | 311 (291, 331)* | 313 (299, 331)* | 312 (291, 331)* |
| Final | 282 (267, 303) | 282 (273, 290) | 282 (267, 331) |
| Mean change | −29.5 (−24, −43) | −31.1 (−12, −42) | −31 (−12, −43) |
| IOP (mm Hg): | | | |
| Initial | 20.4 (15.5, 32.5) | 20.6 (15, 28) | 20.5 (15, 32.5) |
| Final | 18.9 (12, 31) | 22.7 (16, 32.5) | 20.7 (15, 32.5) |
| Mean change | −1.45 (−5, +8) | +2.06 (−5, +9.5) | −0.2 (−5, +9.5) |

* The numbers in parentheses refer to the range of values.

mOsm/L (range 291-331) and 313 mOsm/L (299-331) in the patients dialyzed five and six hours, respectively. The mean starting osmolality for all 19 patients was 312 mOsm/L. Serum osmolality decreased during dialysis in every patient. The change between initial and final osmolality in the five-hour group was −29.5 mOsm/L (12-42) and that in the six-hour group was −31.1 mOsm/L (12-42). These figures are presented in Table 1.

The predialysis IOP of all 19 patients ranged from 15-32.5 mm Hg with a mean of 20.4. The mean initial IOP and range for the five- and six-hour group was 20.4 (15.5-32.5) and 20.6 (15-28) respectively. The five-hour group exhibited a mean change in IOP of −1.45 with a range of −5 to +8. That in the six-hour group was +2.05 with a range of −5 to +9.5. Combining the five- and six-hour groups we find only a 0.2 mm Hg increase in IOP at the conclusion of dialysis (Table 1).

Despite the lack of significance between initial and final IOP, careful analysis of IOP changes during dialysis revealed some interesting points. The changes are presented in Table 2 and Figure 1. For convenience all 19 patients are grouped together for IOP and osmolality values between zero

TABLE 2

MEAN IOP AND SERUM OSMOLALITY AT HOURLY INTERVALS DURING DIALYSIS*

| | Initial | One-Hour | Two-Hour | Three-Hour | Four-Hour | Five-Hour | Six-Hour |
|---|---|---|---|---|---|---|---|
| IOP (mm Hg) | 20.5 ±1.0 | 20.1 ±1.4 | 19.2 ±1.1 | 21.1 ±1.3 | 21.1 ±1.2 | 21.3 ±1.4 | 22.7 ±1.8 |
| Osmolality (mOsm/L) | 313 ±2.5 | 305 ±2.4 | 299 ±2.3 | 294 ±2.2 | 289 ±2.1 | 284 ±2.0 | 282 ±2.0 |

* Values are arithmetic mean, ± standard error of the mean. Up to and including five hours, each group contains 19 patients. The six-hour group has only nine patients.

and five hours. It can be seen that a significant decrease in IOP occurred during the first two hours (from 20.4 to 19.0 mm Hg, $p<.05$). The increase in IOP between two and three hours (19.0 to 20.9 mm Hg) was significant at the 99% level. However, the IOP from three to six hours was not significantly different from the baseline value. The apparent marked increase at six hours is due to the smaller number of observations since only nine patients were dialyzed a full six hours. These IOP changes are not, however, considered clinically significant.

When the IOP changes in individual subjects are considered, marked alterations are evident. In 10 of the 19 patients there was a maximum rise in IOP ranging from 0.5 to 16 mm Hg, with a mean of 6.9 mm Hg. This increase occurred from one to six hours after dialysis was started. The remaining nine patients exhibited either no significant change or a sustained reduction in IOP during dialysis. When the mean IOP changes of the entire group are considered only with respect to time, individual elevated pressures are masked.

The mean value of outflow facility obtained by tonography before dialysis was 0.22 ± .026 (S.E.) and that after four hours was 0.21 ± .027. The IOP values for this smaller group of subjects exhibited a similar maintained elevation at four hours as was ob-

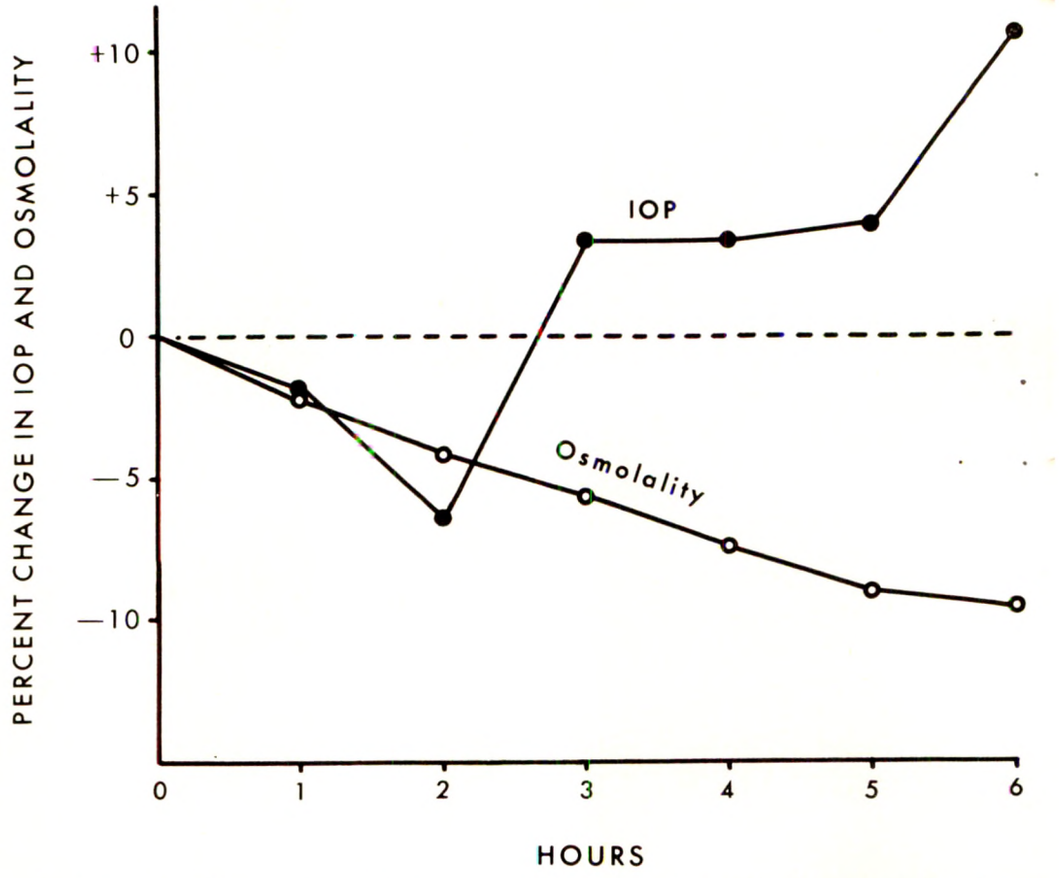

Fig. 1 (Ramsell, Ellis, and Paterson). Changes in IOP and serum osmolality with respect to time during dialysis. Percent change was calculated from the figures in Table 2. It should be noted that the six-hour points are the mean values from only nine patients; the other points are obtained from 19 patients (see text).

served in the original 19 subjects; the mean IOP before dialysis was 20.5 ± 1.03 and 24.6 ± 1.60 after four hours of dialysis.

The patients exhibiting abnormally high IOP readings in this study were found to have normal applanation tensions, visual fields, and gonioscopic findings when examined in the eye clinic on a day when they were not undergoing dialysis.

## Discussion

In the study reported by Sitprija, Holmes and Ellis[1] from this Medical Center in 1964, there was a mean decrease in serum osmolality of 37.6 mOsm/L (range 3-72) after about six hours dialysis. This compares with a mean fall in serum osmolality of 31 mOsm /L (12-43; 5 and 6 hour groups combined), in the present study. Despite the use of smaller coils in this study, 1.45 $m^2$ (Ultra-flo 145) as opposed to 1.9 $m^2$ (Twin-coil 190, Travenol) used in the earlier study,[1] the observed changes in osmolality are obviously not significantly different.

Sitprija and associates[2] found an average increase in IOP of 41.8% of control values in uremic dogs following dialysis, and an average increase in IOP of 4 to 8 mm Hg in the majority of uremic patients during dialysis. Watson and Greenwood[3] reported an average rise in IOP of 8.1 mm Hg in six patients during 12 dialyses. Biagini and Gloria[4] reported a mean increase in IOP of 16% during dialysis of uremic patients. Applemans and associates[5] demonstrated an increase in IOP up to 10 mm Hg in 80% of patients undergoing renal dialysis. These studies suggest a correlation between decrease in plasma osmolality and increase in IOP during dialysis. Presumably an influx of fluid into the eye due to the difference in osmolality between plasma and intraocular fluids results in an increased IOP. In none of the previous studies however was data presented which correlated hourly serum osmolality changes with increases in IOP. The data obtained in this study not only confirm that individual increases in IOP can occur during dialysis but can also be analysed to compare hourly changes in IOP and serum osmolality.

In Figure 1 the hourly percent of change in serum osmolality is plotted against the hourly percent of change in IOP. As described in Results, an initial decrease in IOP is followed by an increase which persists up to six hours. The initial decrease in IOP might be related to decreased intravascular volume as well as to reduced anxiety in the patients as the procedure became more familiar. The initial weight loss in patients undergoing dialysis represents principally a reduction in intravascular volume.[8] Marked decreases in IOP paralleling weight loss in dogs were observed by Sitprija and associates.[2] The increase in IOP between two and three hours is felt to be due to an osmotic influx of water into the eye as a result of the relative hyperosmolality of intraocular fluids. During ensuing hours it is presumed that the intraocular and intravascular fluids approach osmotic equilibrium.

It had been suggested to us that the maintained elevation of IOP at three to four hours might be due to a decrease in outflow facility. For this reason tonographic measurements were made before and after four hours of dialysis. The results, which demonstrated no change in outflow facility, indicate that it is not a significant factor in explaining IOP changes observed during hemodialysis.

Changes in IOP during hemodialysis might be related to the hourly rate of serum osmolality change; a more rapid decrease in serum osmolality resulting in a more pronounced IOP change. IOP in uremic dogs during hemodialysis remained unchanged or showed a minimal increase when the reduction in serum osmolality averaged 8.5 mOsm /L per hour. When the serum osmolality reduction averaged 11 mOsm/L per hour the IOP increased significantly.[2] In the present study serum osmolality decreased at 5-7 mOsm/L per hour and mean IOP changes were not significant.

Barry, Khoury, and Brooks[9] found that, although changes in mean serum osmolality appear to be associated with reciprocal changes in IOP, the two are not closely related. Galin, Aizawa, and McLean[10] consider that the water-drinking test, at its outset, depends upon the level of induced hypo-osmolality, but add that in man the statistical correlation between plasma hypo-osmolality and IOP increase is not adequate to make this an inviolate hypothesis.

It should be recalled that in the present study marked increases in IOP during hemodialysis did occur at various times in 10 of the 19 patients, but the times did not correlate with any particular stage of serum osmolality reduction. The possibility exists that the degree and timing of IOP increases during hemodialysis depends principally upon the extent of changes in intravascular volume. In those patients exhibiting the greatest IOP increase during dialysis the initial fall in IOP (Fig. 1), which is considered to correlate with weight changes, was minimal.

It can be concluded that during hemodialysis IOP is affected by factors other than a relative reduction in serum osmolality. Krupin, Podos, and Becker[11] have suggested that the ocular hypotensive response to hyperosmotic agents might be mediated, in part, by mechanisms in the central nervous system.

## Summary

In 19 uremic patients undergoing hemodialysis the mean final IOP was only 0.2 mm Hg above the mean initial values. However, in 10 of the 19 patients maximum increases in IOP ranging from 0.5 to 16 mm Hg occurred at times ranging from one to six hours. Statistically, but not clinically significant mean IOP changes were observed during the early stages of dialysis and are discussed. Serum osmolality decreased in all patients; the mean decrease was 31 mOsm/L. Hourly IOP changes did not correlate with reduction in serum osmolality. The influence of changes in intravascular volume on IOP during hemodialysis is discussed.

### Acknowledgment

We acknowledge the cooperation of members of the Renal Division during this study.

# A TECHNIQUE FOR CONJUNCTIVO-DACRYOCYSTORHINOSTOMY

CLARENCE WILLIAM COX, JR.
*Birmingham, Alabama*

In the performance of conjunctival and dacryocystorhinostomy procedures, anatomical variations of the distance from the caruncle to the center of the nasal cavity, the size and shape of the nasal cavity, the position of the septum, and the different possibilities of the angle of the channel require that each patient be custom-fitted with a Jones tube of optimum length. Accordingly, I have devised a set of 20 tubes, varying by 1 mm from 10 to 30 mm, (Fig. 1). Each tube has an outside diameter of 3 mm, a lumen of 1.70 mm and a flange of 4 or 5 mm.

Observation of the mechanical difficulties that beset the ophthalmic surgeons at the Eye Foundation Hospital led to the development of a set of instruments (Fig. 2) designed to make the operation technically easier with less trauma to the patient and successful function of the tube more likely.

From the Department of Photography, the Eye Foundation Hospital, Birmingham, Alabama.

Reprint requests to Mr. Clarence William Cox, Jr., Photographer, The Eye Foundation Hospital, 1720 Eighth Avenue South, Birmingham, Alabama 35233.

## PROCEDURE

At our hospital, the operation for emplacing a Jones tube is begun by incising the skin and subcutaneous tissues over the lacrymal area as for a dacryocystorhinostomy. After the tissues are retracted, a sector of lacrymal bone is removed with a burr, a chisel, or an Iliff trephine on a Stryker saw. The nasal mucosa beneath the bone sector is removed also. The lower half of the caruncle is removed and from this conjunctival opening at the medial end of the fornix, a stab inci-

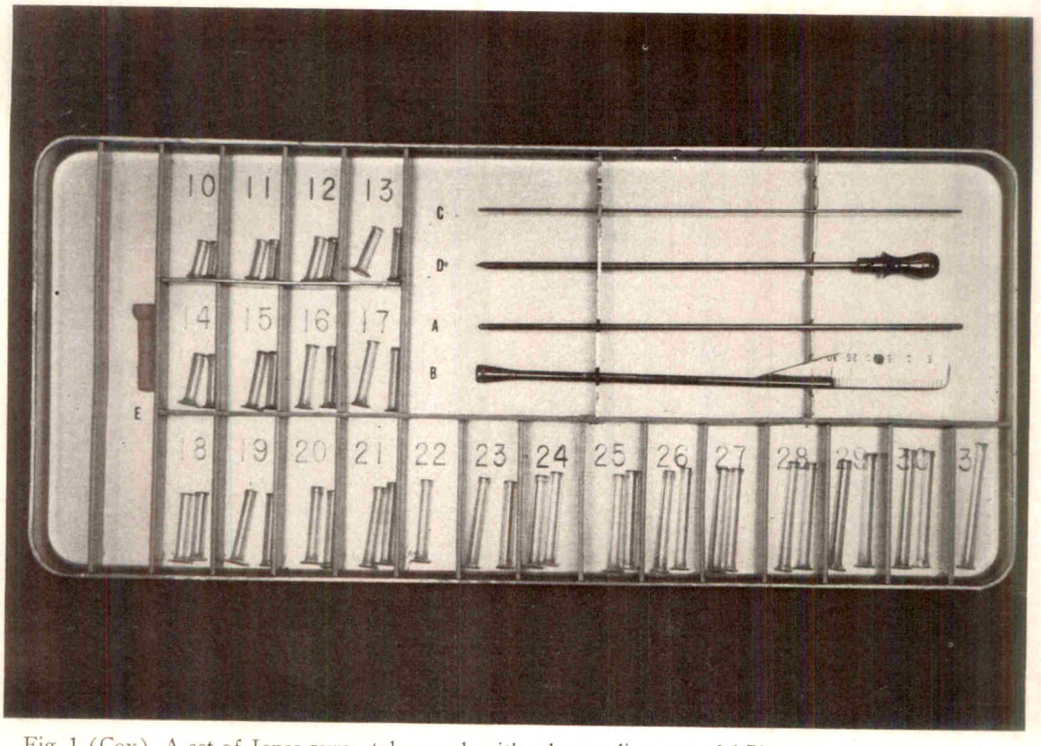

Fig. 1 (Cox). A set of Jones pyrex tubes, each with a lumen diameter of 1.70 mm, and varying by 1 mm from 10 to 30 mm, are kept in an aluminum compartment case. The case also contains special instruments for insertion of the proper tube.

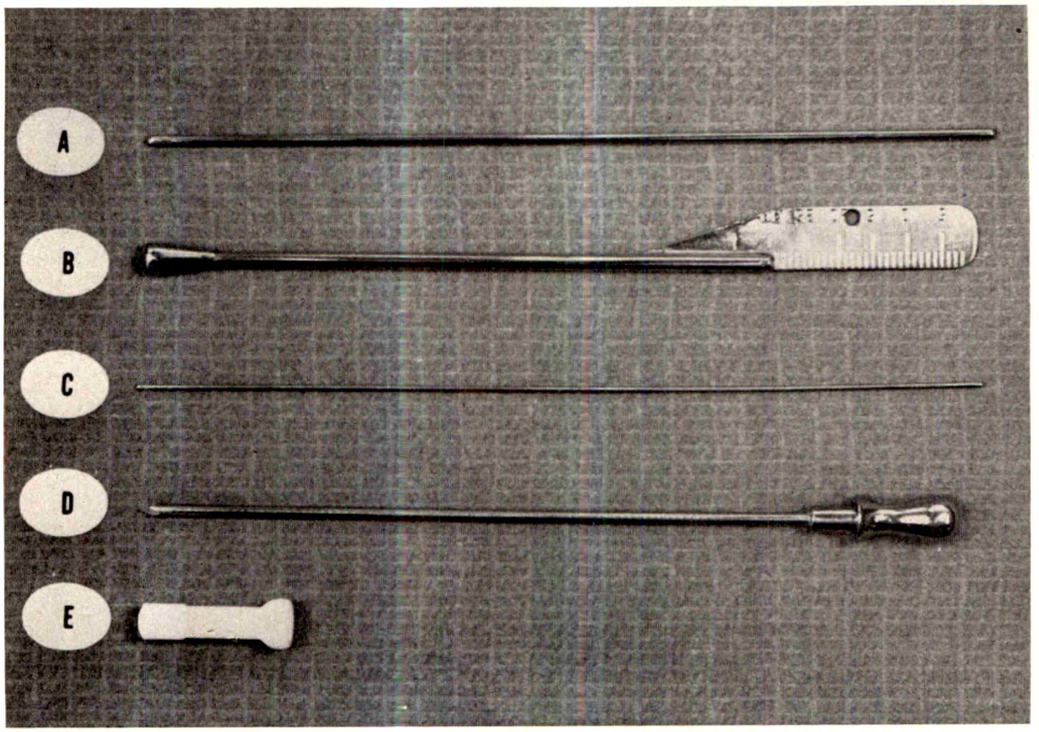

Fig. 2 (Cox). The special instruments for insertion of the tube of proper length are: (A) Stainless steel precision rod (1.6 mm in diameter and 12.5 cm long). (B) Precision millimeter gauge. (C) Stainless steel precision rod (0.75 mm in diameter). (D) Trocar. (E) Teflon inserter.

sion is made with the rounded Beaver blade knife into the bony opening. A stainless steel precision rod, 1.6 mm in diameter and 12.5 cm long, rounded on both ends, is inserted from the caruncular opening into the nasal cavity (Fig. 3-A). With the tip of the rod touching the septum, the sleeve with a millimeter gauge is slipped on the rod and pushed down to the caruncle. The proper length of the tube is indicated. A 3 mm clearance is allowed from the nasal septum (Fig. 3-B). The sleeve-gauge is then removed and a tube of optimal length is placed on the rod. The Teflon inserter, designed to exert even pressure around the top of the tube at the flange, is placed on the rod (Fig. 3-C) and is pushed so that the tube is placed into position (Fig. 3-D). Observation of the tube transnasally and through the surgical window will assure that the tube is the proper length and optimally positioned. Also, the upper end of the tube must not slip deeply into the fornix, or conjunctiva will grow over the top of the tube.

*Postoperative measures*—After the operative edema subsides, a different length tube may be required. In most cases, the tube may be changed as an office procedure without anesthesia, even in children. The rod is inserted through the tube. The tube is slid out, leaving the rod in place, and a longer or shorter tube, as indicated by the gauge, is inserted without trauma. A thinner rod, 0.75 mm in diameter (Fig. 2-C), is used if mucus or discharge has partially blocked the tube, making it difficult to insert the 1.6 mm rod.

If a patient loses a tube, and is not seen for several days by the surgeon, the channel is usually closed with scar tissue, especially if this occurs soon after insertion. The trocar in the set (Fig. 2-D) can be used to reopen the surgical channel and the emplacement with the steel rod is repeated. This may be done under local anesthesia in the office or

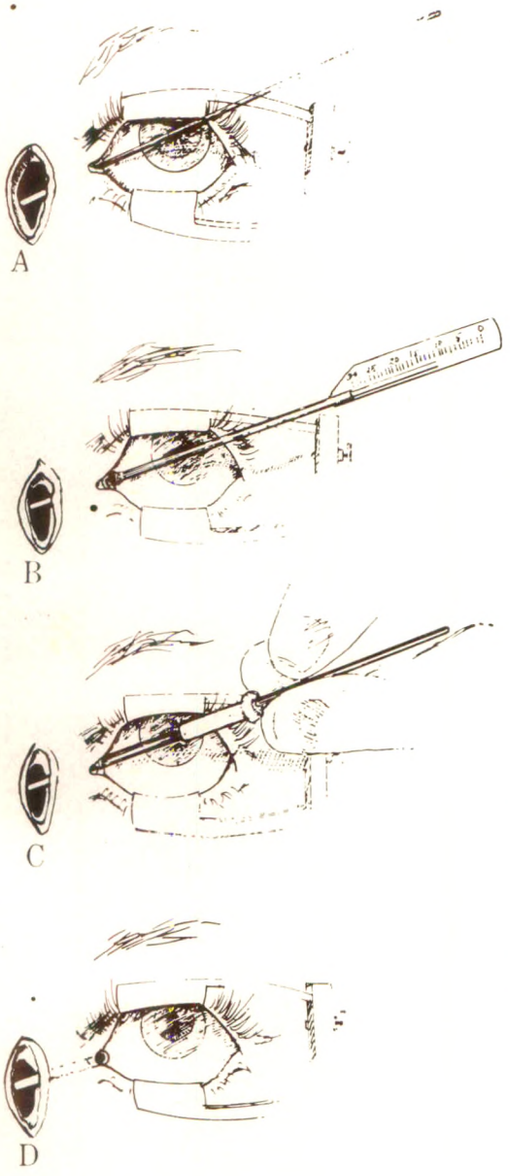

Fig. 3 (Cox). Technique used for emplacement of the Jones pyrex tube by the Cox system. (A) Shows the 1.6 mm precision rod placed in the channel made for the tube, extending from the caruncle through the soft tissues of the medial canthal area and extending through the bony opening into the nasal cavity. (B) The precision millimeter gauge is introduced to measure the length needed. (C) The tube of proper length is inserted with the Teflon inserter. (D) Jones pyrex glass tube now in place.

under general anesthesia in the hospital, depending upon the patient's age and ability to cooperate. The set of instruments and tubes is contained in an aluminum compartment case suitable for autoclaving, dry heat, or gas sterilization. Gas sterilization is recommended as it causes no water residue in the tubes.

## Summary

In order to facilitate conjuncival and dacryocystorhinostomy procedures, a sent of 20 pyrex glass tubes, varying by 1 mm from 10 to 30 mm was devised to span the tissues from the lower edge of the caruncle into the middle of the nasal cavity, according to the anatomical variations of different patients.

Enclosed with the set is a stainless steel rod which can be inserted through the surgical passageway for the tube, a precision millimeter gauge for determining the proper length of the tube, a precision rod 0.75 mm in diameter for use when the tube is blocked with blood or mucus, and a Teflon inserter.

## Acknowledgment

# DERMATOPHYTOSIS AFFECTING THE PERIORBITAL REGION

H. Bruce Ostler, M.D., Masao Okumoto, M.A., and Carlyn Halde, Ph.D.
*San Francisco, California*

Most fungal infections of the cornea are secondary infections, caused by opportunistic fungi that have invaded a diseased cornea or one that has been treated with corticosteroids or broad-spectrum antibiotics. Two exceptions are corneal infections due to Candida albicans or Aspergillus species; these may infect an apparently normal cornea after minimal trauma.

Superficial mycotic infections can be divided into three groups: those caused by (1) the dermatophytes or ringworm fungi, (2) the organisms responsible for tinea versicolor and tinea nigra, and (3) Candida species.[1] It is better to restrict the term dermatophytosis to infections due to the ringworm fungi (the genera Microsporum, Trichophyton, and Epidermophyton) than to use it as an inclusive name for cutaneous fungal diseases.[2]

The dermatophytes occasionally infect the skin of the eyelids[3-11] or the eyelashes.[6-13] This paper reports a case of dermatophytosis of the eyelids due to the organism Trichophyton mentagrophytes.

## Case report

A four-year-old white boy had a pruritic rash around the right eye of four weeks' duration (Fig. 1). A "sty" of the right upper eyelid had opened and drained spontaneously one week before we saw him, and during that week, polysporin ointment was applied three times daily. Prior to the onset of symptoms, the child had played with an apparently normal pet rabbit. The child had a history of otitis media and allergy to certain foods.

Fig. 1 (Ostler, Okumoto, and Halde). Appearance of patient 30 days after onset of symptoms.

Examination revealed vesicles and pustules on an erythematous base that extended from the brow over the entire upper eyelid to the midline of the nose, thence to the lower eyelid and laterally several millimeters to the lateral canthus. There was minimal crusting. The conjuctiva and cornea appeared normal. Two moderate-sized, firm, nontender, anterior cervical nodes were palpable on the affected side. The lashes and hair of the eyebrows did not fluoresce under Wood's light.

The diagnostic possibilities appeared to be pyoderma or herpes simplex infection. Treatment of the eyelids was stopped, and two days later the lesions were elevated and more heavily crusted (Fig. 1). Several members of the staff of the Dermatology Division were consulted, and in their opinion the lesion resembled pyoderma.

The appearance of the lesions changed very little during the first two weeks of observation, in spite of the immediate institution of topical erythromycin ointment, hot packs, and 5% ammoniated mercury, and the addition of systemic erythromycin, 100 mg four times daily, at the end of the first week of treatment. At the end of the second week, all topical medication was stopped and the hot packs were changed to warm milk packs.

At this time, six weeks after the onset of symptoms, the skin lesions began to show improvement for the first time; both the erythema and the crusting diminished. Three weeks later (nine weeks after onset), moderate crusting of the eyelid margin

Dopamine-β-hydroxylase catalyzes the β-hydroxylation of dopamine to form norepinephrine.[21] It is of interest to note that in a separate study of catecholamine metabolite formation in the retina following dopamine infusion,[22] we found little formation of norepinephrine and almost no formation of normetanephrine, although other dopamine metabolites (DPA and HVA) were present. This is in contradistinction to the striking formation of norepinephrine from dopamine in the uveal tissues in the present study (Fig. 3). These findings are consistent with the fact that little or no norepinephrine is found endogenously in the mammalian retina and that dopamine is the only catecholamine which seems to be present in this tissue.[14,23] The inference is clear that dopamine-β-hydroxylase is active in the uveal tract, but is not present in retinal catecholamine-containing neurons.

## Summary

Following intracarotid infusion of tritiated catecholamines ($^3$H-norepinephrine or $^3$H-dopamine) in cats, radiochromatography of extracts of the iris and ciliary body was done. After norepinephrine infusion, small amounts of radioactivity were found associated with catecholamine metabolites, although most remained associated with the original norepinephrine. After dopamine infusion, on the other hand, a large amount of radioactivity became associated with norepinephrine, suggesting conversion of the infused dopamine to norepinephrine. This was consistent with the high concentration of endogenous norepinephrine found in the anterior uveal tract, and was in contradistinction to the retina, in which dopamine is the only catecholamine present in significant endogenous amounts.

OPHTHALMIC MINIATURE

There was another woman who rushed in, drawing attention to a thing like a tiny bead of glass sticking to her baby's cheek. The child had acute inflammation of the eyeball, which the mother had treated with cold tea. The eye had long been closed, but when the mother made a clumsy attempt to open the swollen lid something had popped out, some fluid and this thing like glass. She was afraid to touch it. She viewed it with horror as a strange thing that had come out of the eye. Hugging the child, she had run a mile or so with the dread object still adhering to the skin of the cheek. This glistening thing was the crystalline lens. The globe had been burst, and the child was, of course, blind.

# NORRIE'S DISEASE

## Congenital Progressive Oculo-Acoustico-Cerebral Degeneration

Allan H. Fradkin, M.D.

*Galveston, Texas*

Norrie's Disease is a rare type of progressive, hereditary, congenital degeneration of the eye, ear, and brain. The entity was named for Gordon Norrie, consulting ophthalmologist to the Royal Danish Institute for the Blind, who described several cases of blindness under the name of atrophia oculi congenita.[1] Warburg published the first Danish pedigree and suggested the eponym for this syndrome; her extensive monograph[2] summarized the cases from all geographic areas of the world. At present there are only four known families with Norrie's disease in the United States.[3-6]

Although previously included in a familial survey by Holmes,[6] the patient present in this report warrants a separate report, since he is the youngest patient diagnosed with Norrie's disease and, therefore, affords us a view of the evolution of ocular changes, possibly permitting the earlier recognition of this entity, and thus allowing genetic counseling for the parents.

### Case report

This white boy was born at the University of Texas Medical Branch on November 10, 1969, after an unremarkable pregnancy, labor, and delivery. I was consulted when the child was 12 hours of age because of his anisocoria.

Ophthalmologic examination revealed decreased orbicularis function on the left, but was otherwise unremarkable externally. The globes were of normal size. Each eye showed a random gaze pattern independent of the other. Chemical conjunctivitis from silver nitrate instilled at birth was present.

Both corneas were clear and measured approximately 10 mm. The anterior chambers were shallow. The right pupil measured 2 mm and was sluggishly reactive to light; the left was 5 mm and nonreactive Rubeosis iridis was present bilaterally. The lenses were clear.

From the Department of Ophthalmology, University of Texas Medical Branch. This study was supported in part by Public Health Service Grant 5T01 EY 0058 05 from the National Institute of Health.

Reprint requests to Allan H. Fradkin, M.D., Department of Ophthalmology, University of Texas Medical Branch, Galveston, Texas 77550.

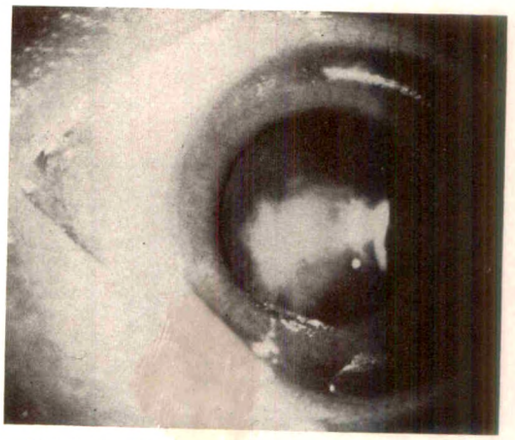

Fig. 1 (Fradkin). Left eye, showing vitreous hemorrhage (black in picture) and yellowish membrane (white in picture).

Fundus examination revealed no normal retinal tissue in either eye and was very difficult to interpret. Vitreous hemorrhages were seen bilaterally in addition to a yellowish-white vascular membrane (Figs. 1 and 2). Ocular tensions were normal by palpation.

Family history was then elicited (Fig. 3). The X-linked recessive inheritance pattern is apparent, since only males are affected and the trait can be passed on through carrier females who are themselves normal. It is of interest that the patient's family originated in Sweden, which is where the majority of cases have been found. Of the two maternal uncles affected with Norrie's disease, one had both blindness and retardation and the other had

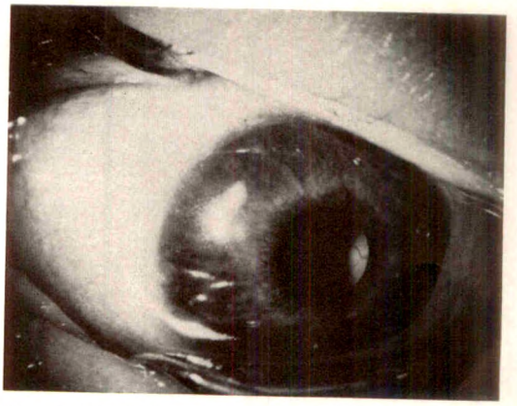

Fig. 2 (Fradkin). Right eye, showing retrolental vascular membrane.

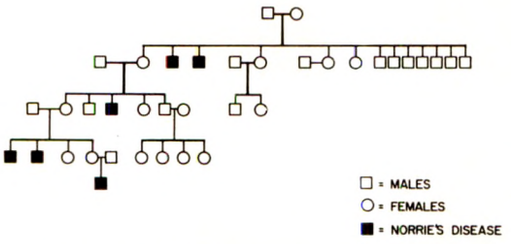

Fig. 3 (Fradkin). Genealogy chart of patient's family. The patient is the individual affected in the last generation.

blindness alone. Neither had grossly retarded hearing, but one was reported to have a "slight abnormality" in the hearing test. The affected males were all reported to have developed blindness at an early age, but none was examined in the first few months of life.

Laboratory work, including complete blood count, urinalysis, VDRL, amino acid and mucopolysaccharide screening were all negative or within normal limits, as were the chest x-ray and skull films.

During the first four months of life, the child developed a pendular nystagmus. The corneas enlarged markedly and became cloudy due to elevated intraocular pressures. The anterior chambers were obliterated. Additional vitreous hemorrhages occurred.

The boy was last seen in February, 1971, at 15 months of age. He was noted to have developed subjective entoptic stimulation by eye rubbing. Both globes had become phthisical, precluding any further fundus examination. The external appearance showed very shrunken eyes set deep in the orbits.

His developmental milestones were considered by the pediatrician to be within normal limits and there was no evidence of hearing loss.

## Comment

Norrie's disease is an X-linked syndrome of retinal malformation, mental retardation, and deafness. The clinical picture of Norrie's disease has been obtained by examining patients from eight days to 60 years of age. All affected individuals are, for all practical purposes, blind. The external examination is unremarkable. The corneas are usually clear in infancy, but during childhood develop opacities, eventually becoming opaque. In most cases, the anterior chamber is abnormally shallow or partially obliterated. Iris atrophy, ectropion uveae, as well as anterior and posterior synechiae are seen. The pupil, of course, is nonreactive. The lens is clear or slightly opaque early in the course of the process. However, cataractous changes begin early, so that by five years of age most patients have developed a true cataract.

The vitreous cavity in Norrie's disease is most unusual. A grey or greyish-yellow retrolental mass with a few vessels on its surface precludes visualization of the retina in most children. Also, the vitreous may contain hemorrhage and other opacities. In a few cases in which the retina was visible, it was partially veiled by preretinal proliferation.

The end result in adult life is a deep-set phthistic eye.

Mental retardation of varying degrees is present in 50% of these children, and progressive hearing loss occurs in one-third, beginning in childhood or later.

The description of the pathology of Norrie's disease is derived from a very few cases in which the eye had already become phthisical.

No biochemical or chromosomal abnormalities have been consistently found.

## Summary

The youngest diagnosed case of Norrie's disease, an X-linked congenital degeneration of the eye, ear, and brain, is presented. The ocular findings at birth included anisocoria, shallow anterior chambers, rubeosis iridis, retrolental vascular membranes, and vitreous hemorrhages. Subsequently, glaucoma developed and the globes became phthisical.

# IRIDOGONIODYSGENESIS WITH CATARACT

PAUL HENKIND, M.D., AND ALAN H. FRIEDMAN, M.D.
*Bronx, New York*

A variety of heritable disorders may affect the anterior segment of the eye. This report describes two brothers who show identical abnormalities of the anterior segment. These patients have anomalies of the iris and anterior chamber angle (iridogoniodysgenesis) and cataracts which developed and progressed to maturity in early adulthood. We have been unable to find reports of similar associated ocular abnormalities in the literature. The relationship of this syndrome to other inherited anterior segment anomalies is discussed.

## CASE REPORTS

This family is of Italian origin (Fig. 1). There is no history of consanguinity. The eyes of the two affected boys ($III_1$ and $III_2$) and their parents ($II_2$ and $II_3$) were examined. Data concerning other family members were obtained from the parents.

*Case* 1—This 21-year-old truck driver ($III_1$) was seen in consultation for evaluation of a cataract in his right eye and elevated intraocular pressure in his left eye. He stated that he always had poorer sight in his right eye and that recently he noted a rapid decrease in its vision. The patient denied ocular trauma or exposure to physical or chemical agents. Family history revealed that an older brother ($III_2$) had undergone cataract surgery at the age of 23 years and the mother had had repair of a retinal detachment at the age of 45 years. Medical evaluation revealed the patient to be a healthy man with a mild erythematous, scaly skin rash over his cheek bones. He was the product of a full-term pregnancy without history of maternal infection, and his growth and development were normal. Laboratory studies, including chromosomal analysis and x-rays, were normal.

*Ocular examination*—Visual acuity was RE: 20/400 (−5.50 sph. ⊃ +2.50 cyl. ax. 90°) and LE: 20/40 (−8.00 sph. ⊃ +2.50 cyl. ax. 90°). Color vision (AO-HRR plates) was normal in the left eye. Ocular rotations were full and the eyelids and conjunctivae normal. Both corneas were normal and each measured 12 mm in diameter. Keratomer readings were: RE: 40.00 mer 5°, 40.75 mer 95°, and LE: 39.75 mer 5°, 41.75 mer 95°. Schwalbe's line was not evident on slit-lamp examination. Corectopia was present with each slightly oval pupil displaced superonasally (Fig. 2). Both irides were greyish-blue, showed scant stroma, and lacked a colarette. The pupillary ruff was absent superonasally. The periphery of each iris transilluminated. Gonioscopy revealed deep, heavily pigmented, abnormal angles (Fig. 3). A veil of pigmented tissue of varying density lined the angle from the angle recess to schwalbe's line. Normal angle structures could not be visualized. A heavily pigmented ciliary body band was apparent behind the more diaphanous portions of the abnormal angle tissue. Radial and circumferential angle vessels were present bilaterally. A moderately cataractous lens with wrinkled anterior lens capsule was present in the right eye. The left lens showed prominent cortical spokes and pigment stars on the anterior lens capsule. The right fundus was not visualized. The left fundus had an optic disk with myopic crescent and early posterior staphyloma.

The intraocular pressures (applanation) were RE: 20 mm Hg and LE: 31 mm Hg, while tonography revealed a coefficient of outflow of RE: 0.18 and LE: 0.19. Perimetry (Goldmann) showed a full left field with normal blind spot.

During a three-week observation period, the right lens rapidly matured and the capsular wrinkling increased. Follow-up tonometry showed normal intraocular pressures in both eyes. An intracapsular cataract extraction with sector iridectomy was performed and although alpha chymotrypsin (in 1: 5000 dilution) was utilized, direct zonulysis was required. Firm adhesions between vitreous and posterior lens capsule were present and were severed during delivery of the lens. There was no vitreous loss.

*Case* 2—This 26-year-old man ($III_2$) had worn glasses since early childhood. He was the product of a full-term pregnancy without history of maternal infection, and his growth and development were normal. He stated that at the age of 15 years his left eye was struck with a lead pencil. This necessitated patching for a day. At the age of 23 years, while serving in the US Navy, he noted a sudden decrease in vision in his left eye. A cataract was found and after cataract surgery he was advised that the lens "broke" during the operation.

Examination showed the patient to be well-devel-

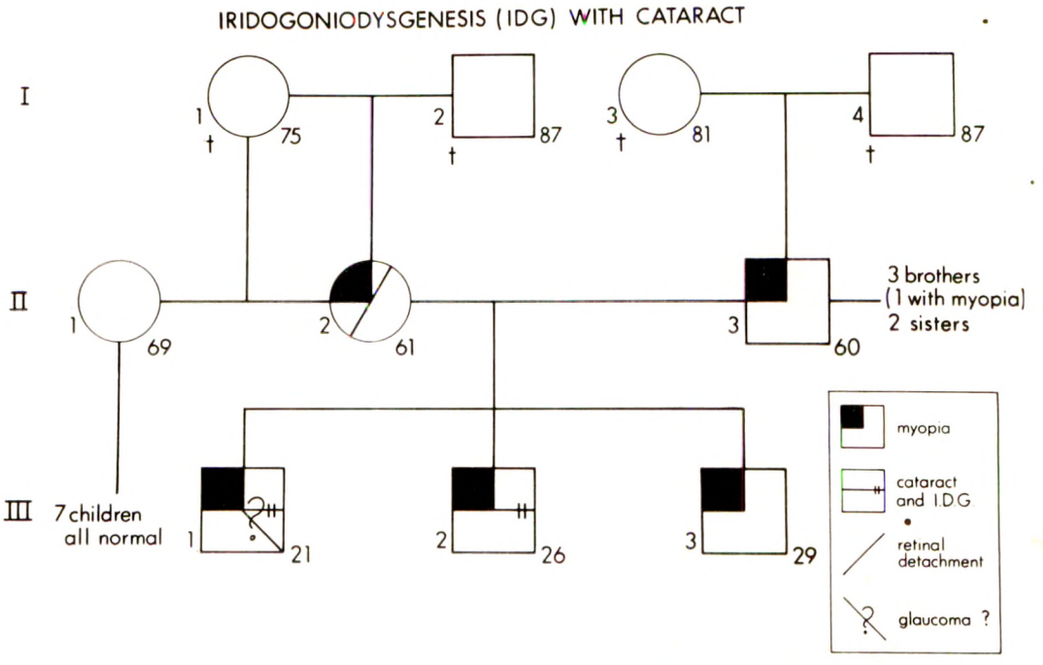

Fig. 1 (Henkind and Friedman). Pedigree of patients with iridogoniodysgenesis with cataract. The affected family members are $III_1$ and $III_2$.

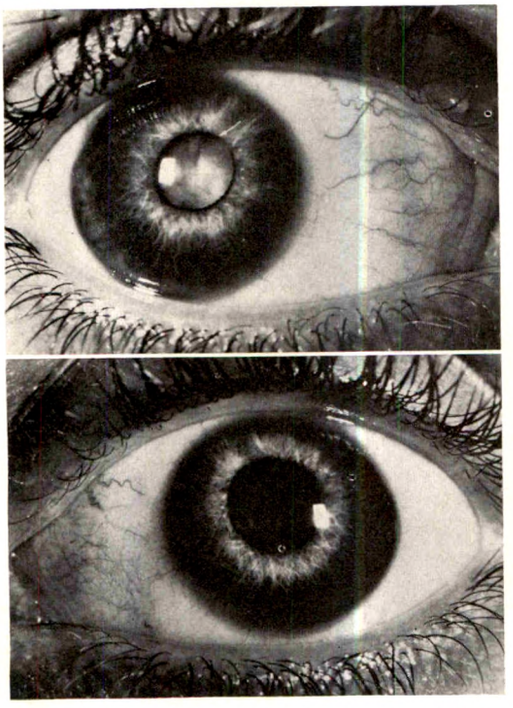

Fig. 2 (Henkind and Friedman). Case 1. Top: Right eye with iris hypoplasia, deficient pupillary ruff (arrow) corectopia and cataract. Bottom: Left eye with iris hypoplasia and cataract.

oped with no gross abnormalities except an orthodontic problem which was being corrected by braces.

*Ocular examination*—The eyes of this patient were strikingly similar to those of his brother ($III_1$). Visual acuity was RE: 20/25 (plano sph. ⊃ +1.00 cyl. ax. 90°) and LE: 20/30 (+6.75 sph.). Color vision (AO-HRR plates) and Amsler Grid testing were normal in each eye. The intraocular pressures (applanation) were 11 mm Hg. Ocular motility, eyelids and adnexae were normal. Both corneas were clear except for peripheral scar-

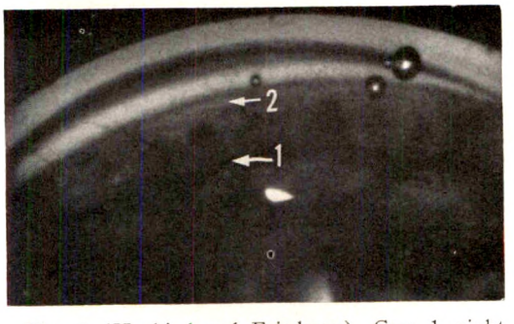

Fig. 3 (Henkind and Friedman). Case 1, right eye. Goniophotograph of angle at six o'clock (Goldmann gonioprism). Arrow 1 points to line of iris insertion. Arrow 2 points to Schwalbe's line. The area between 1 and 2 is lined by a veil of pigmented tissue of varying density. Note the diaphanous areas between the arrows.

ring superiorly and a superficial central scar in the left eye. In the right eye, Schwalbe's line was barely visible nasally on slit lamp examination. Horizontal corneal diameters were RE: 12 mm, and LE: 11 mm. Keratometer readings were: RE: 40.75 mer 5°, 43.00 mer 95°, and LE: 41.50 mer 180°, 41.75 mer 90°, with irregular mires. Corectopia was present with each slightly oval pupil displaced superonasally (Fig. 4). Both irides were greyish-blue, showed scant stroma, and lacked a collarette. There was absence of the pupillary ruff superonasally in both eyes. The periphery of each iris transilluminated. In the left eye, a basal iridectomy was present at 10 o'clock and a slit-like opening at 12 o'clock. Gonioscopy was virtually identical to that seen in his brother. Both angles were deep, heavily pigmented, and lined by a veil of abnormal tissue (Fig. 5). There were prominent radial and circumferential angle vessels in both eyes. After iris dilatation, the right lens was noted to have numerous pigment stars on the anterior capsule and a relatively dense posterior subcapsular opacity. Vitreous floaters were present in the right eye. The right fundus appeared normal. Examination of the left fundus revealed an optic disc with myopic conus.

*Case* 3—This 61-year-old housewife is the mother of both patients ($III_1$ and $III_2$). She has worn a myopic correction since childhood. In January, 1956, she underwent surgery for a retinal detachment in her right eye. There is no history of ocular trauma or infection and her general health is excellent.

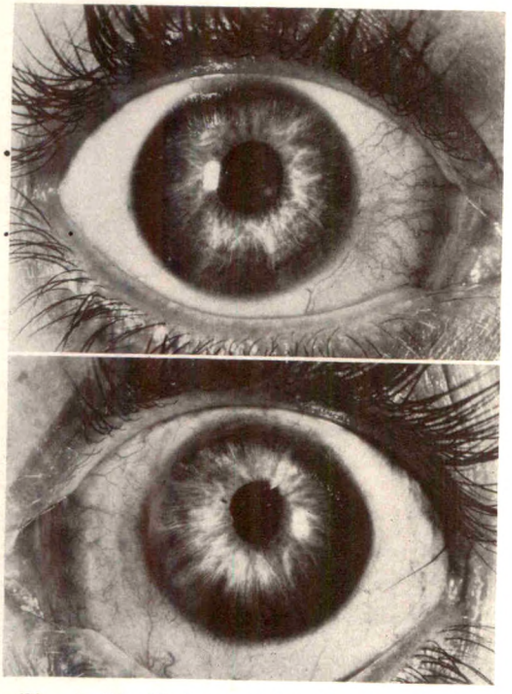

Fig. 4 (Henkind and Frieman). Case 2. Top: Right eye with iris hypoplasia and corectopia. Bottom: Left eye with peripheral iridectomy at 10 o'clock, iris hypoplasia and corectopia.

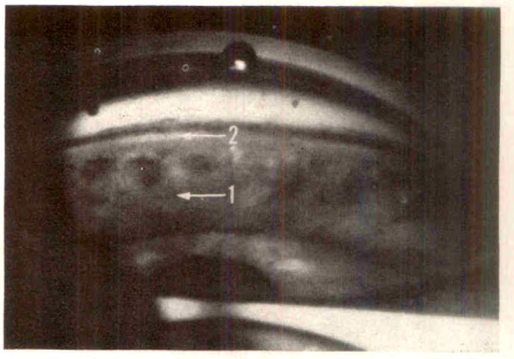

Fig. 5 (Henkind and Friedman). Case 2, right eye. Goniophotograph of angle at six o'clock (Goldmann gonioprism). Arrow 1 points to line of iris insertion. Arrow 2 points to Schwalbe's line. As in Figure 3, the area between 1 and 2 is lined by a veil of pigmented tissue. Note the diaphanous zones between the arrows.

*Ocular examination*—Visual acuity was RE: hand motion only (−4.25 sph.), and LE: 20/40+ (−5.50 sph.). Color vision (AO-HRR plates) was normal. The intraocular pressures (applanation) were 12 mm Hg. Ocular rotations were full and the eyelids and conjunctivae normal. The corneas were normal and both diameters measured 11 mm. Both irides were hazel and displayed a normal collarette and pupillary ruff. The pupils were centric, reactive to light and 4 mm in diameter. Gonioscopy revealed wide open angles (3+) with a normal configuration. Slight pigment speckling was present overlying the meshwork especially inferiorly. The lenses showed early cortical changes, more so in the right eye. Vitreous floaters were seen in the right eye. The right fundus displayed a number of pigmented chorioretinal scars in the inferotemporal quadrant and a retinal band nasally. The left fundus was normal.

*Case* 4—This 60-year-old man is the father of both patients ($III_1$ and $III_2$). He denies any ocular complaints and is in excellent health.

*Ocular examination*—Visual acuity was RE: 20/25 (−2.00 sph. ⊃ −0.50 cyl. ax. 160°) and LE: 20/60+ (−2.75 sph. ⊃ −0.50 cyl. ax. 165°). The intraocular pressures (applanation) were 14 mm Hg. Ocular motility, eyelids and conjunctivae were normal. The corneas were normal and both corneal diameters measured 10 mm. Both irides were hazel and displayed normal markings; the pupils were centric, reactive to light and 4 mm in diameter. Gonioscopy revealed open angles (3+) with a normal architecture. A prominent circular vessel was seen in the right chamber angle. The lens showed early cortical opacities inferonasally in each eye. The fundi were normal.

## Discussion

These two brothers display an unusual

combination of ocular findings: iridogoniodysgenesis and rapidly maturing cataracts. Three major points are to be considered: the genetic aspects of the condition, the relation of this syndrome to other anterior segment anomalies, and the early appearance of cataracts.

The occurrence of an almost identical clinical picture in two brothers suggests an hereditary etiology. Both were healthy from birth without stigmata or prenatal infection. The normal appearance of the parents' anterior ocular segments, and the absence of a family history of cataract during the preceding two generations, are strong evidence against autosomal dominant inheritance. Sex-linked recessive inheritance is doubtful because the maternal grandfather presumably had normal eyes and the mother's eyes are unlike those of her affected sons. We must consider, therefore, that iridogoniodysgenesis and early cataract formation is an expression of autosomal recessive inheritance. Further evidence for this is the striking similarity of the affected brothers' eyes. In this regard, recessive conditions often present a limited range of expressivity while dominant ones have a variable phenotype.[1]

The relation between the present condition and other anterior segment anomalies is summarized in Table 1.

The posterior embryotoxon of Axenfeld[2] consists of a prominent Schwalbe's line which can be seen by direct observation without gonioscopy. A prominent Schwalbe's line is present in about 15% of all individuals.[3] In more pronounced cases of posterior embryotoxon, the iris may be hypoplastic and adhesions between the corneal opacity and the peripheral iris stroma may occur. Such cases probably represent variants of Rieger's anomaly. Dominant pedigrees, particularly where there is involvement of the iris, have been reported, but autosomal recessive inheritance has also been documented.[4] Cataract formation is not a feature of this condition. One of our patients ($III_2$) has an externally visible posterior embryotoxon in his right eye, but we do not feel that it is a characteristic of this syndrome.

Mesodermal dysgenesis of the iris and cornea is an anomaly that was clearly delineated by Rieger.[5] Its primary features are hypoplasia of the anterior iris stroma, iris strands bridging the angle and posterior embryotoxon. Glaucoma is common in the first few decades of life and a variety of lens opacities have been noted, but early onset of cataract has not been described.[6] Rieger's anomaly is inherited as an autosomal dominant and a wide range of expressivity is evident in affected families. When associated with dental or skeletal anomalies, the condition has been termed Rieger's syndrome. Our affected patients can be separated from those with Rieger's anomaly both by the different clinical appearance of the eyes and by the presumably different mode of inheritance.

Peters' anomaly,[7] considered a mesoder-

TABLE 1

COMPARISON OF THE HERITABLE ANTERIOR SEGMENT ANOMALIES

| Condition | Heredity | Ocular Abnormalities | | | | | Other Findings |
|---|---|---|---|---|---|---|---|
| | | Cornea | Iris | Angle | Lens | Glaucoma | |
| Posterior embryotoxon[2-4] | Recessive(?) dominant(?) | Common | Occasional* | Occasional* | None | Occasional* | None |
| Mesodermal dysgenesis of iris and cornea[5,6] | Autosomal dominant | Common | Common | Common | Occasional* | Common | May have dental or skeletal abnormalities |
| Peters anomaly[7,8] | Recessive(?) | Common | Common | Common | Common | Common | None |
| Goniodysgenesis with glaucoma[10,11] | Autosomal dominant | Occasional* | Common | Common | None | Common | None |
| Iridogoniodysgenesis and cataract (present cases) | Autosomal recessive | None | Common | Common | Common | ? | None |

* Involvement has been noted.

mål dysgenesis of the cornea,[8] is a congenital disorder in which there is a central corneal opacity with abnormalities of the deep stroma and a local absence of Descemet's membrane. Though the anomaly may be limited to the cornea, various defects in the anterior segment, including corectopia, iris hypoplasia, persistant pupillary membranes, and anterior polar cataract have been recorded.[8] While there are human pedigrees with combinations of Rieger's and Peters' anomalies, the latter is generally considered to involve recessive inheritance.[8] On the other hand, Reese and Ellsworth[9] have classified the various anterior segment conditions together under the broad title, anterior chamber cleavage syndrome, and have noted that mothers of a number of their patients had rubella or other presumably viral infections during the first trimester of pregnancy.

Goniodysgenesis and hereditary juvenile glaucoma[10] is characterized by an abnormal iridocorneal angle, iris hypoplasia, and glaucoma which develops in the first few decades of life. Inheritance is autosomal dominant in nature. The iris hypoplasia, corectopia, and appearance of the angles in this condition are very similar to that found in our patients. One of our patients ($III_1$) had several elevated intraocular pressure readings in his left eye, but tonography, visual fields, and repeat applanation tonometry failed to confirm the presence of glaucoma. It is conceivable that elevated ocular tensions will be manifest as glaucoma at a later date. In the large pedigree reported by Jerndal[10] and that of Weatherill and Hart[11] a number of family members had "minor" dysgenesis of the angle and normal ocular pressure. Early onset of cataract was not noted in either of these pedigrees, nor is it a feature of congenital glaucoma, with the possible exception of that seen with rubella. While our patients resemble those with goniodysgenesis and juvenile glaucoma, the presence of cataracts, lack of glaucoma, and different mode of inheritance are significant distinguishing characteristics.

We presume that the early appearance and maturation of cataracts in our cases are related to the anterior segment abnormality. The possibility does exist, however, that the lens changes are unrelated to the iris and angle changes. A number of heritable conditions are characterized by the early appearance of rapidly progressive cataracts. Werner's syndrome[12] is one such disorder, with cataracts developing between the ages of 20 and 35 years and rapidly progressing to intumescence. The premature senility and endocrine disturbances of Werner's syndrome were not present in our cases. The cataracts found in Rothmund's syndrome develop in the first few years of life. Neither Werner's nor Rothmund's syndromes have associated angle anomalies. Rapidly maturing cataracts are also seen in association with diabetes mellitus. Neither of our affected patients manifested chemical or clinical evidence of diabetes. Patient $III_1$ had a very mild eczematoid eruption overlying his malar prominences. There were no other skin lesions and therefore one cannot relate the cataracts to a dermatologic disorder. Neither affected patient was ever treated with x-radiation nor were they exposed to the wide variety of chemical agents which have been reported to induce cataracts.[12] Conradi's syndrome (dysplasia epiphysealis punctata) has recently been reported to have an anterior chamber angle anomaly similar to that found in mesodermal dysgenesis.[13] Patients with this condition also have cataracts. Our patients lack the typical clinical appearance of patients with this syndrome. Pigmented lens capsule stars were present on the anterior capsule of the less cataractous lens of each affected brother and represents remnants of a persistant pupillary membrane. Such remnants are not usually associated with cataract formation and are commonly seen in otherwise normal eyes.[14]

## Summary

Two brothers manifested abnormalities of the iris and anterior chamber angle (iridogoniodysgenesis) and cataract. The cataracts developed in early adulthood and rapidly progressed to maturity. The absence of a

family history of cataract during the preceding two generations, and the normal appearance of the parents' anterior ocular segments, provided strong evidence against autosomal dominant inheritance.

ACKNOWLEDGMENTS

We thank Dr. Herbert Vogel for referring his patient for our observation. We also thank Miss Leslie Rosenberg for typing the manuscript and Mr. Henrick Malpica for the photographs.

# CATARACTS IN THE SMITH-LEMLI-OPITZ SYNDROME

EDWARD COTLIER, M.D., AND PAUL RICE, M.D.
*Chicago, Illinois*

A constellation of phenotypic anomalies are present in the Smith-Lemli-Opitz syndrome: (1) microcephaly with narrow transverse diameter of the cranial vault, (2) broad maxillary alveolar ridge, (3) short nose with anteverted nares, (4) micrognathia, (5) polydactyly and syndactyly of the second and third toes, (6) hypospadias and cryptorchidism (male pseudohermaphroditism), (7) mental retardation, and (8) congenital pyloric stenosis. Four children with the Smith-Lemli-Opitz syndrome were initially described in 1964.[1] Eleven additional children have been reported since,[2-6] but none in the ophthalmic literature. The pediatric reports included brief descriptions of the eyes; cataracts were noted in two such patients.[4,6] A child with Smith-Lemli-Opitz syndrome and cataracts who underwent successful cataract surgery is described here.

## CASE REPORT

At the time of this report, this boy was eight years old (Figs. 1 and 2). His eyes were examined on repeated occasions, twice under general anesthesia. He was born March 1, 1962, to apparently healthy parents. The mother (age 22) had experienced four spontaneous abortions prior to his birth. There was, however, no history of familial diseases or consanguinity. Gestation lasted 40 weeks and the only recorded illness was a "skin rash" during the second trimester of pregnancy. Her medications during the pregnancy included occasional injectable calcium and iron prescribed by the obstetrician.

Fig. 1 (Cotlier and Rice). Catatonic position of child with Smith-Lemli-Opitz syndrome.

Fig. 2 (Cotlier and Rice). Typical facies of child with Smith-Lemli-Opitz syndrome. Note narrow transverse diameter of the cranial vault, short nose and anteverted nares, low-set ears, slight antimongoloid slant of eyes, meeting of eyebrows at the midline.

At birth, the child weighed six pounds and two ounces. From his birth, he fed poorly, and at the age of 29 days he was admitted because of frequent vomiting without diarrhea. Examination at that time revealed marked dehydration. His weight was five pounds and five ounces. There was poor head control, marked inactivity, poor sucking ability. He showed simian creases. There was a 2 cm phalloclitois bound by a chordae in which the urethra was not identified (Fig. 3). He had bilateral polydactyly, syndactyly of the second and third toes (Fig. 4), and talipes calcaneovalgus.

Laboratory tests showed the complete blood count to be within normal limits. White blood cells were numerous (too numerous to count); other blood chemistries were normal. Urine culture revealed Aerobacter cloacae sensitive to kanamycin. Urinalysis was otherwise normal, including 17-ketosteroids. An intravenous pyelogram and electrocardiogram were normal. X-ray examination showed the long bones to be normal and appropriately developed for his chronological age. An upper gastrointestinal series revealed pyloric stenosis. Buccal smear revealed a chromosomal male (3% Barr bodies).

Intramuscular kanamycin 35 mg every 12 hours

From the Department of Ophthalmology, University of Illinois Eye and Ear Infirmary, Chicago, Illinois. This study was supported in part by Public Health Service Training Grant EY 24-13 from the National Institute of Health.

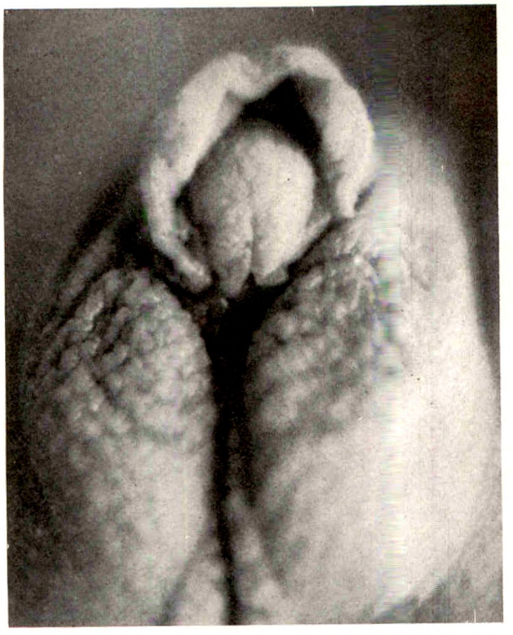

Fig. 3 (Cotlier and Rice). Pseudohermaphrodite genitals, hypospadias.

and intravenous fluids cleared the urinary tract infection. Because of the protracted vomiting and the pyloric stenosis, a Ramstedt pyloroplasty was performed on April 7; and this was followed by a gastrostomy on April 30. The patient regained his birth weight on May 20, at which time he was discharged. At three months of age (10 days later), the child had gained seven ounces (weight: six pounds and nine ounces). He smiled and was able to fixate with both eyes. Head circumference was 40.5 cm.

At six months of age, ocular fixation was absent, and at 10 months of age bilateral cataracts were noted. Ophthalmic evaluation on January 21, 1963, revealed bilateral anterior cortical lens opacities and iris synechiae to the lens. There was bilateral pendular nystagmus and esotropia. He was admitted for cataract surgery of the right eye. Blood chemistries at that admission revealed normal CBC, urinalysis, VDRL, Kahn, and Wasserman, and no galactosuria.

*Cataract surgery*—Under general anesthesia, a 1% lidocaine retrobulbar injection was given. A superior rectus 4-0 silk suture was placed in the right eye. A fornix-based flap was dissected and two 6-0 chromic gut sutures were preplaced in a limbal groove extending from 10 to 12 o'clock. A keratome incision was made and the anterior chamber entered. The wound was enlarged with corneoscleral scissors to 120 degrees. A full iridectomy, capsulotomy, and irrigation of lens material followed. The preplaced sutures were tied, leaving a 5 mm air bubble in the anterior chamber.

The postoperative course was uneventful. Mydriatics were applied topically once a day. Postoperative retinoscopy was +13.00 sph. ⊃ +2.50 cyl. ax 90°. Fundus details were easily visualized in the operated eye.

Aphakic glasses were prescribed, but in following visits it was noted that he did not wear them. Because of his mental retardation and absent speech, visual acuity could not be determined.

In September, 1970, the patient was re-admitted to the University of Illinois Eye and Ear Infirmary for ophthalmoscopy of the right eye and evaluation of the fundus and the cataract in the left eye (Fig. 5).

X-ray films on this admission revealed a skull small for the patient's age with prominent convolutions. The extremeties showed osteoporosis suggestive of disuse and muscle wasting, and an extra epiphysis at the proximal end of the second metacarpal. Complete blood count, urinalysis, serum calcium, phosphorus and serum protein electrophoresis were normal. Karyotype in peripheral leukocytes was normal. Urine amino acid analysis (Table 1) was within normal limits. Rubella antibody titer in serum was 1 : 16.

The eye examination revealed 40 prism diopters of constant left esotropia, an antimongoloid slant, and brows meeting at the midline, but no blepharoptosis. The conjunctivae and corneas were unremarkable. The anterior chamber of the right eye was

clear and of aphakic depth. An iridectomy was present and the pupil was free of lens material (Fig. 6). The fundus revealed a normal disk, vessels and macular area. By indirect ophthalmoscopy, the retinal periphery was normal in the right eye. The left eye showed a mature, partially resorbed cataract with iris synechiae to the lens (Fig. 5). Normal retinal vessels and choroidal architecture could be seen around the nasal side of the cataractous lens. The vitreous appeared clear and normal in both eyes. Schiøtz tensions were 18.9 mm Hg in the right eye and 12.6 mm Hg in the left eye. Gonioscopy revealed wide open angles without anomalies in both eyes.

## DISCUSSION

An excellent summary of the first 13 cases with Smith-Lemli-Opitz syndrome is found in the report by Park and associates.[4] We tabulated the data reported in patients with the Smith-Lemli-Opitz syndrome (Tables 2 and 3), including the two most recently reported cases[5,6] and the present one, and analysis disclosed several factors of interest. There is a higher incidence of the Smith-Lemli-Opitz syndrome in males (male:female ratio 4:1). All Smith-Lemli-Opitz babies have had a normal gestation period and all parents were young (in the 20- to 30-year bracket). Most (10 out of 16) were first or second babies in the obstetrical order. Birth weights and lengths of infants with the Smith-Lemli-Opitz syndrome cases were slightly below, but still within normal limits, and all had a history of retarded growth, failure to thrive, and mental retardation. Repeated vomiting

due to pyloric stenosis was reported in 70%. Microcephaly, micrognathia, and anteverted nares were found in 100% of the patients. Slightly less frequent findings were low-set ears slanted away from the eyes; epicanthal folds, blepharoptosis, and strabismus; broad maxillary alveolar ridge and cleft palate or bifid uvula. Genital anomalies (consisting of hypospadias and cryptorchidism) were frequently present, and syndactyly or polydactyly were perhaps the most distinct diagnostic signs of the syndrome; palmar and finger anomalies were less frequently seen.

Laboratory studies have failed to uncover a metabolic or chromosomal defect responsible for the Smith-Lemli-Opitz syndrome. Our patient had a normal chromosomal pattern (46, XY) in cells derived from the culture of peripheral leukocytes. Chromosomal analyses were normal in all 12 Smith-Lemli-Opitz syndrome cases in which karyotype studies were made.

Thus far, only one generation has been involved. The presence of affected siblings and the high incidence of maternal abortions would indicate a genetic pattern not compatible with orthodox dominant inheritance or sporadic mutation. Because of the high incidence of affected males, it has been suggested that the syndrome may be lethal to females, who are eliminated by abortion (an X-linked dominant mutation).[1] Park and his co-workers analyzed the sex distributions of siblings of male propositi.[4] Two of six males

and two of six females were affected, thus eliminating the possibilities of sex segregation. In fact, these authors believe an autosomal recessive mode of inheritance is most probable, although an environmental factor cannot be eliminated. History of consanguinity has been absent from families of Smith-Lemli-Opitz syndrome patients. Further studies on the genetics of the Smith-Lemli-Opitz syndrome are needed to clarify this complex presentation pattern.

The association of cataracts and pseudohermaphroditism is unique and found only in the Smith-Lemli-Opitz syndrome. Polydactyly, the facial features, and mental retardation are not exclusive to the Smith-Lemli-Opitz syndrome. Thus, the differential diagnosis[8] of these congenital cataracts is as follows:

*With poly- or syndactyly*—Down's syndrome (also with duodenal obstructions); 13-15 trisomy and 18-trisomy (75% death rate within the first six months of life); chondroectodermal dysplasia (Ellis-van Creveld syndrome); De Lange syndrome, Cockayne's syndrome, Turner's syndrome, Lawrence-Moon-Biedl syndrome, achrocephalosyndactyly (Apert's syndrome).

*With mental retardation*—Miller's syndrome (aniridia, Wilms' tumor), mannosidosis, Cockayne's syndrome, Lowe's syndrome, galactosemia, congenital rubella.

Two other Smith-Lemli-Opitz patients with cataracts have been recorded. The five-year-old patient of Park and co-workers[4] had congenital heart disease "compatible with tetralogy of Fallot" and a cataract in the left lens evident only on slit-lamp examination, but the type was not described. The eight-year-old patient with Smith-Lemli-Opitz syndrome described by Finley and associates[6] had bilateral cataract surgery, but the type of cataract and surgical result was not stated.

The surgical removal of mature cataracts is nearly always indicated. However, in patients with cataracts, CNS degeneration, and mental retardation, the visual prognosis may not be dramatically changed by such surgery. It is to be hoped that research in genetics, chromosomal defects, and in enzyme deficiency in the coming decades may make cataract extractions in such children more meaningful.

## Summary

Successful cataract surgery was performed in a child with the Smith-Lemli-Opitz syndrome. Clinical signs included microcephaly, short nose with anteverted nares, polydactyly, syndactyly of the second and third toes, mental retardation, male pseudohermaphroditism, and congenital pyloric stenosis. Chromosomal studies were normal in this child, and in all 12 of those in whom such studies were performed among 15 previously reported cases. In the case described, and others described earlier, this syndrome does not conform to any known human genetic inheritance pattern.

# SYMPATHETIC OPHTHALMIA AND LYMPHOCYTE TRANSFORMATION

VERNON G. WONG, M.D., RICHARD ANDERSON, B.S., AND PAUL J. O'BRIEN, PH.D.
*Bethesda, Maryland*

There is considerable evidence to suggest that lymphocytic transformation in vitro is an immunologic response. Since this reaction was shown to be related to an antigen to which a patient is selectively sensitized, interest has turned to the possible roles it may play in the interaction of immunity and disease. Enhanced reactivity to homologous tissue antigens is demonstrable in patients afflicted with diseases of alleged autoimmune mechanisms.[1-16]

Sympathetic ophthalmia is felt by many to represent a form of hypersensitivity to uveal tissue following a perforating injury to one eye. Although convincing evidence is still lacking, there are a number of reports which lend support to the role of hyperimmunity in the pathology of this ocular clinical entity.[17-22]

To the best of our knowledge, the in vitro lymphocytic reaction in sympathetic ophthalmia was not previously reported. This is a report of the stimulation of peripheral blood lymphocytes with soluble extract of homologous uveal-retinal tissues in histologically proven cases of sympathetic ophthalmia.

## MATERIAL AND METHODS

Eight patients with histologically proven sympathetic opthalmia were selected for study from the ophthalmology service of the National Eye Institute. Each patient was referred to the Institute because of progression of disease in his remaining eye. All were previously treated or maintained on corticosteroids. Patients 1, 6, and 8 had also been on immunosuppressive methotrexate.

Control studies were performed on patients from the same facility with active ocular diseases other than sympathetic ophthalmia as well as from a normal volunteer.

Blood was drawn 48 hours after the last dose of all medications into a heparinized syringe (20 units/1 ml blood) and allowed to stand between one to three hours at room temperature for RBC sedimentation. The blood was centrifuged in an IEC centrifuge at 450 rpm for 30 seconds and advanced immediately to 1000 rpm before the machine was turned off. The plasma and buffy coat were aspirated and cells were adjusted to $1 \times 10^6$/ml with Eagle's basal 199 medium containing penicillin and streptomycin. The cell mixture was aerated with 95% oxygen and 5% $CO_2$ and 6 ml aliquots were placed into 25 ml tissue culture bottles. Antigens (uveal-retinal preparation) were added in concentration of 500 and 1000 λ along with appropriate controls of human muscle extract of the same concentrations and phytohemagglutinin (PHA). Cultures were incubated at 37°C for five days.

### PREPARATION OF SLIDES FOR BLAST TRANSFORMATION

After five days of incubation, the cells were transferred into a 40-ml conical tube and centrifuged at 500 to 700 rpm for five to seven minutes. The supernatant was discarded; the cell button was resuspended and dispersed through vigorous shaking. The latter was fixed by slowly adding freshly prepared modified Carnoy's solution (8 methyl alcohol: 1 glacial acetic acid) for 10 minutes. The cell suspension was centrifuged again and the supernatant discarded. The cell button was dispersed by shaking and 0.5 to 1.0 ml freshly made Carnoy's fixative was again added resulting in a slightly cloudy suspension. A few drops of the latter was placed on a clean glass slide and allowed to air dry. The cells were subsequently stained with

Giemsa or other Romanowsky stains in the usual manner. Examination was under oil immersion and 1000 continuous cell count was made for each slide. Each slide was coded and remained unknown to the examiner until all preparations were read.

Since the study began in 1963, to insure the uniformity of methodology, lymphocytic transformation continued to be determined by light microscopy, in preference to the more sensitive radioactive incorporation methods.

### Preparation of soluble tissue extract

*Uveal-retinal antigen(s)*—Approximately 10 g of human uveal-retinal tissues (obtained from a local eye bank) was homogenized in two volumes of pH 7.6 buffer containing: 0.35M sucrose, 0.004M $MgCl_2$, 0.025M KCl, and 0.05M TRIS. The homogenate was centrifuged for 30 minutes in a Beckman ultracentrifuge, Model L-2 with a titanium No. 50 rotor. The supernatant was decanted with a Pasteur pipette and brought to 100% saturation with ammonium sulfate (6.97 g for every 10 ml of sucrose extract); ammonium sulfate was slowly introduced in the already mixing sucrose extract, and allowed to continue mixing in ice for 30 minutes. The solution was again centrifuged for 30 minutes. The clear supernatant was discarded and the pellet was resuspended in 0.05M phosphate buffer, pH 7.4. The suspension was then dialyzed against two liters of the same buffer three times at one hour, six hours, and eight hours. The final concentration of the dialyzed contents was adjusted to 10 mg/ml as determined by the standard procedure according to Lowry.

*Human muscle antigen(s)*—Striated muscle was obtained at autopsy from the quadraceps and the soluble extract was prepared in the same manner as the uveal-retinal tissues. The final total protein concentration was adjusted to 10 mg/ml.

## Results

The transformed lymphocyte is a large cell which has deeply basophilic, nongranular cytoplasm surrounding a rounded nucleus which contains homogeneously staining chromatin and prominent nucleoli (Fig. 1). In the cytoplasm there is often a highly stained area bordering one side of the nucleus. In addition, there are often several small, unstained cytoplasmic vacuoles. The diameter of the largest cells may be three times that of a small lymphocyte. Smaller blastoid cells, intermediate in size between these very large cells and the small lymphocyte are also present. Many, but not all, of the blastoid cells are found aggregated in clusters. Mitotic division as a result of blastogenetic activity is regularly seen.[23]

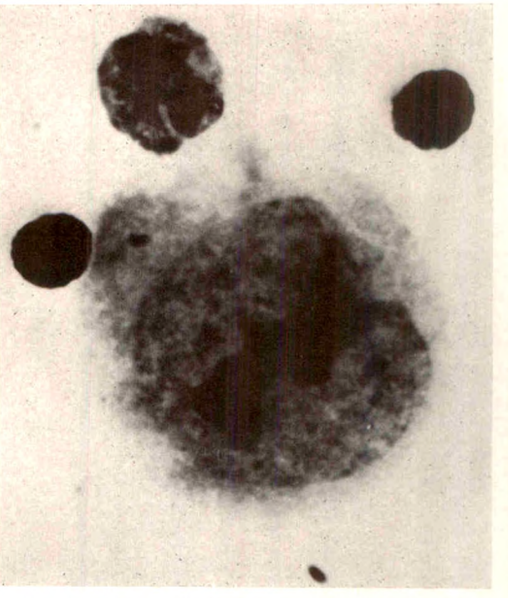

Fig. 1 (Wong, Anderson, and O'Brien). Large cell is typical of lymphoblast after undergoing transformation from small lymphocyte. Intermediate-sized blast cell and small lymphocytes are also seen (Giemsa, ×480).

In the present study, all but one of the patients with active sympathetic ophthalmia demonstrated enhanced lymphocytic transformation in the presence of homologous human uveal-retinal extract (Table 1). The mean blastogenic enhancement showed a 10-fold increase (55.5) in the presence of uveal-retinal extract when compared to its own control incubated in the absence of ocular antigens (5.6). In the control group of

patients without sympathetic ophthalmia, there was no significant increase in lymphocytic transformation (Table 2). The mean values were identical (13.6 vs 17.3). The increase in blastogenesis in the sympathetic ophthalmia group is significant ($P<0.05$) (Table 3).

The sympathetic ophthalmia patient with the highest degree of transformation manifested the least clinical evidence of active disease. The anterior segment was entirely free of inflammatory activity and the media into the fundus were clear. He had extensive multifocal areas of chorioretinal atrophy which corresponded to large Dalen-Fuch nodular formations in the histopathology of the enucleated eye. The only control patient who showed a twofold enhanced blastogenesis was a 14-year-old girl with presumed Vogt-Koyanagi-Harada's disease.

The human uveal-retinal preparation used in this study contained up to six antigenic components as determined by diffusion precipitin immunoelectrophoresis using several preparations of rabbit antihuman-uveal-retinal antisera (unpublished observation). The

concentration of antigen giving rise to the best degree of enhancement in each patient showing blastogenesis appears to be 1000 λ (consisting of 10 mg/ml total protein).

The lymphocytes from all patients tested were markedly stimulated when incubated with PHA. The mean percentage of cells affected for the sympathetic ophthalmia group was 37.8% and for the control group 31.1%.

## DISCUSSION

The cellular and chemical reactions seen with in vitro stimulation of blood lymphocytes have been reported with numerous stimuli to induce these cellular changes.[1-16,24-33] The enhancement is quantitated by determining the percentage of transformed cells by microscopy or by the radioactive precursors of DNA, with subsequent measurement of the incorporation by the blastoid or transformed cells.[1,26]

Our data show enhanced lymphocytic transformation of patients with sympathetic ophthalmia when their peripheral leukocytes were exposed to homologous uveal-retinal antigens. The reaction appears to be specific, since control cultures containing homologous skeletal muscle antigens failed to evoke any significant degree of response. The present study indicates, in the light of our present knowledge, that patients with clinically active sympathetic ophthalmia contain sensitized lymphocytes to some component or components of uveal-retinal antigen(s). The ability of lymphocytes to transform in the presence of the sensitizing antigen involves the conditioning of lymphoid cells upon their initial exposure to antigen in the primary response. Cells which have thus been conditioned, but which morphologically are still indistinguishable from other lymphoid cells, react to a further dose of antigen by rapid transformation into blastoid cells. The blastogenic or mitogenic effect of tuberculin and other known antigens in previously sensitized individuals support these assumptions. This ability of immunologically competent cells to respond to antigen by transformation appears to be a general character of the immune response.[33,36] Here the antigen is clearly the stimulus which provokes antibody producing cells to proliferate. Although the etiology of sympathetic ophthalmia is still unknown, autoimmunization of one's own tissue, such as the uvea, may occur following a perforating ocular injury. Once sensitization is established, sympathetic ophthalmia develops. The results of the study lend support to the theory that lymphocyte sensitized to ocular tissues are present in patients with sympathetic ophthalmia. The suspected role of uveal sensitization in sympathetic ophthalmia is not new. Years ago, Woods and Friedenwald developed a skin test consisting of uveal pigment and found a significant correlation between positive skin reaction and the clinical occurrence of sympathetic ophthalmia.

Experimentally, homologous retinal and uveal sensitization with adjuvant has been repeatedly shown to result in clinically active uveitis in various laboratory animals.[37-46] However, there appear to be no major distinguishing pathologic differences between the diseases produced by these two immunizing tissues. Because of possible cross-contamination, due to the natural anatomic association of the disparate tissues, it is difficult at present to ascertain whether the disease-producing antigen(s) is the same. Von Sallmann[47] has shown in primates that chorioretinitis produced with homologous retina was unassociated with possible vascular and neural antigenicity, since control studies using heterologous kidney and homologous

choroid plexus as antigens failed to produce uveitis.

Unpublished experiments in our laboratory have shown that human uveal-retinal tissues contain at least six antigenic components. Because clear-cut anatomic separation of retina and uvea is difficult, if not impossible, only the combined uveal-retinal tissue extract was used in this experiment. Attempts to isolate the antigenic or transforming factor(s) through fractionation and purification are currently being carried out.

The enhanced lymphocytic response in patients with sympathetic ophthalmia is certainly modest compared to responses to other known antigenic stimulation. Depressed transformation is observed in active disease states, such as tuberculosis. Although antibody titers were not performed in our study, depressed transformation may be due to a specific antibody in the serum which reacts in vitro with the uveal antigenic determinants, thereby making them unavailable for antigenic stimulation of susceptible cells.

Although the present study demonstrates enhanced lymphocytic response to uveal antigen in sympathetic ophthalmia, it is still unclear whether the defect in this disease is primarily due to autosensitization. It is of interest to note that in the control group only the patient with Vogt-Koyanagi-Harada syndrome showed any significant degree of transformation. Pathologically, these two disorders are remarkably similar. But whether the enhanced in vitro blastogenic response to ocular antigens of these two conditions is in response to the same pathogenetic defect is not yet established.

It appears that the in vitro transformation phenomenon is a specific reaction between an antigen and sensitized cells. Because the normal reaction to antigenic stimulus is the production of antibody, it seems reasonable to suppose that the phenomenon of lymphocyte transformation is limited to antibody production.[3,4] The lymphocyte transformation in vitro is probably part of the delayed type of hypersensitivity reaction. It is noteworthy that in the graft-vs-host the response of the immunologically provoked small lymphocytes resembles that of tuberculin-stimulated cells under light and electron microscopic examination.[2,48,49]

PHA from the bean, Phaseolus vulgaris, has been shown to induce blastogenesis of lymphocytes when cultured with leukocytes of normal human peripheral blood.[50] Results of the present study indicate that the lymphocytes from all patients were markedly stimulated with PHA and the results of the two groups showed no significant difference in the percentage of cells transformed.

The exact manner in which PHA and other mitogens stimulate leukocytes to division is still not entirely clear. It appears that the mechanism requires PHA to attach itself onto a receptor structure in the leukocyte and thus initiate a biochemical reaction ultimately leading to cellular division. The mitotic property of various mitogens would thus be nonspecific. It is possible that antigen-stimulated cell division is brought about by a similar mechanism.[51] However, the low percentage of cell stimulation from ocular antigens in this experiment, compared to those obtained by PHA, implies that the mechanism may be different.

## Summary

Enhanced lymphocytic transformation was demonstrated in patients with sympathetic ophthalmia when their peripheral leukocytes were exposed to homologous uveal-retinal antigens in tissue cultures. Similar challenge failed to evoke any significant degree in blastogenesis in a control group of patients with active ocular disease other than sympathetic ophthalmia. The results indicate that in patients with clinically active sympathetic ophthalmia the lymphocytes were sensitized to some component or components of ocular tissues.

# SYMPATHETIC OPHTHALMITIS

G. E. Brauninger, M.D., and F. M. Polack, M.D.
*Gainesville, Florida*

Sympathetic ophthalmitis is generally considered to be a relentless ocular inflammation that leads to bilateral loss of vision in 60 to 70% of cases.[1] In fact, however, during a single course of therapy, the disease often remits, does not recur when therapy is discontinued,[2,3] and leaves no permanent visual loss in its wake.

Such a case of sympathetic ophthalmitis is reported here. This patient's non-traumatized eye responded to corticosteroid therapy and there was no permanent loss of vision. No evidence of recurrence was noted over a two-year period of follow-up observation.

## Case report

On April 28, 1969, a 37-year-old woman was seen with a blind, painful left eye following a penetrating injury one month earlier. The laceration had involved the cornea, sclera, and ciliary body and had been surgically repaired. Ocular examination of the right eye showed this eye to be normal with best corrected visual acuity of 20/25.

The blind left eye was soft to palpation. Examination revealed corneal stroma and epithelial edema with folds in Descemet's membrane. The anterior chamber was shallow and revealed marked cells and flare. A dense cataract was noted behind the eccentric and unreactive pupil. The retina was not visible. The eye was enucleated on April 29, 1969. Pathologic examination disclosed sympathetic ophthalmitis (Fig. 1).

On May 23, 1969, the patient complained of photophobia and decreased vision in her remaining eye. Best corrected visual acuity was 20/40 and a moderate number of cells and flare were noted in the anterior chamber. There were no keratic precipitates and the retina was normal.

She was treated with a corticosteroid (Prednisone) 80 mg daily, and the eye improved rapidly. Two weeks later, ocular examination was normal and visual acuity was correctible to 20/25. Corticosteroid therapy was gradually tapered; after six weeks of therapy it was discontinued. The patient experienced no further difficulty during the following 24 months.

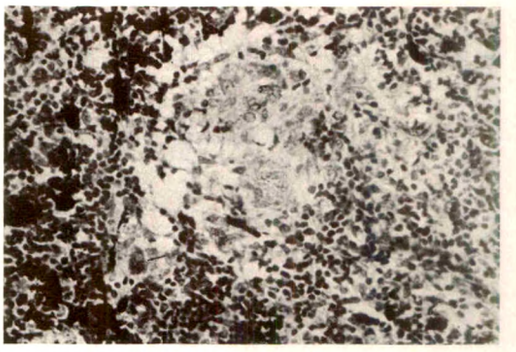

Fig. 1 (Brauninger and Polack). Granulomatous inflammation in the choroid. The epithelial cells contain numerous pigment granules (arrow) and a giant cell is present (hematoxylin-eosin, ×200).

## Pathology

Examination of the enucleated eye revealed a 9 mm laceration, surgically repaired, which had extended through the peripheral cornea and adjacent sclera, and involved the trabecular meshwork and ciliary body. The laceration was filled with fibroblastic tissue which was patchily infiltrated with small round cells. There was early neovascularization of the corneal stroma, with edema and infiltration of lymphocytes and polymorphonuclear leukocytes. In one quadrant the angle was obliterated by the iris root which was displaced forward against the cornea. The trabecular meshwork and iris root contained numerous scattered lymphocytes and plasma cells. Throughout the ciliary body and choroid there was a diffuse infiltrate of lymphocytes and scattering of eosinophils. Throughout the choroid there were nodular accumulations of epithelioid cells which contained fine pigment granules within their cytoplasm. These granulomatous foci of choroidal inflammation did not involve the adjacent choriocapillaris. The retina was totally detached and folded upon itself; however, the nuclear layers were well defined and without inflammatory involvement.

An organizing vitreous hemorrhage was present and the lens was cataractous but there were no inflammatory cells in or on the lens surface. Leukocytes and eosinophils were seen in the sclera along the ciliary nerves and emissary vessels.

## Discussion

Sympathetic ophthalmitis is characterized in its early stages by an insidious uveitis, anterior, posterior, or both, with disproportionate and early decrease in visual acuity in an eye that does not seem to be particularly red or painful.[2,4] Cells and flare in the anterior chamber are prerequisites for the clinical diagnosis, while keratic precipitates, swelling in the iris, papillitis or scattered yellowish spots in the fundus may occur early, all eventually leading to panuveitis.[2,4] The process in the "exciting" eye usually begins two weeks after injury and 80% of cases occur within three months.[1] The "sympathizing eye" becomes involved at the same time or shortly thereafter.

The incidence of sympathetic ophthalmitis has declined with modern surgical technique and postoperative care.[5] Nevertheless, the disease is a cause of great concern to the clinician who surgically repairs an injured eye and later finds both globes involved in an inflammatory process that threatens vision.

Sympathetic ophthalmitis may spontaneously remit without therapy, disappear under a course of systemic corticosteroids, or follow a complicated course characterized by remissions and exacerbations with eventual irreversible eye damage.[2-4] At present, prognosis is uncertain and not well understood, partly because those cases in which the course of the disease is mild are generally not reported in the literature. Further, the clinician who treats an apparent case of sympathetic ophthalmitis that responds quickly and completely is then inclined to doubt his own initial diagnosis, and pathologic confirmation is not usually available in mild cases. Nevertheless, Makley and Liebold[5] have indicated that a favorable visual result can be obtained with systemic corticosteroid therapy in 75% of cases.

The case of sympathetic ophthalmitis reported here emphasizes that this disease may present as a mild iritis which disappears during a course of corticosteroid therapy and does not recur or result in permanent clinical damage to the eye. Early detection of this disease process, combined with adequate corticosteroid therapy can provide a better visual result for the patient.[3]

## Summary

A pathologically documented case of sympathetic ophthalmitis in a 37-year-old woman began as a mild iritis which responded rapidly to systemic corticosteroid therapy and did not recur or result in permanent eye damage. This case is reported in support of the modern clinical impression that many cases of sympathetic ophthalmitis, with early recognition, adequate systemic corticosteroid therapy and careful patient follow-up, do not recur or cause permanent eye damage.

# EVULSION OF THE OPTIC NERVE

JOHN H. PARK, M.D., MARCEL FRENKEL, M.D., J. GRAHAM DOBBIE, M.D. AND EARL CHOROMOKOS, B.S.

*Chicago, Illinois*

The intraorbital portion of the optic nerve is relatively fixed to the optic foramen by its dural attachment. Optic nerve injuries caused by blunt trauma to the globe commonly occur at the foramen either by shearing of the motile portion of the nerve or by hemorrhage and edema within the confined sheath spaces. Since the anterior portion of the nerve is motile, it is uncommon to incur injury at the papilla. It is our purpose to present a rare case of evulsion of the optic nerve.

## CASE REPORT

A 29-year-old man claimed complete loss of vision in his left eye immediately after being "jabbed" with a finger while playing basketball. Concurrently he experienced a transient intense flash of light in that same eye. He was seen at the Cook County Hospital one hour after the accident, at which time he complained of severe left frontal headache and nausea.

Ocular examination revealed vision in the right eye to be 20/20 without correction. There was no light perception in the left eye. The anterior and posterior segments of the right eye were normal. Applanation tensions were within normal limits in both eyes. There was no external evidence of trauma or enophthalmos in either eye and the ocular motility was full.

Biomicroscopic examination showed the pupil of the left eye to be in mid-dilatation. It did not react directly to light, but responded consensually. A few scattered cells were seen in the anterior chamber of the left eye. The lens appeared to be clear and in its normal position. There was gross hemorrhage in the posterior nasal vitreous, fanning out from the disk. The margin of the left disk was skirted with a "sunflower" hemorrhage of moderate extent (Fig. 1). The central retinal vessels were displaced nasally and superiorly. An elliptical excavated defect was noted in the inferior quadrant of the disk. No posterior limit was discernible. There was no evidence of vitreous filling the defect. It appeared that clear serous fluid occupied the excavated cavern in the disk.

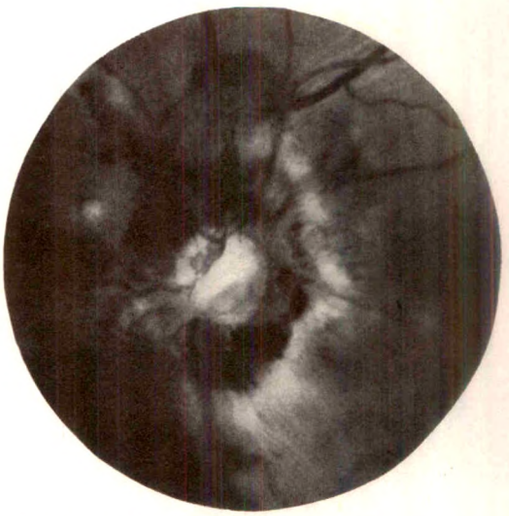

Fig. 1 (Park, Frenkel, Dobbie, and Choromokos). Excavated defect of the optic nerve and vitreoretinal hemorrhage at admission.

Moderate retinal edema was noted in the paramacular as well as papillomacular area. Retinal folds radiated from the temporal margin of the disk toward the macula.

The retinal vessels appeared to be normal in caliber and color. The peripheral retina was unremarkable. Fluorescein angiography substantiated this finding. At 29 seconds following the dye injection, the blood vessels were full and clearly outlined (Fig. 2).

Four weeks after the initial trauma, gliosis was apparent, filling the defect in the disk (Fig. 3). At six weeks further gliosis of the optic nerve and peripapillary areas was evident. The vitreous and retinal hemorrhages were essentially resorbed (Fig. 4).

At three months the depression of the optic nerve head was completely filled by fibrotic tissue. A white veil of tissue protruded into the vitreous from the inferonasal margin of the disk (Fig. 5).

## DISCUSSION

An unusual instance of evulsion of the optic nerve head has been documented by serial photography and fluorescein angiography.

The mechanism of optic nerve evulsion has been elaborated by various authors. Salzmann[1] defined evulsion of the optic

Fig. 2 (Park, Frenkel, Dobbie, and Choromokos). Fluorescein angiography during the venous phase demonstrating full and normal blood vessels and preretinal hemorrhage obscuring choroidal pattern in the peripapillary area five days following trauma.

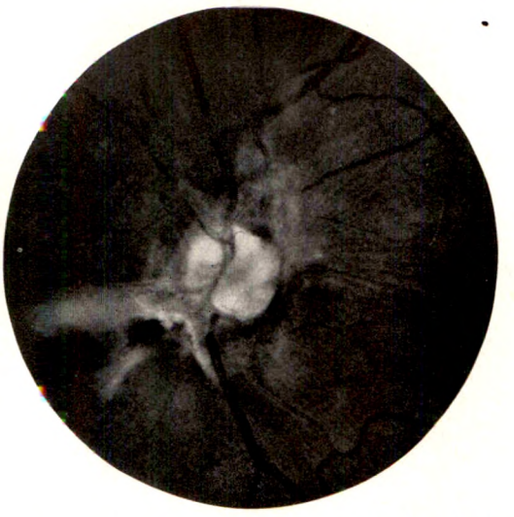

Fig. 4 (Park, Frenkel, Dobbie, and Choromokos). Six weeks after trauma, further gliosis and clearing of vitreous and retinal hemorrhage are evident.

nerve as the forceful backward dislocation of the optic nerve from the scleral canal without any break in the continuity of the adjacent coats of the globe.

While most cases have massive intraocular hemorrhage and disorganization, the present case is unique and interesting in that no evidence of external ocular injury was seen, even though the patient sustained evulsion of the optic nerve by the forceful jab of a finger into his orbit.

Among the various explanations of the mechanism of evulsion of the optic nerve, the most universally accepted theory impli-

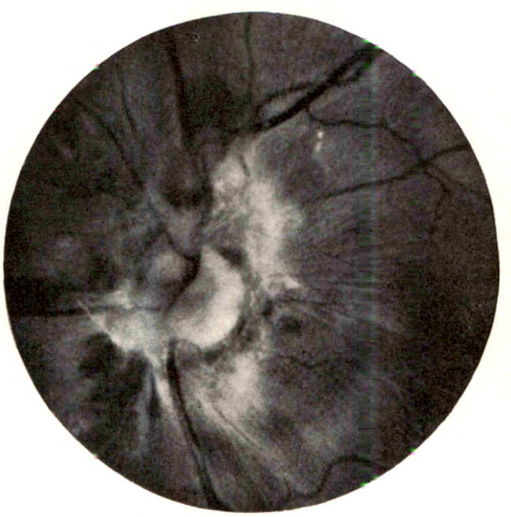

Fig. 3 (Park, Frenkel, Dobbie, and Choromokos). At four weeks following trauma, gliosis fills the defect in the disk and retinal folds radiate toward the macula.

Fig. 5 (Park, Frenkel, Dobbie, and Choromokos). At three months, complete gliosis of the excavated cavern of the optic nerve has occurred; a veil of fibrotic tissue protrudes into the vitreous.

cates extreme rotation and forward dislocation of the globe. A tear of the lamina cribrosa results, this being the weakest portion of the ocular envelope.[2] Simultaneously, the nerve fibers are torn at the margin of the disk. At this level, they consist merely of naked axon cylinders without supporting myelin sheath and may retract a variable distance up the sheath once they are torn.[3] The sheath, being elastic, can stretch and retain its continuity. This mechanism may apply to our case.

Lister[3] proposed that a blow on the front of the eye produces a sudden increase in intraocular pressure, rupturing the lamina cribrosa and expelling the nerve. He stated that such cases would be correctly described as expulsion rather than evulsion of the nerve.

In another vein, Lagrange[4] theorized that an indirect facial injury sets up concussion waves which travel through the pterygomaxillary fissure into the orbit. The globe is then propelled forward, stretching the nerve and causing evulsion.

Direct injury to the intraorbital portion of the optic nerve in cases of gunshot or knife wounds can result in the evulsion of the optic nerve by retropulsion.

Because of similarities in appearance, coloboma of the disk must be considered in the evaluation of evulsion of the optic nerve.[5] In this static condition one does not find retinal and vitreous hemorrhages nor subsequent gliosis which are always seen with evulsion of the optic nerve.

Congenital pit of the optic nerve head is sometimes associated with serous detachment of the macula. Fluorescein angiography may demonstrate a focal decrease in vascularity in the region of the optic pit or leakage of dye from the capillaries around the pit.[6] Fluorescein angiography performed in our patient failed to demonstrate any of these features of congenital optic nerve pit.

Pathologic examination of cases of optic nerve evulsion demonstrates a fairly constant site of injury. The rupture of the nerve is found at the level of the termination of Bruch's elastic lamina. The fibers of the lamina cribrosa are torn and the nerve retracts.[3]

Although the evulsion of the optic nerve head in our case involved only the inferior temporal quadrant of the left disk, there was no light perception in the eye. Kommerell[7] reported a case of partial evulsion of the optic nerve where his patient retained a visual acuity of 20/400 and demonstrated a visual field defect commensurate with the extent of the optic nerve evulsion.

## Summary

An unusual case of evulsion of the optic nerve without visible evidence of external ocular trauma was observed by serial fundus photography. Fluorescein angiography was normal. Extreme rotation and forward dislocation of the globe causing tear of nerve fibers at the lamina cribrosa with subsequent retraction along the nerve sheath are implicated.

# MODIFIED CEILING-MOUNTED ZOOM OPERATING MICROSCOPE

SHINICHIRO SUGITA, M.D., AND KENICHIRO SUGITA, M.D.
*Nagoya, Japan*

Various methods of mounting an operating microscope on the ceiling have been developed by Barraquer, Draeger and others.[1-7]

The ceiling mounting eliminates the awkwardness and inconvenience caused by a supporting table or floor column. In order to utilize Barraquer's method, however, the operating room must be specifically designed to accommodate the microscope, while Draeger's method involves considerable expense, with too many things attached to the microscope. We have developed a less expensive and more efficient method of ceiling mounting by making a number of modifications in the Zeiss zoom microscope (OPMi-II) and a Zeiss foot plate. The modified foot plate permits remote control of the microscope.

## MATERIAL AND METHOD USED FOR CEILING MOUNTING

The microscope was disconnected from its stand and fixed to the ceiling column of a Siemens 3-D overhead support used for x-ray tubes, using an intermediate plate (Fig. 1). All electrical parts were removed from the foot-casing of the Zeiss stand and built into the ceiling column of the Siemens. Cables were used to connect the ceiling column to a foot plate which was provided with all essential control switches. The coarse-gross positioning along the vertical axis, with a range of 165 cm, and a speed of 40 cm/second, is changed by the Siemens column. Fine focusing, with a speed of 5 mm/second, is altered within the operating microscope itself. When the microscope is retracted, it is 272 cm from the floor, with this suspension method thus allowing the surgeon to make the fullest use of the operating lamp (Fig. 2).

*Fitting the microscope to the ceiling column*—A shorter working distance between the surgeon and the operating field was attained by replacing the inclined tube of 160 mm with one of 125 mm, and the objective of 200 with 150. The coaxial illuminator was removed and two fiber bundle illuminators,* with condenser lenses attached to their ends, were installed on the circumference of the 150 mm objective. The working distance was thus shortened from 475 to 365 mm. In theory it should be 300 mm, but the surgeon still can work in a relaxed posture when the

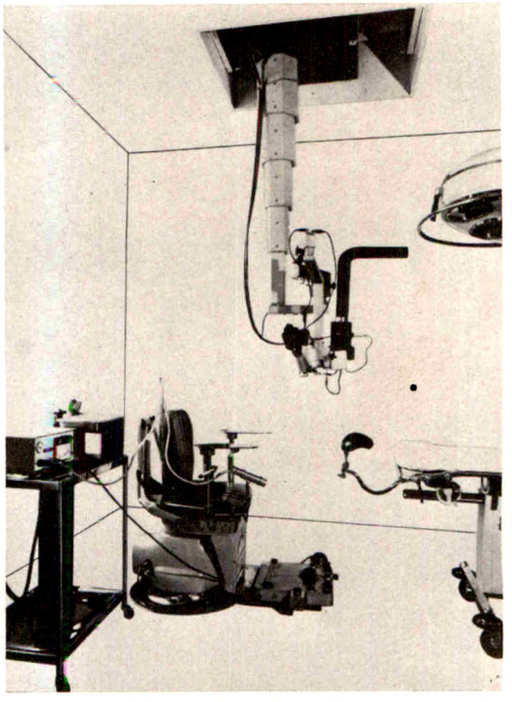

Fig. 1 (Sugita and Sugita). The operating microscope, the operating stretcher-table, the operating chair and the operating lamp shown in their relationship to one another. With the exception of the operating table, all are remotely controlled by the foot switches. Thus, the surgeon can maneuver the operating lamp without changing his position. On the right side of the chair is the casing for the Amoils cryopencil.

* The fiber optics bundles were made by the Nagashima Medical Company, Tokyo, Japan.

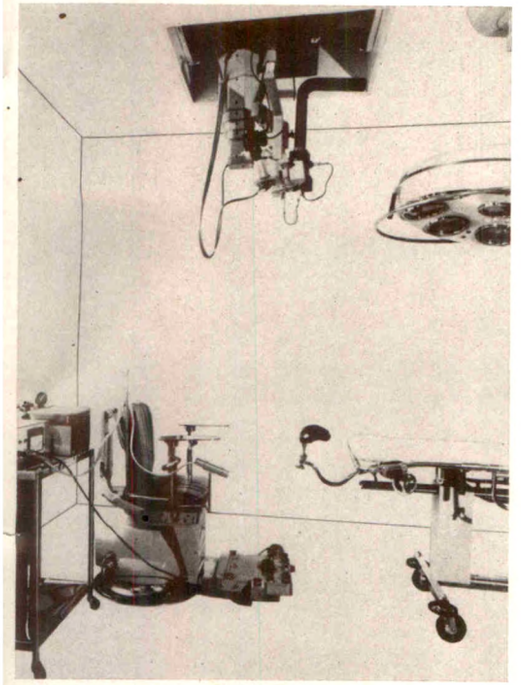

Fig. 2 (Sugita and Sugita). Same view as shown in Figure 1, but with ceiling mounted microscope in fully retracted position.

distance is 365 mm. The clearance between the objective lens and the patient's eye was reduced to 140 mm by the addition of the condenser lenses. However, this distance proved sufficient to allow both the surgeon and the assistant to work together satisfactorily. Furthermore, the use of the two fiber bundle illuminators eliminated disturbing shadows cast by the surgeon's hands when additional oblique illuminators are employed. Since the light intensity was increased by approximately 100%, additional flash is no longer necessary for photography.

*Modification of the foot plate*—Button switches were added to the Zeiss foot plate for the positioning of the microscope, the zoom, the operating lamp, and the chair, and for photography.

## Modification of operating chair

In microsurgery it is essential that proper focus on the operating field is maintained at every step of a surgical procedure. It is equally important that the surgeon's hands remain free so that he may concentrate their effort on the surgical maneuver. It follows that the adjustment of focus may be best performed with foot controls if the surgeon is seated in an operating chair.

One of the most important considerations in regard to the operating chair, however, is whether the surgeon should remain in a fixed position or be able to move around the patient's head. Dannheim developed a chair that allows the surgeon to move around the patient's head while remaining seated, but after some experience with this device, he revised his opinion and stated that a static and relaxed position is better. Barraquer[8] and others concur with the latter opinion.

For practical purposes it is advisable that the operating chair be provided with arm rests. These may be designed to support the surgeon's arms at the elbows, at the forearms, or near the wrists. Mackensen[9] pointed out the arms would be most secure if they are supported near the wrists, but this would prove somewhat inconvenient in cases where considerable movement of the forearms is required (for example, corneal incision with a cataract knife). If the only support is at the elbows, on the other hand, the elbows may tend to slide. These considerations led us to develop a fixed-position chair that can be moved up and down smoothly by foot controls (upward, 40 mm/second; downward, 8 mm/second) in order to obtain different levels of support from the screw-fixed arm rests for different steps of the various surgical procedures. In suturing, for example, the arm rests should be 30 mm below the level of the patient's eye, but for making a corneal incision the arm rests should be lowered 70 mm. For further convenience, the arm rests are designed to rotate horizontally on the axis of a supporting column. By the use of a spring device, the arm rests can be turned to any desired angle. Finally, if the surgeon must leave the chair during the operation, the arm rests can be pushed outward. On the right side of the

chair there is a support for the Amoils cryopencil hose and a casing for insertion of the pencil when it is not in use. Operating maneuvers are further facilitated when this operating chair is used in combination with an operating table supplied with an adjustable headrest. The spatial relationship between the surgeon's eyes, his hands, and the operating field can thus be made the same for every patient. In certain special operations (goniotomy, etc.), the desired angle of approach may be obtained by rotating the chair and placing the operating table diagonally toward either side.

## Summary

The 3-D overhead tube support for x-ray tubes (Siemens) was used for the ceiling mounting of the Zeiss zoom (OPMi II) operating microscope. The facilities of the microscope were further increased by replacement of the coaxial illuminator with two fiber optic bundles for increased illumination without shadowing. In addition, a relaxed posture was achieved for the surgeon by the development of a fixed, but adjustable operating chair provided with a foot plate for the remote control of the microscope and the chair.

# PERIPHERAL RETINAL NEOVASCULARIZATION IN CHRONIC MYELOCYTIC LEUKEMIA

PETER H. MORSE, M.D., AND JOSEPH L. MCCREADY, M.D.
*Philadelphia, Pennsylvania*

Leukemic retinopathy is common in both acute and chronic myelocytic and lymphocytic leukemia at some stage in the course of the disease. Clinically and histopathologically, infiltration of the conjunctiva, episclera, sclera, choroid, iris, ciliary body, optic nerve, retina and rarely the vitreous may be seen. There may be hemorrhage involving the conjunctiva, episclera, anterior and posterior chambers, retina, choroid and vitreous. Focal necrosis of the retina involving the nerve fiber layer and ganglion cell layer have been described as well as serous retinal detachment.

Retinal vessel and choroidal background color changes which reflect an increased leukocytosis or decreased erythrocyte concentration have been reported. In addition, there have been reports of vascular dilatation, irregularity in vessel caliber, tortuosity of the veins and to a lesser extent the arterioles, grey-white linear sheathing of vessels, hard yellow-white exudates, microaneurysms, and soft cotton-wool patches. Flame shaped, rounded, deep or preretinal hemorrhages and subretinal hemorrhages also have been noted. They often have a white central component which may appear, singly or multiply, even when hemorrhages are absent.[1-9]

This paper describes a case of peripheral retinal neovascularization in a patient with chronic myelocytic leukemia which may be unique in the ophthalmic literature.

## CASE REPORT

A 32-year-old black man was first seen in the hematology clinic at the Hospital of the University of Pennsylvania, July 7, 1969, with a three-month history of anorexia, 25-pound weight loss, fatigue, weakness, upper abdominal discomfort, and pains and knots in the legs. One month prior to examination he had noted muscle pain and pruritis of both legs. He had observed painless swellings, 2 to 3 cm in diameter, which spontaneously disappeared in three to seven days, on his left side, both thighs and ankles. The past medical history and family history were noncontributory.

Physical examination revealed a well-developed, somewhat thin man in no acute distress. Blood pressure was 110/85 mm Hg, pulse 80 and regular, respirations 16 per minute, and temperature 37°C orally. Small hemorrhages were noted in both fundi. There was slight enlargement of the cervical lymph nodes and moderate general lymphadenopathy. Heart and lungs were within normal limits. The liver was not palpable, but the spleen was firm and greatly enlarged.

Laboratory values revealed a hemoglobin of 9.5 g%, white blood count of 340,500 $mm^3$, hematocrit 44%, reticulocytes 3.2% and platelets 328,000 $mm^3$. Differential smear contained 41 polymorphonuclear leukocytes, 10 band forms, three eosinophils, one basophil, four monocytes, two lymphocytes, 27 myelocytes, eight metamyelocytes, and four promyelocytes. There was 2+ hypochromasia and polychromasia. Hemoglobin electrophoresis had 96.5% type A and 2.6% type $A_2$ hemoglobin; protein electrophoresis showed only a slight elevation in the gamma fraction of 1.52 g%, the normal range being 0.62 to 1.2 g%. Fasting blood sugar was 60 mg%, Sia test was negative, and immunoelectrophoresis, serum viscosity studies, and test for cryoglobulins were unremarkable. Bone marrow aspirate showed many early myelocytic forms with a high myeloid:erythroid ratio. Chest x-ray examination was within normal limits. The patient was treated with busulfan (Myleran) 8 mg and allopurinol (Zyloprim) 300 mg daily.

Follow-up examination, July 14, 1969, showed the white blood count elevated to 524,500 $mm^3$, and the medication was continued. On August 4, 1969, the patient had improved subjectively with a return of appetite and strength. The spleen was no longer palpable, and the leukocyte count had dropped to 45,000 $mm^3$. By November 3, 1969, the white count had dropped to 9150 $mm^3$ after a course of busulfan therapy.

Subsequently, with regulation of busulfan and chlorambucil (Leukeran) treatment the blood leukocyte count ranged between 8700 and 97,300 $mm^3$, averaging 40,000 $mm^3$, with the maintenance of subjective well being on the part of the patient.

On February 22, 1971, an eye consultation was obtained because of follicular conjunctivitis in both eyes and a small chalazion of the left lower

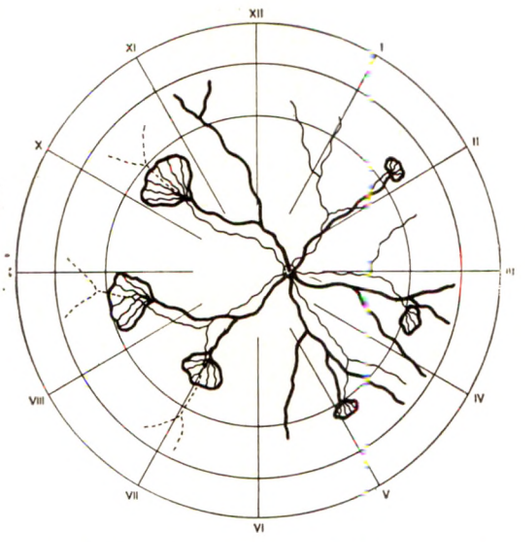

Fig. 1 (Morse and McCready). Right eye. Fundus diagram showing sea fan neovascularization. The obliterated terminal arterioles are represented as broken lines, veins as thick lines and arteries as thin lines.

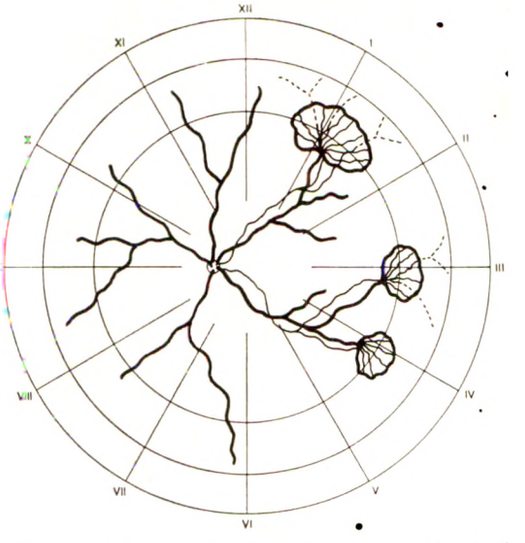

Fig. 2 (Morse and McCready). Left eye. Fundus diagram showing the areas of neovascularization. The obliterated terminal arterioles are represented as broken lines, veins as thick lines and arteries as thin lines.

eyelid. The patient had never worn spectacles and had never been troubled with impaired vision. There was no family history of ocular disease. Visual acuity without corection was 6/6-1 and Jaeger 1 for near in both eyes. With the exception of the conjunctivitis and the small chalazion, external and slit lamp examinations were within normal limits. The intraocular pressure was 7.5/5.5 = 11.2 mm Hg (Schiøtz) in each eye. Ophthalmoscopy revealed clear media with normal disks and maculae in both eyes. There was slight fullness of the veins and small- to medium-sized blot and preretinal hemorrhages, some with white centers, in each eye. A few small microaneurysms were seen. Peripheral linear white sheathing of some arterioles and veins was noted as well as white with and without pressure. Large and small areas of neovascularization with a sea-fan configuration and gliosis were observed at the equator and just posterior to the equator in both eyes. The average size of these neovascular areas was two to three disk diameters. The right eye had six such sea-fans at 2, 3:30, 4:30, 7, 8:30 and 10:30 o'clock (Fig. 1). The left eye had three areas of neovascularization, the largest at 1:30 o'clock, covering a four- to five-disk diameter span, with smaller ones at three and four o'clock (Fig. 2). Anterior or further peripheral to these patches of new blood vessel formation the terminal branch arterioles appeared white and seemingly obliterated (Figs. 3–5). Fundus fluorescein angiography confirmed the branch arteriolar obliteration and showed late-stage neovascular leakage (Figs. 6 and 7).

## Discussion

Clinically, it is not possible to separate the various leukemias and related diseases on the basis of ocular findings alone. The retinal changes seem to appear without any definite

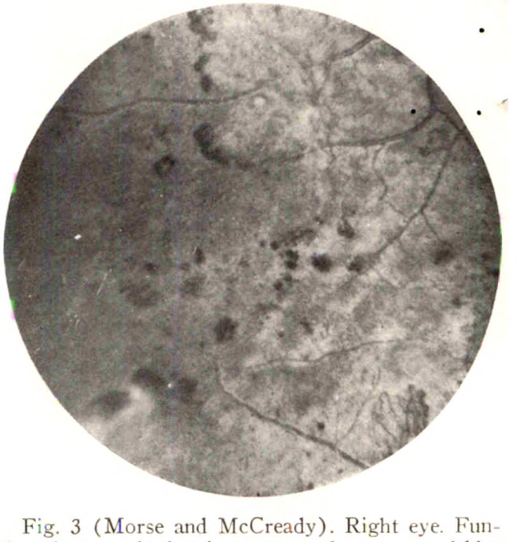

Fig. 3 (Morse and McCready). Right eye. Fundus photograph showing neovascular areas and blot hemorrhages.

Fig. 4 (Morse and McCready). Right eye. Fundus photograph showing a single neovascular patch with blot hemorrhages.

relation to the degree of anemia, thrombocytosis, or leukocytosis, and may disappear during the treatment of leukemia.[9] In one pathologic study, the finding of microaneurysms was confined to those patients who had died of chronic lymphocytic and myelocytic leukemia.[7] Similar, if not identical fundus changes are described in macroglobulinemia, multiple myeloma, cryoglobulinemia, lymphomas, paraproteinemias, and dysproteinemias.[10] One must also consider diabetes

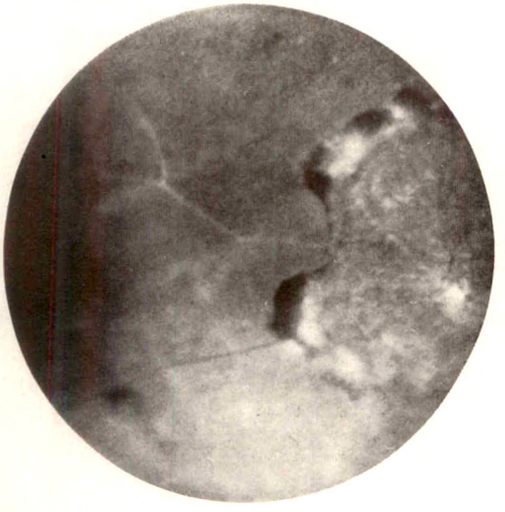

Fig. 5 (Morse and McCready). Right eye. Fundus photograph showing larger sea-fan shaped area of neovascularization with some hemorrhage localized to the peripheral rim. A white obliterated branch arteriole is seen more peripherally.

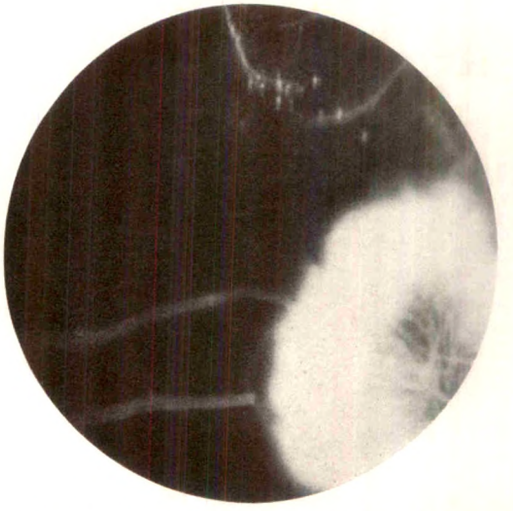

Fig. 7 (Morse and McCready). Right eye. Arterio-venous phase fluorescein angiogram showing vein and main arteriole to be patent and confirmed arteriolar branch occlusion.

mellitus, sickle cell hemoglobinopathy, Eales' disease, polycythemia, central retinal vein occlusion, carotid cavernous sinus fistula, and congenital tortuosity and dilatation of the retinal vessels.

Hyperviscosity of the blood may be due to increased cellular content or serum factors. A previous examination of patients with serum hyperviscosity, in cases of cryoglobulinemia and hypergammaglobulinemia, found histopathologic evidence of attempted new vessel formation in the form of microscopic endothelial nests.[11]

Neovascularization of the type here reported has not been previously described in leukemia. The extensive neovascularization with sea-fan morphology in the reported case is strikingly reminiscent of that seen in the sickle cell hemoglobinopathies.[12] Further studies of this retinopathy, seen most commonly with S-C hemoglobins, and more rarely in S-thalassemia, S-S and S-A, have shown it to be a response to vaso-obliteration preceded by arteriolar occlusion, peripheral arteriovenous anastomosis, with neovascular and fibrous proliferation which may lead to vitreous hemorrhage and retinal detachment.[13]

Examinations have shown a significant increased blood viscosity with a white blood cell count over 50,000 mm³ above which level the blood viscosity increases directly in relation to the number of circulating white cells.[14]

The presumed mechanism for this case of leukemic neovascular retinopathy involves the increased blood viscosity caused by the markedly elevated number of circulating white blood cells, resulting in obliteration of the terminal arterioles and thereby provoking the neovascular response. The findings in the reported case of leukocyte counts of 340,500 and 524,500 mm³ early in the course of the patient's examination and treatment, the absence of alteration of the serum viscosity, as well as the absence of coexisting paraproteinemia or dysproteinemia, and the finding of obliterated arterioles peripheral to the neovascular areas are all consistent with this hypothesis.

## Summary

A 32-year-old man with no visual complaint and chronic myelocytic leukemia was examined 19 months after diagnosis. Ophthalmoscopy revealed large and small areas of neovascularization with a sea-fan configuration and gliosis at the equator and just posterior to it in both eyes. Increased blood viscosity caused by a markedly elevated number of circulating white blood cells that obliterated the terminal arterioles and thereby provoked a neovascular response are presumed to be the mechanism for this case of leukemic neovascular retinopathy.

# RETINAL CHANGES IN CONGENITAL POIKILODERMA

WILLIAM TASMAN, M.D.
*Philadelphia, Pennsylvania*

In 1923, Thomson[1] reported two infant sisters who had a bright red, tense swelling of the face and body. Through this swelling there gradually appeared a telangiectatic network which subsided after the passage of several months, leaving a linear reticulated pigmentation. These changes were very similar to those described by Rothmund[2] in 1868, and later by Wodniansky[3] in 1957. Abnormalities which occur in congenital poikiloderma affect the skin predominantly and consist of telangiectasia, atrophy, and pigmentation which may be smudged or reticulated. The onset of the skin changes is generally in infancy, usually between the third and sixth month of life. Reviews of the literature and case reports[4-8] have emphasized that girls are more often affected and that there is a familial history in about 70% of cases. The primary ocular manifestations are cataracts, and these are present in 52% of cases. The present report is of interest because it is a case of congenital poikiloderma with retinal changes.

## CASE REPORT

A six-year-old white girl was seen for a routine eye examination. There were no ocular symptoms and the only antecedent history was the dermatologic diagnosis of congenital poikiloderma established during the first year of life. There was no familial history of the disease and no systemic abnormalities were present. The skin changes consisted of diffuse telangiectases over the entire body. These were particularly prevalent on the face (Fig. 1). Visual acuity was RE: 20/20, LE: 20/20. Pupillary reactions, motility, and slit-lamp examination of the anterior segment were all normal. Ophthalmoscopy with scleral depression revealed a normal fundus in the right eye, but in the left eye peripheral aneurysmal dilations of the retinal veins were noted just anterior to the equator (Fig. 2). No exudation was present in the fundus. Periodic retinal examinations have been continued and over the last two years, no change has taken place, and the patient has remained asymptomatic.

Fig. 1 (Tasman). Telangiectasia of skin in patient with congenital poikiloderma.

## DISCUSSION

This case is of interest because it describes retinal changes in a patient with presumed congenital poikiloderma. The primary features were capillary telangiectatic changes in the skin. No abnormalities of the skeleton, loss of hair, defects of the nails and

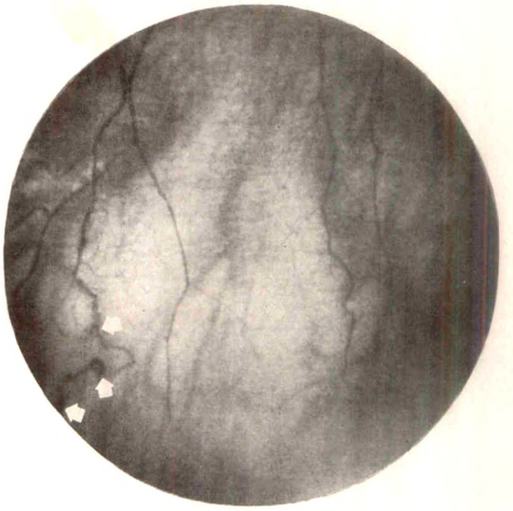

Fig. 2 (Tasman). Aneurysmal vascular changes (arrows) in a patient with congenital poikiloderma. The change is similar to that sometimes seen in Coats' disease.

teeth, disturbance in sexual development, saddle-nose or syndactylism were noted, and no hereditary history could be elicited. Thus, it is difficult to comfortably categorize this patient as having Rothmund's, Thomson's or Wodniansky's syndrome, xeroderma pigmentosum, dyskeratosis congenita, anhidrotic ectodermal dysplasia, Werner's syndrome, or progeria, all of which may have overlapping characteristics.

In the past, cataract is the ocular complication emphasized in many of these syndromes. These were absent at the time of examination, but peripheral aneurysmal dilations of the retinal veins were present in one eye and were similar in appearance to those sometimes seen in Coats' disease. No exudation was present at the initial examination and none has developed over the two years during which the patient has been followed.

## Summary

Peripheral aneurysmal dilations of the retinal vein were noted anterior to the equator in the routine examination of a six-year-old white girl with congenital poikiloderma. She had diffuse telangiectases over the entire body, but was otherwise without symptoms or complaints. In the past, the main complication of this disease was thought to be cataracts. Cataracts were absent in this patient, but retinal vascular changes were present similar to those sometimes seen in Coats' disease. The patient's eyes were asymptomatic, however, and there was no subretinal exudation at the time of her initial examination nor during the two years in which she was followed.

# INTRACRANIAL HYPERTENSION AND TETRACYCLINE THERAPY

CONRAD L. GILES, M.D., AND ALLEN R. SOBLE, M.D.
*Southfield, Michigan*

Intracranial hypertension secondary to tetracycline therapy in infants is frequently recorded.[1-4] The occurrence of this syndrome in adults is apparently rare, with only one patient thus far reported.[5]

This paper presents an additional case; in an adolescent girl with acne, papilledema was associated with the oral administration of tetracycline.

## CASE REPORT

A 16-year-old white girl was admitted to Sinai Hospital of Detroit with a five-day history of severe headaches, dizziness, nausea, and occasional vomiting. The patient stated that she was feeling entirely well prior to the present illness. Tetracycline therapy in a dosage of 250-500 mg daily had been employed in the preceding five months for treatment of acne.

Physical examination at admission revealed evidence of bilateral papilledema with scattered superficial hemorrhages and a few exudates around the disks bilaterally. Except for blind spot enlargement, visual fields were normal. The remainder of the general physical and neurologic examination was entirely within normal limits, except for the complaint of low back pain with extreme flexion of the neck. There was no evidence of nuchal rigidity.

Routine laboratory examinations, including complete blood counts, urinalysis, sedimentation rate, and 24-hour urine studies for 17-keto- and 17-hydroxy-corticosteroids, were within normal limits. Antistreptolysin-O titer, infectious mononucleosis tests were normal; and estimations of blood urea nitrogen, serum calcium, serum phosphorus, and serum electrolytes were also normal. VDRL was nonreactive. The patient was seen in consultation by a neurosurgeon, and neurologic studies including brain scan, electroencephalography, arteriography, and pneumoencephalography; these were reported as being within normal limits. Skull and chest x-ray studies were also normal. Cerebrospinal fluid obtained at the time of the pneumoencephalogram showed no cells protein 16 mg%, and negative cultures. Cerebrospinal fluid pressures were not recorded by the neurosurgeon who performed the spinal tap in the upright position during pneumoencephalography.

The patient brought her tetracycline with her to the hospital, and for several days after admission she continued to take this medication. When this was discovered, the medication was discontinued. Following discontinuance of the tetracycline, the patient noticed a definite improvement in the severity and frequency of her headaches until the time of pneumoencephalography, when severe frontal headaches began to occur. These headaches seemed typically postspinal in nature, with relative comfort in the supine position and exacerbation of the pain upon sitting or standing up. Over a two-week period, the papilledema gradually regressed and the optic disk margins were once more sharp, with resolution of the previously noted hemorrhages and exudates. The headaches persisted, however, despite prolonged bedrest and a trial course of intravenous lactated Ringer's solution. It was felt that the patient would best benefit by convalescing from the postspinal headaches at home. Accordingly, she was transported by ambulance in the supine position to her home.

Shortly thereafter, the headaches disappeared. On follow-up examination six weeks later, central visual fields were normal to a 2 mm white test object at 1000 mm. Vision was 20/20 in each eye, and the optic nerves were normal bilaterally.

## DISCUSSION

This case calls attention to the association between intracranial hypertension and oral tetracycline therapy. The disease states known to produce papilledema and increased intracranial hypertension are noted by Buchheit, Burton, Haag, and Shaw.[6] In addition to tetracycline therapy, nalidixic acid,[7] excess or deficiency of vitamin A,[8] and prolonged corticosteroid administration[1] are implicated as possible etiologic factors in the production of intracranial hypertension. Before a consideration of these agents as possibly causing this patient's intracranial hypertension, space occupying lesions—brain tumors, abscess, or hematoma—and hypertensive encephalopathy were eliminated by careful history, physical examinations, and pneumoencephalography. Medical causes such as hypocalcemia (secondary to hypoparathyroidism), Addison's disease, and pulmonary emphysema were also ruled out by appropriate x-ray and laboratory studies.

From the Departments of Ophthalmology, Sinai Hospital and Wayne State University College of Medicine, Detroit.

Reprint requests to Conrad L. Giles, M.D., 20905 Greenfield, Suite 407, Southfield, Michigan 48075.

The possibility of associated hematologic disorders—sickle cell disease, macroglobulinemia, and polycythemia—was also eliminated as unlikely, and hemoglobin electrophoresis, or immuno-electrophoresis studies were not performed. Since the patient was a Caucasian, sickle cell disease was considered improbable; polycythemia was ruled out following normal peripheral blood counts; and the prompt spontaneous reversal of the central nervous system process belied the presence of macroglobulinemia.

The absence of prior signs and symptoms related to the menses was considered sufficient evidence to eliminate this entity as contributing to the patient's increased intracranial pressure.

Tetracyclines are now commonly employed in the therapy of acne vulgaris, thus a large number of patients are presently being exposed to these agents. In view of the infrequency of the association of intracranial hypertension with the administration of tetracycline in this large patient population of young adults, one might question whether the association in this patient was coincidental. Prompt response to the withdrawal of this agent, coupled with the previously well-described syndrome in infants, argues against this.

Buchheit and associates[6] suggest that the terms commonly used to describe this entity —"benign" intracranial hypertension or pseudotumor cerebri—should be eliminated since the syndrome is neither uniformly benign nor a false tumor. They proposed two designations more apropos: when the etiology is known, the syndrome should be described as intracranial hypertension secondary to the known factor (tetracyclines, for example); where no cause for the process is isolated, it should be designated as idiopathic intracranial hypertension.

## Summary

Intracranial hypertension probably secondary to tetracycline therapy was seen in a 16-year-old girl. Definite improvement occurred following cessation of tetracycline therapy. Laboratory examinations ruled out the commonly associated disease states associated with the production of papilledema and increased intracranial pressure. The terms intracranial hypertension associated with a known etiology (in this case, tetracycline), or idiopathic intracranial hypertension (when no cause is found) are suggested in place of the commonly used terms "benign" intracranial hypertension or pseudotumor cerebri to describe this disorder.

# MODIFIED LANDOLT RINGS AND SLOAN LETTERS IN ADULT VISUAL ACUITY SCREENING

PETER M. HOLLAND, M.D., AND WILLIAM V. BANKS, M.D.
*Baltimore, Maryland*

A major problem involved in the development of a visual acuity screening program for adults is the selection of test targets which have been adequately standardized with those in common use. The broken ring of Landolt was introduced in 1889[1,2] and adopted as the standard test object by the Eleventh International Ophthalmological Congress in Naples in 1909.[3] The Committee on Optics and Visual Physiology of the American Medical Association recognized the problem of standardization in 1930 when they demanded that all test letters for visual acuity be based on comparison with the standard test—the Landolt ring.[4] Aware that the Snellen letters were not of equal difficulty in recognition, in 1951 Sloan[5] proposed the choice of 10 familiar sans serif letters of nearly equal legibility. In 1952, Sloan, Rowland and Altman[6] presented 10 such letters that had vertical, horizontal, and oblique contours. This assured that blurring in any one axis would impair recognition of the letter. The Snellen principle was adhered to in their design in that the height and width of the letters was five times the width of the strokes. Sloan and her associates showed that the Sloan letters yielded scores which were comparable to those achieved with Landolt rings. This study was done with a vision testing device which simulated the optical distance by means of a system of lenses.

Those involved in the development of vision screening programs assumed that testing with Landolt rings or Sloan letters would yield approximately equal numbers of "abnormals." This paper reports the significant difference in scores and numbers of "abnormals" generated by testing with commercially available Sloan letter and modified Landolt ring slides in a vision testing device. The testing of monocular vision with the modified Landolt rings under conditions of binocular seeing is also reported.

From the Department of Health Services Research, United States Public Health Service Hospital, Baltimore, Maryland.

Reprint requests to Peter M. Holland, M.D., 14 West Cold Spring Lane, Baltimore, Maryland 21210.

## MATERIALS AND METHODS

Among the patients who appeared for routine multiphasic health testing at the Baltimore Public Health Service Hospital two groups were formed, each consisting of 100 patients, and all were tested on a Titmus (T/O) Vision Tester. This is a stereoscopic instrument that tests far vision at an optical distance of 20 feet through the interposition of lenses. Near vision is tested at 14 inches without the interposition of lenses. Far vision is tested at 15 degrees below the horizontal plane, and near vision at approximately 45 degrees below the horizontal. The targets are reproduced on slides. Patients who wore corrective lenses for near and far vision were allowed to wear them for that particular test. All testing was done by paramedical personnel skilled in health evaluation testing.

Both groups were tested with the modified Landolt ring slides, and with the Sloan letter slides. Tests were administered in the following order: Landolt-far, Sloan-far, Landolt-near, Sloan-near. Right eye was tested before left in each case. The modified Landolt ring slide contains a group of diamond-shaped borders each containing four rings. Three of the rings have a break in an oblique axes. The patient is asked to name the position of the ring without the break. The examination on the modified Landolt rings continues until the patient misses two consecutive answers. The maximum allowable number of errors per visual acuity level on the Sloan letter slides is dependent on the number of letters at that level (Table 1).

TABLE 1

SLOAN LETTER CHARTS

| Acuity Level | | No. Letters | No. Errors Allowed |
|---|---|---|---|
| Far | Near | | |
| 20/200 | 14/140 | 1 | 0 |
| 20/100 | 14/70 | 2 | 0 |
| 20/70 | 14/49 | 4 | 1 |
| 20/50 | 14/35 | 5 | 1 |
| 20/40 | 14/28 | 6 | 2 |
| 20/30 | 14/21 | 7 | 2 |
| 20/25 | 14/17.5 | 7 | 2 |
| 20/20 | 14/14 | 8 | 3 |

Both the modified Landolt ring and Sloan letter slides have different targets for far and near, as well as left and right eye. There are 10 acuity levels for the modified Landolt ring slides and eight for the Sloan letter slides between 20/20-20/200, and similarly for 14/14-14/140. No patient was tested to a visual acuity better than 20/20 or 14/14.

Both groups of patients had monocular acuity with the Sloan letter slides tested with occlusion of the non-tested eye. The first group of patients had monocular acuity with the modified Landolt ring slides tested under conditions of binocular vision. This was accomplished by providing the non-tested eye with only the group of diamond-shaped borders. (The slides are sold this way commercially, and this is the procedure recommended by the manufacturer.) This group is designated A. The second group of patients had monocular vision with the modified Landolt ring slides tested with occlusion of the non-tested eye. This group is designated B. For purposes of data, each eye was considered individually—thus there are 200 eyes per group.

Each group was composed of approximately equal numbers of men and women. The average age of group A was 41 years and of group B, 38 years. Since these groups are essentially equivalent in their makeup, the scores for the Sloan letter slides were combined for purposes of computing mean, median, and standard deviation.

For purposes of calculating the McNemar adaptations of the chi-square[7] the following were considered abnormal: far-20/30 or worse, near-14/35 or worse. These are the values currently used in the multiphasic health testing center. The reason for 14/35 rather than 14/21 is that this is essentially a test for presbyopia, and 14/35 is equivalent to the size of type used in newspapers.

## RESULTS

The mean far visual acuity scores (Table 2) expressed in decimal notation, are 0.91 for Sloan letters, 0.82 for the Landolt B (monocular vision) and 0.76 for the Landolt A (binocular vision). As visual acuity scores do not represent equal interval data, the median scores are probably of greater value than the mean scores in describing the central tendency of the data. The median scores are 1.00, 0.91 and 0.80, respectively.

Mean and median near visual acuity scores (Table 2) follow the identical trend, with the Sloan letter slides yielding the best

TABLE 2

STATISTICAL ANALYSIS—DECIMAL NOTATION

| | Far Vision | | | Near Vision | | |
|---|---|---|---|---|---|---|
| | Landolt A | Landolt B | Sloan | Landolt A | Landolt B | Sloan |
| No. eyes | 200 | 200 | 400 | 200 | 200 | 400 |
| Mean | .76 | .82 | .91 | .77 | .82 | .92 |
| Standard deviation | .26 | .24 | .19 | .27 | .23 | .18 |
| Median | .80 | .91 | 1.00 | .87 | .87 | 1.00 |

Correlation Coefficients: Sloan vs Landolt B
Far 0.71
Near 0.73

visual acuity scores and Landolt A the worst.

The correlation coefficients between Landolt B and Sloan targets are 0.71 for far vision and 0.73 for near.

There is a higher percentage of individuals reaching a particular acuity level on the Sloan targets than on the Landolt B targets for both near and far vision (Tables 3 and 4). Similarly, there is a greater cumulative relative frequency for the Landolt-B case than for the Landolt-A case at all acuity levels.

If a score of 20/30 or worse for far vision and 14/35 or worse for near are considered abnormal, the referral rates would be as in Table 5.

The McNemar adaptation of the chi-square (Tables 6 and 7) indicates that the probability of our observing a difference as great as that noted between the Landolt A and Sloan, and between the Landolt B and Sloan values, both near and far, due to chance alone, is less than 0.001.

## Discussion

In the report of Sloan, Rowland, and Altman,[6] comparing visual acuity achieved with Sloan letters with that achieved with Landolt rings, the product moment correlation was found to be 0.90. It should be noted that their study was done using the classic Landolt rings. The target was composed of rows of rings with breaks in the horizontal and vertical axes. The patient was required to name the position of the break in the ring. The modified Landolt rings used in the present study have breaks in the oblique axes. This should yield better scores, as most astigmatisms are on the horizontal and vertical axes. The product moment correlation between the modified Landolt rings administered in the mode which yielded the best acuity scores (Landolt-B), and the Sloan letters at far is 0.71. The problem with the modified Landolt rings appears to lie in the task of comparison and selection of the unbroken ring.

Comparison of the product moment correlation of 0.90 with that of 0.71 does not do justice to the importance of the difference in scores obtained with the classical Landolt ring and the modified Landolt ring when compared with Sloan letters. Of greater sig-

†Abnormal = 20/30 or worse.

nificance is the issue of referral levels. The practical benefit to an individual participating in a screening program is limited to those designated abnormal who are able to obtain follow-up care. Reasonable referral levels are set so that serious disease will not be missed. Once this has been accomplished, changes toward better visual acuity levels can be made based on the facilities available for follow-up. If the modified Landolt rings and Sloan letters are used in a testing device, different standards of referral should be set

TABLE 7

NEAR VISUAL ACUITY—MCNEMAR TEST

†Abnormal = 14/35 or worse.

for the different targets. If it were decided to refer approximately 15% of those adults screened for far visual acuity, the referral level for Landolt-A would be 20/50 or worse, Landolt-B 20/40 or worse, and Sloan 20/30 or worse. This provides referral levels which are reasonable in terms of not missing pathology. Also our follow-up facilities are capable of handling the number of follow-ups generated.

There certainly are reasons to continue to use the Landolt rings. It is a good test for illiterates and those who speak a foreign language. The problem with the modified Landolt rings in these situations is that it is difficult to explain the concept of the test to those individuals.

Because of suppression, the acuity of the nondominant eye will be worse when monocular vision is tested under conditions of binocular seeing. Cook[8] identified the ability to overcome the effect of suppression as "resistance to interference." He noted that this was one of the functions of a visual acuity test which was "not pertinent to the function they attempt to measure." This is demonstrated by the fact that Landolt-B acuity is better than Landolt-A. There is no reason to test monocular vision under conditions of binocular vision, as it is a poor test of monocular vision, and a poor test of binocular vision.

The modified Landolt ring targets used for testing in this study were those which are commercially available. The tests were administered as suggested by the manufacturer. This should serve once again to make the medical community aware of the fact that there is inadequate control over the production of medical devices. We, as physicians, must evaluate testing devices in our own practices and clinics for quality control.

## Summary

Visual acuity scores of adults obtained with commercially available Sloan letters were better than those obtained with modified Landolt rings in a vision testing device used in a screening program. Scores with the Landolt rings were poorer when monocular vision was tested under conditions of binocular seeing. The number of "abnormals" referred from a screening program should be no greater than community resources available to provide follow-up can handle. The referral level must be set so that no serious pathology is missed. In order to refer equal numbers of patients with the two types of targets different levels of referral must be used. To refer 15% of those adults tested for far visual acuity, referral levels should be 20/50 or worse for modified Landolt rings testing monocular vision under conditions of binocular seeing, 20/40 or worse for modified Landolt rings testing monocular vision with occlusion of the nontested eye, and 20/30 or worse for Sloan letters. As testing binocular vision under conditions of monocular seeing is a poor test of binocular vision and lowers the level of monocular acuity, there is reason to discontinue the use of this test in this fashion.

# LOCALIZATION OF THE HUMAN VISUAL EVOKED RESPONSE

## Early components specific to visual stimulation

Zenju Nakamura, M.D., and William R. Biersdorf, Ph.D.
*Columbus, Ohio*

The objectives of this study were to identify components of the human visual evoked response (VER) most directly related to visual stimulation and to localize their origin by scalp recording. The approach used was to study differences in the visual evoked response to stimulation of various regions of the visual field. Early attempts at analyses of this type showed a greater correlation with handedness of the subject than with stimulation of sectors of the visual field.[1,2] More recently however, reports showing correlation of spatial visual stimulation with changes in the VER have appeared.[3-5] These reports dealt with relatively long latency components of the VER. Ciganek[6] has analyzed the VER into a primary response having the characteristics of a specific visual response and a secondary response with the characteristics of a nonspecific discharge. This analysis has received support from studies comparing recordings at scalp and cortex and after removal of visual cortex.[7] In the present study, attention was paid specifically to early components of the VER (before 100 msec) in relation to stimulation of the lateral visual half-fields.

As expected from the anatomy of the visual pathways, the maximum visual evoked responses occur in the occipital area. The distribution of the VER, however, is reportedly widespread over the scalp.[8-10] In this study, detailed spatio-temporal mapping across the scalp has been carried out of the early and later VER components in response to full-field and half-field stimulation.

### Method

To avoid contamination of the response by rod functioning, and to minimize the effects of scattered light, the VER was recorded by stimulation in a uniformly light-adapted condition of the retina. A hemisphere one meter in diameter provided high-luminance white light adaptation at a level of 100 ft-L. The subject was positioned at the center of the hemisphere with a head and chin rest 50 cm from the stimulus light. An aperture (15-degree visual angle) in the hemisphere in front of the subject admitted light from a xenon flash lamp and reflector (Grass photic stimulator). One half of the aperture could be occluded with a white cardboard mask, presenting to the subject a half disk 15 degrees vertical by 7.5 degrees horizontal, extending to the right or left in his visual field. The aperture was backed by a red glass filter (Corning 2412) and a diffusing ground glass in front of the flash lamp. The photic stimulator was enclosed in a sound-shielded box to reduce the click attendant on the light flash. Masking noise provided by a ventilating fan on the shielded recording room made the clicks inaudible to the subject.

Standard EEG electrodes (5 mm in diameter) of the chlorided silver type were attached to the scalp with electrode cream following the International 10-20 EEG system with interpolations.[11] Monopolar recording was used with linked ear lobes as the common reference. Amplification was by differential a-c amplifiers with a band pass of 0.2 to 50 Hz. Nine channels were recorded simultaneously with a four-channel signal averager (Fabri-Tek 1052) and an

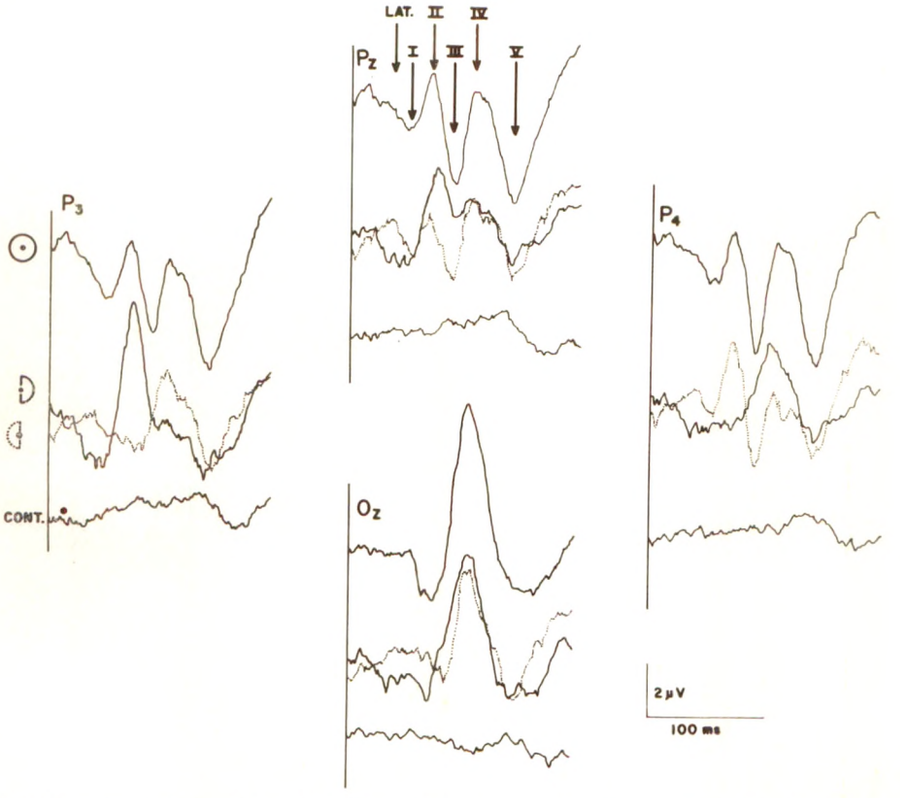

Fig. 1 (Nakamura and Biersdorf). Visual evoked responses (VER) from four electrode positions ($P_3$, $P_z$, $P_4$, $O_z$) on subject C, right eye. Top VER is full disk, next down is right half-field (solid line) and left half-field (dotted line). Bottom VER is control, with light covered. VER components are labeled at $P_z$ position (LAT. is latency). A positive potential at the labeled electrode is an upward deflection in all figures.

FM tape recorder. Responses were displayed on an x-y recorder. For contour mapping, nine channels were recorded twice. The area covered by the first recording covered electrode positions clustered around $O_z$. The second recording covered electrode positions on the periphery of the first, with one position repeated for reliability. When necessary, a third recording covered positions in the central and frontal scalp regions. Three responses were recorded and averaged from each area. The experiment was performed on six normal subjects with corrected or uncorrected vision of 20/20.

Stimulation consisted of the red stimulus light flashing at a rate of 3.3 $H_z$ for a summation of 256 flashes. The photic stimulator intensity was maintained at a constant moderate level (I-4). Stimulation was monocular, with the other eye covered by an opaque black eye patch. For full disk stimulation, fixation was on a black dot at the center of the disk. For half-field stimulation, fixation was on a black dot at the center of the vertical edge of the stimulus.

## Results

Visual evoked responses (Fig. 1) were obtained from three kinds of stimuli: full disk, left and right half-field stimulation, from four representative electrode positions ($P_3$, $P_4$, $P_z$, and $O_z$). The waveform of the VER obtained in the parietal area ($P_3$, $P_4$, $P_z$) is apparently more complex than that from the occipital pole, with earlier components found in the former. Components have been labeled at $P_z$ beginning with a negative component I at 54 msec, with successively alternating

polarities; II at 74 msec, III at 96 msec, IV at 114 msec, and V at 146 msec. Mean latencies of these components at $P_z$ for both eyes of all six subjects are presented in Table 1 for full disk stimulation. As can be seen, component II is quite reliable, having the lowest variance in latency of any component.

For right half-field stimulation, component II is larger over the anatomically corresponding left cerebral hemisphere at $P_3$ than over the right ($P_4$). In contrast, component II is clearly larger over the right hemisphere for left half-field stimulation. This same relationship held for the three early components I, II, and III. Sometimes the polarity of the component was even reversed over the noncorresponding hemisphere. Control experiments show that these VER's are not artifacts of eye movements or reference electrode position.[12]

The latencies of the VER components measured at $P_z$ for the full disk stimulus, at $P_3$ for right half-field and at $P_4$ for left half-field stimulation were used as criteria for drawing potential contour maps of each component. The amplitude of each component was measured from the preceding component at these criterion latencies.

Contour maps were made for each component to the three types of stimuli for the right eye of the same subject (Fig. 2). For the full-disk stimulus, the location of the maximum potential differs from one component to the next. The focus starts near $P_3$ for component I then shifts clockwise temporally. As far as the early three components are concerned, their potential maxima occur in the parietal area with a zero crossing near the occipital pole and a polarity reversal below. The focus of the latter is not found in detail because of contamination from neck muscle potentials.

For half-field stimulation, the foci of the three early components (I, II, and III) are located over the hemisphere anatomically corresponding. When the left half-field is stimulated, the focus is over the parietal area of the right hemisphere. The zero line occurs near the occipital pole, and a reverse polarity maximum occurs in the left hemisphere opposite or below the inion. The opposite results obtain for stimulation of the right half-

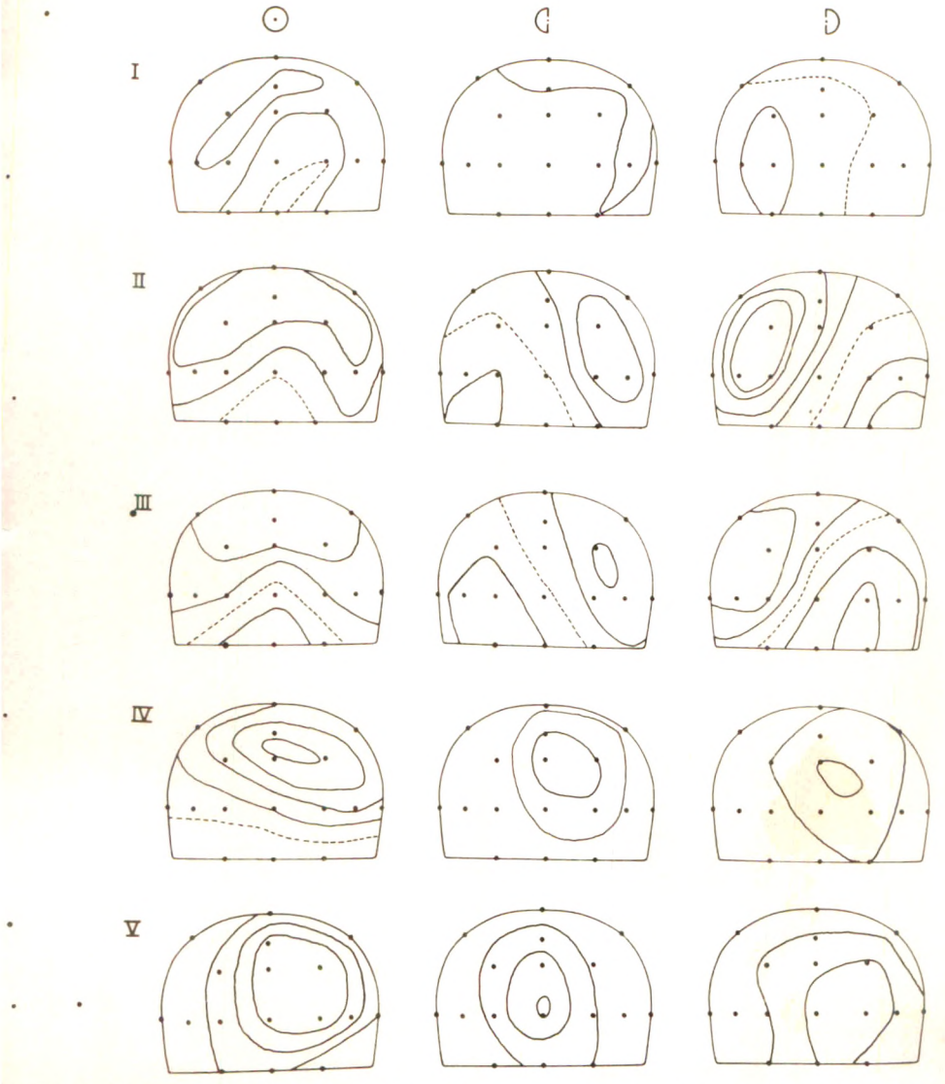

Fig. 2 (Nakamura and Biersdorf). Potential contour maps on posterior scalp for first five VER components. Subject C, right eye stimulation for full disk, right and left half-fields. Positive maxima are occipital or parietal with zero line dotted. Electrode location at the bottom midline is the inion. Moving up are electrodes at 10% distance ($O_z$), 20%, 30% ($P_z$), and 50% ($C_z$). Moving left horizontally from $O_z$ are electrodes at 15% distance, 30% ($T_5$), and 50% ($T_3$). Also shown in the upper left quadrants are electrodes $P_3$ and $C_3$. Directly below the first electrode to the left of $O_z$ is one on line horizontally with the inion. Similar positions are recorded on the right hemisphere (even-numbered). Contour lines for component I are spaced every 0.5 μv, for component II, IV, and V at 1.0 μv, and component III at 2.0 μv.

field. These results appear to hold for component I, but it is quite small under these conditions, and is more variable than components II and III. The later components IV and V did not have this relation to the side of the visual field stimulated, and very often were localized near the midline. Similar results were found for stimulation of either the right or left eyes.

VER waveform variability was found in five subjects under these experimental conditions (Fig. 3). Although intersubject variability is present, component II is clearly visible in all five subjects at position $P_z$ for full-

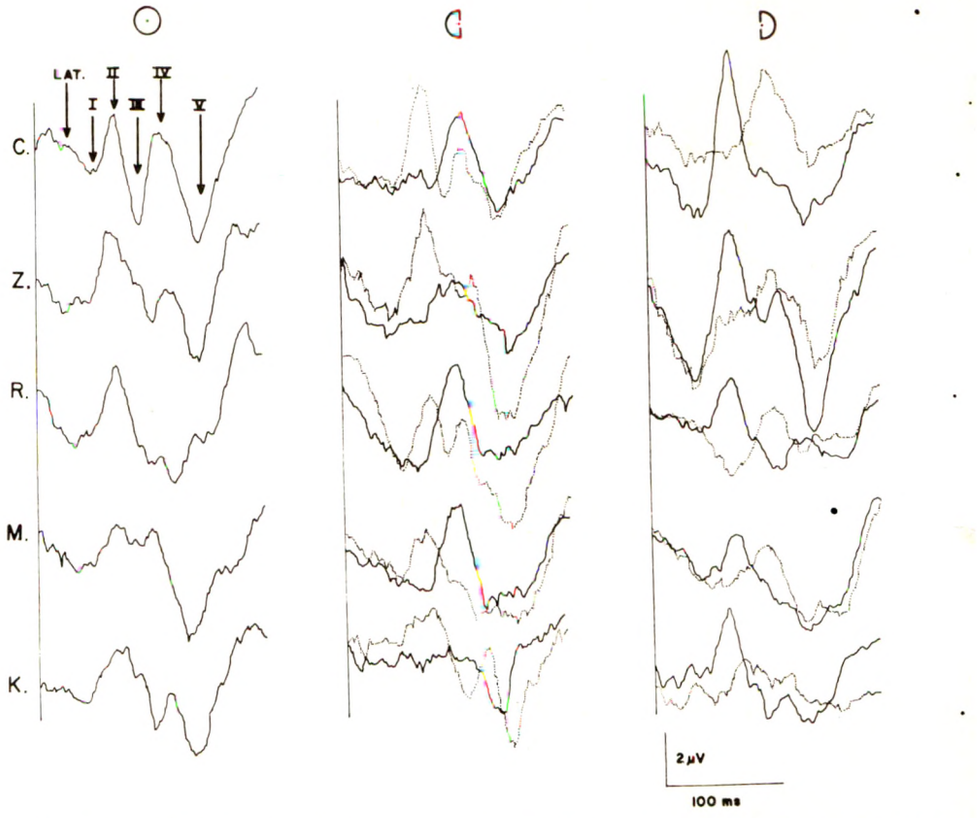

Fig. 3 (Nakamura and Biersdorf). VER's from five subjects, right eyes, for full-disk, right and left half-field stimulation. For full-disk, electrode position is $P_z$. For half-fields, positions are $P_3$ (solid line) and $P_4$ (dotted line).

disk stimulation. For half-field stimulation also, the contrast between the two hemispheres in component II for the two half-field stimuli is clearly present.

Potential contour maps on the four additional subjects for component II in response to half-field stimulation are presented in Figure 4. The similarity to the maps of subject C (Fig. 2) is evident, as is also the individual variability. Variability occurred in the position of the zero lines, the location of the positive and negative voltage maxima, and the resulting potential distribution axes. This axis was usually tilted with the horizontal, perhaps 30 to 60 degrees or more. The same relationship of the positive potential maxima to the corresponding hemisphere, however, occurred in all subjects even though this maxima might occur from the parietal to the frontal area. The contour maps for stimulation of the right or left eyes for each subject were very similar.

Contour maps for the full-disk stimulus were also variable between subjects. In general, the potential maxima of the early components was located in parietal to central areas, while the maxima of the later components were located more posteriorly. The axis of the distributions were nearly sagittal, but might be tilted slightly to one side or the other. Similar results held for the right and left eyes.

## Discussion

The study of localization of the VER is complicated by several factors. One of these

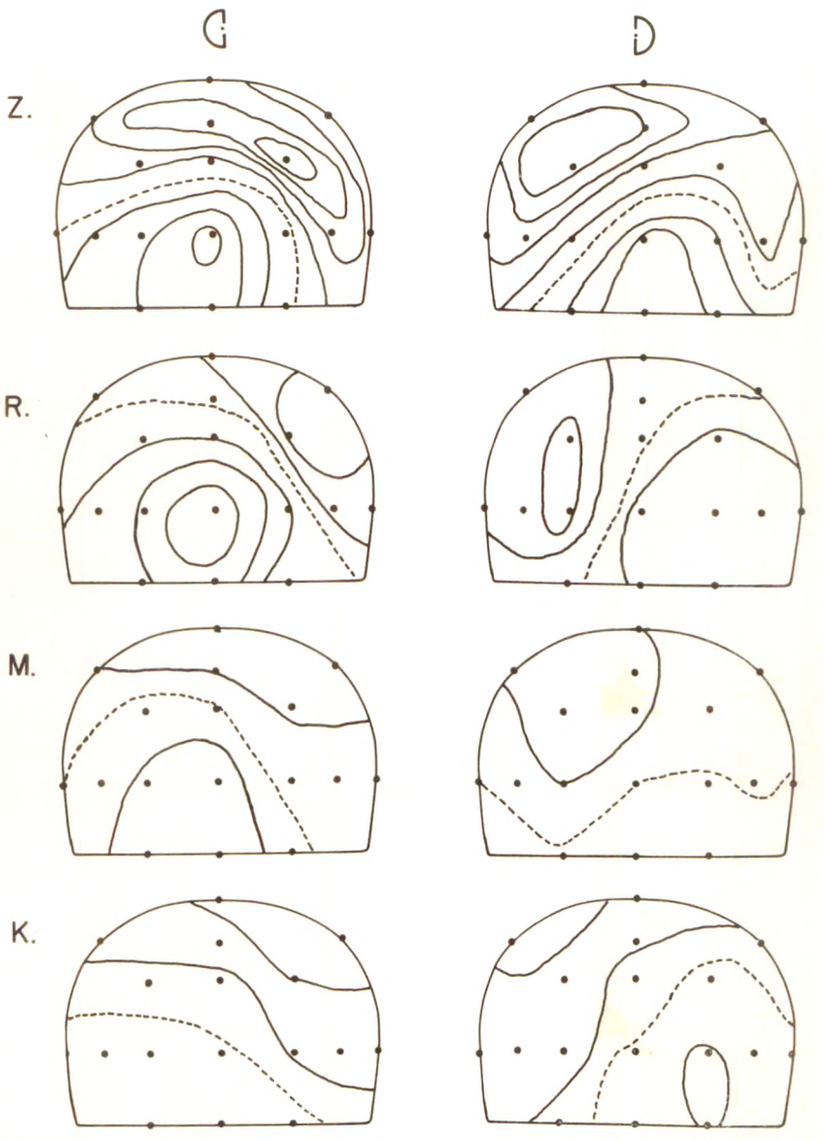

Fig. 4 (Nakamura and Biersdorf). Potential contour maps on posterior scalp from four subjects, right eyes, for right and left half-field stimulation. Maps are of component II with contour lines every 1.0 μv. The positive maxima occur forward with the zero line dotted. Electrode positions are the same as in Figure 2.

is the accessibility of various cortical areas to scalp recording. The macula, occupying a small area of the retina, is projected to a comparatively larger area of the cortex than is the extramacular retina. In addition, the macula is represented at the occipital pole while the extramacular retina is within the cortex along the calcarine fissure. Thus from anatomical considerations it might be expected that scalp potentials would be dominated by macular functioning. This is indeed true, although a number of investigators have recorded VER potentials to extramacular stimulation.[2,13-15]

The anatomical pathways to higher visual centers of man involve the semi-decussation of the optic nerve fibers. The fibers from each nasal half-retina cross at the chiasma

and run to the contralateral cerebral hemisphere while the fibers from the temporal retina run to the ipsilateral hemisphere. Therefore, a stimulus light presented to one lateral half of the visual field will be transmitted by the lens of the eye to the contralateral half-retina and the excitation will proceed to the contralateral cerebral hemisphere.

The results of this experiment with half-field stimulation show clearly that component II is maximally positive in the hemisphere receiving the primary projection pathways and smaller or negative in the other hemisphere. Indeed, the contour maps of the several components measured indicate that the three early components I, II, III (peaks at 47, 68, 95 msec) are localized in the correct hemisphere, while the later components are not so specifically localized. These three early components are thus considered "specific" to local visual stimulation and are related to what early workers have called the primary response of the VER.[6,7] Although the techniques are different, the present components I, II, and III probably correspond to Ciganek's II, III, and IV. An earlier component corresponding to Ciganek's component I was not reliably detected with the present technique. The detailed distribution for these early components for right half-field stimulation indicates a potential maximum in the contralateral parietal area ($P_3$) with a reverse polarity maximum located ipsilaterally below and to the right of the inion. The axis of this potential distribution crosses near the occipital pole. The axis is not horizontal, but tilted 30 to 60 degrees with horizontal. For stimulation of the left half of the visual field, the axis of the potential distribution shifts oppositely with the potential maximum now located symmetrically in the right parietal area (near $P_4$).

The question of intersubjective variability is always prominent with the VER. The present results are no exception. Potential contour maps were obtained on six normal subjects. Component II, the largest and most prominent among the three early components, was easily identified in some cases, but identified only with difficulty in others. The axis and gradient of the potential distributions for hemi-retinal stimulation varied between subjects. For some cases the maxima were in the parietal area ($P_3$, $P_4$), while in others the maxima occured farther forward in the central or precentral areas. The temporal shift of component loci over the scalp to full-field stimulation also varied between subjects. The qualitative results described held for all subjects, although the most detailed data was obtained from subject C, who showed large and distinct early components.

Several previous researchers have studied visual evoked responses in normal subjects by lateral half-field stimulation. Early work by Gastaut and Regis[16] appeared to find maximum potentials over the non-corresponding hemisphere. The explanation for these results can be seen in Figure 1, where the response at $O_z$ is of relatively simple waveform with the salient peaks $N_1$ and $P_1$.[17] If amplitudes are measured between $N_1$ and $P_1$, the maximum potentials may appear localized over the wrong hemisphere. The response waveform is actually more complex than this, however, as can be seen at $P_z$ or laterally over the hemispheres. Two distinct positive peaks are present (labeled II and IV) with respective preceding negative potentials (I and III). If amplitudes are measured peak-to-peak at these latencies, we find the earlier potentials are localized over the correct hemispheres for half-field stimulation. The explanation for the prior erroneous conclusion is that these early potentials tend to pass through zero potential on a phase reversal near $O_z$ and hence are unnoticed.

Normal subjects were studied by Lehmann and associates,[18] who failed to find localization for hemi-retinal stimulation in a dark room situation. They attributed this failure to stray light. In light-adapted experiments, some evidence for differences with hemiretinal stimulation was found by Eason and White.[19] Larger differences were re-

ported by Schreinemachers and Henkes,[3] also using small-spot stimuli. Recently, Cobb and Morton[5] have reported half-field differences for patterned stimulation. All of these studies have dealt with relatively long latency components of the VER. Insufficient electrode positions were used to compare with the potential distributions of the early components in this experiment.

Clinical studies on hemianopic patients support the interpretation that these localized evoked potentials result from the simulation of visual half-fields. Vaughan and associates[20] tested patients with full-field stimulation and found early components, peaking at 45 and 70 msec, to be reduced or missing over the affected hemisphere. Vaughan[17] suggested that these early components were a product of stimulation of the geniculo-calcarine pathways. Kooi and associates[21] found early EP components (peaking at 46, 72, and 93 msec) to be lengthened in latency over the affected hemisphere in hemianopes in response to full field stimulation. Regan and Heron[22] have also reported left-right amplitude differences on a homonymous hemianope with high frequency sinusoidal stimulation.

Lehmann and associates[18] recorded VERs at many electrode positions on a rare case of bitemporal hemianopia with a split chiasm. Stimulation of one eye produced a maximum-amplitude VER localized 3 cm from the midline and 6 cm above the inion on the ipsilateral hemisphere. Despite the difference in subjects and waveforms, it is interesting to compare their localization with ours. Their maximum potential was located in approximately the same position as the present results. Whether the axis of their distribution would be similar to the present results is unknown, as all their electrode positions were 3 cm or more above the inion.

The interpretation for the sources of the potentials found in this experiment can be sought by means of dipole models.[23-25] This assumes that the source can be represented by an equivalent dipole generator imbedded in a finite homogeneous spherical volume conductor. Although the amplitude and sharpness of the potential distribution is changed by assumptions of multiple shells representing the brain coverings, the basic shape of the potential distribution remains similar for a simple dipole generator.[26] Two different dipole models appear as possibilities to fit the potential distributions for the present (e.g., component II) data from half-field stimulation. The first model requires a single dipole approximately tangential to the brain surface below the occipital pole. The second model requires two radially oriented dipoles, one surface positive in the parietal area of the corresponding hemisphere, and one surface negative opposite the inion in the non-correspondng hemisphere. Both models can predict the potential maximum in the parietal area and a potential near zero at the occipital pole. The first model implies that these early VER components are generated in primary visual cortex, while the second model implies that these potentials are generated in secondary visual areas. The present data appear insufficient to decide between these possibilities. One model for the generation of the VER in the primary visual area has been proposed by Vaughan (cited in MacKay[27]).

For full-field (15-degree disk) stimulation, the three early VER components were found to reach their maxima in the midline parietal area. In this case also, an equivalent tangential dipole near $O_z$ provides a possible model for the excitation. The orientation of this dipole is approximately along the anterior-posterior axis although it may be tipped somewhat to one side. Individual differences, from both full-disk and half-field stimulation, can be represented by tilt of the dipole axis, with respect both to horizontal and to the brain surface.

Previous localization research for large area centrally-fixated stimulation has been performed by several investigators. Monnier[28] reported phase reversals in the VER with bipolar recording above and below the

inion. Cobb and Dawson[29] reported phase reversals in bipolar recording in an anterior-posterior direction at a point 3 to 6 cm above the inion for a potential peaking near 70 msec. They also reported phase reversals in the lateral direction for the same component. On the other hand, Gastaut and associates[9] found a phase reversal in the anterior-posterior direction near the occipital pole with monopolar recording. Thus, there is considerable variance in results between investigators. It was also found true in the present experiment that there was greater variability between subjects for large area stimulation than for half-field stimulation. Recent research on a foveal-sized stimulus centrally fixated by Bourne and associates[30] shows a shift in localization for successive components of the VER similar to the present full-disk results.

A variety of electrode positions have been used both in research and on clinical testing of hemianopic patients. Based on the present results, the usual $P_z$–inion bipolar placement is quite good for recording the early components from large area stimulation. For most subjects in the present study, the early components arose more from the $P_z$ position than from the inion. To test the present technique out on hemianopic patients, a double monopolar placement from $P_3$ and $P_4$ to the ears would be advantageous. As an alternative, bipolar placements from $P_3$ and $P_4$ to the inion could also be used.

## Summary

Visual evoked responses were recorded in normal subjects to full-disk (15-degree diameter) and lateral half-disk stimulation in a full-field light adapted situation. Early components of the VER, peaking at 47, 68, and 95 msec, were found to be maximal over the cerebral hemisphere corresponding to the half-field stimulated. From 17 electrode positions on the posterior scalp, detailed potential contour maps were plotted for each component. The maximum focus for the three early components occurred in the parietal to central area of the corresponding hemisphere with a potential near zero at the occipital pole. While early components of the VER were thus specific to the lateral half-field stimulated, this was not true for later components. Results were similar for either right or left eyes.

# PATHOGENESIS OF OCCLUSION OF THE CENTRAL RETINAL VESSELS

SOHAN SINGH HAYREH, F.R.C.S.
*Edinburgh, Scotland*

The pathogenesis of central retinal vein occlusion has been a subject of great controversy since its first description by Michel[1] in 1878. The subject is of great importance, not only because of the common occurrence of retinal vascular occlusion and the marked visual disturbances associated with it, but also because a proper understanding of its pathogenesis may give a clue to the management of this condition, which has, so far, had a hopeless prognosis.

My[2-4] earlier experimental studies in rhesus monkeys on this subject showed that:

1. Occlusion of the central retinal vein at its site of exit from the optic nerve is associated with engorged and turgid retinal veins only, and with no other retinal damage.

2. Occlusion of the central retinal artery at its site of entry into the optic nerve produces immediately the classic clinical picture of arterial occlusion. Six to nine days after the occlusion, ophthalmoscopy reveals more-or-less normal retinal arteries.

3. Simultaneous occlusion of the central retinal artery and vein at their site of entry and exit from the optic nerve produces the classic clinical picture usually associated with so-called central retinal vein occlusion —i.e., retinal hemorrhages, engorged retinal veins, and retinal edema.

It was concluded from these findings that arterial ischemia is an important factor in the production of the clinical picture of central retinal vein occlusion. Other workers[5-7] have expressed similar opinions. Venous stasis retinopathy,[8] seen in conditions associated with chronic arterial insufficiency (e.g., in occlusion of the internal carotid artery,[8-12] pulseless disease,[13,15] aortic arch syndrome,[16,17] ophthalmic artery insufficiency,[18] and retinal branch arterial occlusion[19]) and resembling central retinal vein occlusion, provides further evidence in support of this view. However, this conclusion excited a good deal of controversy because: (a) there was no clinical evidence to support the finding of arterial occlusion in these cases; (b) fluorescence fundus angiography in those cases with the classic clinical picture of central retinal vein occlusion did not show any arterial occlusion[7,20,21]; and (c) in pure central retinal vein occlusion unassociated with hemorrhagic retinopathy, the question of where the blood pumped in by the artery goes still remained to be answered.

In order to explain the discrepancy between the experimental results and the fluorescence fundus angiographic findings in patients, I have investigated the fallacies in interpretation of the angiographic studies in retinal vascular occlusive disorders in man. The crucial question to be answered in the fluorescence angiographic studies of such cases is whether the inability to demonstrate a block in the retinal arteries in such studies is a true index of the absence of arterial occlusion or not. The mechanism of restoration of flow in cases with central retinal artery occlusion and the pathogenesis of the hemorrhagic retinopathy associated with retinal vascular occlusion are discussed.

## OBSERVATIONS AND COMMENTS

### CENTRAL RETINAL ARTERY OCCLUSION

The presence of normal retinal arterial circulation on fluorescence angiography may be thought to exclude the existence of a retinal arterial occlusion. The following three cases are presented as examples to demonstrate the fallacies of such a conclusion in many cases.

## Case reports

*Case* 1.—A 27-year-old man was seen in the casualty department with a four-day history of "inability to see the tip of his nose on closing the left eye." On examination, the visual acuities in both eyes were 6/5. The right eye showed keratic precipitates (KPs), mild flare and a few cells in the anterior chamber; cells in the vitreous; and evidence of superior temporal retinal arteriole occlusion distal to a patch of acute choroidal retinitis over which the arteriole crossed. There was retinal edema in the area involved.

Fluorescence fundus angiography that day revealed an almost complete occlusion of the arteriole (Fig. 1-A), with only a minute trickle of fluorescein beyond the block very late in the transit of the dye (Fig. 1-B). Interestingly, the patch of choroiditis revealed by intense leakage of fluorescein was seen to be many times bigger than the one seen ophthalmoscopically (Fig. 1-C). Thus, the ordinary ophthalmoscopically visible patch of choroiditis is just the tip of an iceberg lying underneath.

The patient was treated with systemic corticosteroids. The chorioretinitis lesion responded very well to this therapy. Three months after the onset of the trouble, when the choroiditis had completely cleared, fluorescence fundus angiography was repeated. No block in the originally occluded arteriole was seen (Fig. 1-D), and a normal retinal circulation was seen in the area involved. A permanent destruction of the choroid in the center of the patch of choroiditis was seen.

This case shows the importance of the time elapsing between the onset of the arterial occlusion and the carrying out of the angiographic studies. Though, at the beginning, the arteriole was completely occluded, later on a normal circulation was seen. If this patient had not been seen for some months after the occlusion, investigations by fluorescence fundus angiography for the inferonasal field defect would have shown the presence of normal circulation, which would have excluded completely a diagnosis of arterial occlusion as the cause of the field defect.

*Case* 2—A 58-year-old man was seen with a history of sudden onset of defective vision in the left eye three days previously. On ophthalmoscopy, he showed a classic fundus picture of central retinal artery occlusion, with a cherry red spot in the macular region and his visual acuity in that eye was reduced to the perception of light only. The other eye was perfectly normal. His blood pressure was 230/130 mm Hg. Fluorescence fundus angiography that day revealed a normal dye transit, with the retinal arterioles starting to fill 8.5 seconds after the injection of fluorescein and emptying in 16-17 seconds after the injection. The retinal vascular tree, including the capillaries, filled normally (Fig. 2).

Although this patient showed the classic clinical picture of central retinal artery occlusion, fluorescence angiography revealed a perfectly normal retinal circulation with no abnormality of any kind. The transitory block in the artery was most probably the result of a spasm due to arterial hypertension.

*Case* 3—A 14-year-old girl was attending the Eye Outpatient Department because of herpes zoster ophthalmicus of the left side. Her visual acuity, which had been normal despite her disease, suddenly became defective in the left eye. When seen about 24 hours later, she had a classic clinical picture of central retinal artery occlusion with a small normal area of the retina temporal to the optic disk because of a patent cilioretinal arteriole. Nine months later, fluorescence fundus angiography was performed. The central retinal artery of the left eye filled normally (Fig. 3-A), though the arterial phase was slightly prolonged. She showed a complete absence of the usual arteriovenous phase (Fig. 3B). In this eye, the small retinal veins started to fill only after the arterial phase was over (Fig. 3-B) and the venous phase was very much prolonged (Fig. 3-C). I have called this phenomenon "hibernation of the blood in the retina," because in between the arterial and the venous phase the blood hibernates somewhere in the retina to emerge slowly and fill the veins gradually. Cilioretinal anastomoses were prominent on the disk and peripapillary retina (Fig. 3-A).

This patient also showed a normal arterial filling in spite of having had an undisputed central retinal artery occlusion nine months previously.

From these three examples, and based upon the findings of the studies in which these cases were investigated, it could be concluded that in fluorescence fundus angiography the presence of a normal retinal circulation by no means excludes the previous occurrence of a retinal arterial occlusion. A review of the fluorescence fundus angiographic studies in retinal arterial occlusion reported in the literature confirms this conclusion,[20-24] although not much significance seems to have been attached to this observation. Thus, in central retinal artery occlusion, a few hours or days after the onset of the occlusion, circulation is almost always seen on fluorescence fundus angiography; the amount of flow increases with the pas-

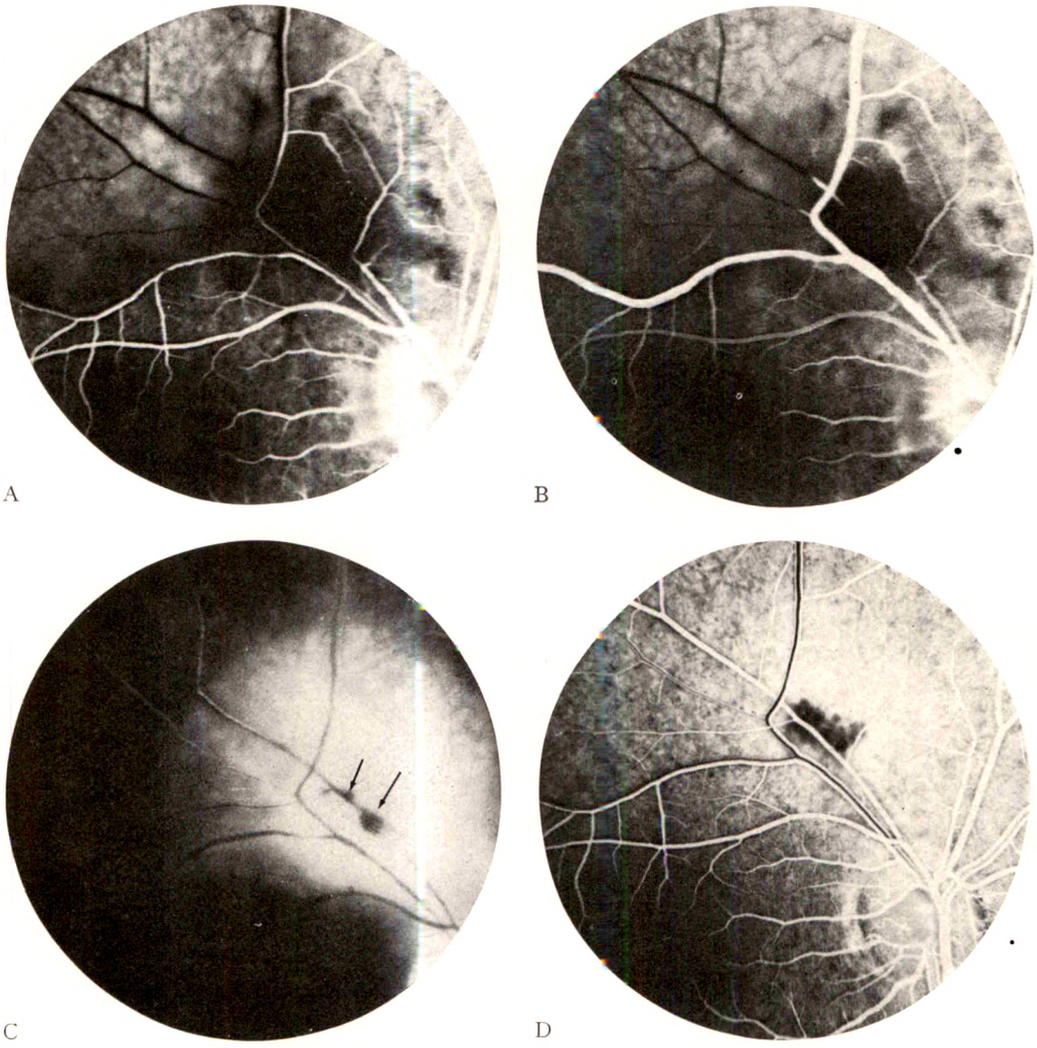

Fig. 1 (Hayreh). Fluorescence fundus angiograms in a 27-year-old man with occlusion of superior temporal artery secondary to a patch of acute choroidoretinitis. Views (A), (B) and (C) were taken four days after the occlusion, and (D) three months after the occlusion. (A) Arteriovenous phase, showing occlusion of superior temporal artery and the area supplied by it. The nonfluorescent area at the site of occlusion corresponds to the ophthalmoscopically visible patch of acute choroidoretinitis. (B) Venous phase, showing a small trickle of dye in the occluded artery. (C) Late phase, 15 minutes after the injection of dye, showing marked fluorescence of the area of choroidoretinitis (compare the size with that of the arteriovenous phase), with some filling of the vessels in the occluded area. Two hemorrhages (arrows) were seen on the ophthalmoscopically visible patch of choroidoretinitis. (D) Arteriovenous phase, taken three months after the occlusion, showing normal filling of the superior temporal artery and the area supplied by it. Nonfluorescent patch on the artery represented the healed patch of choroidoretinitis.

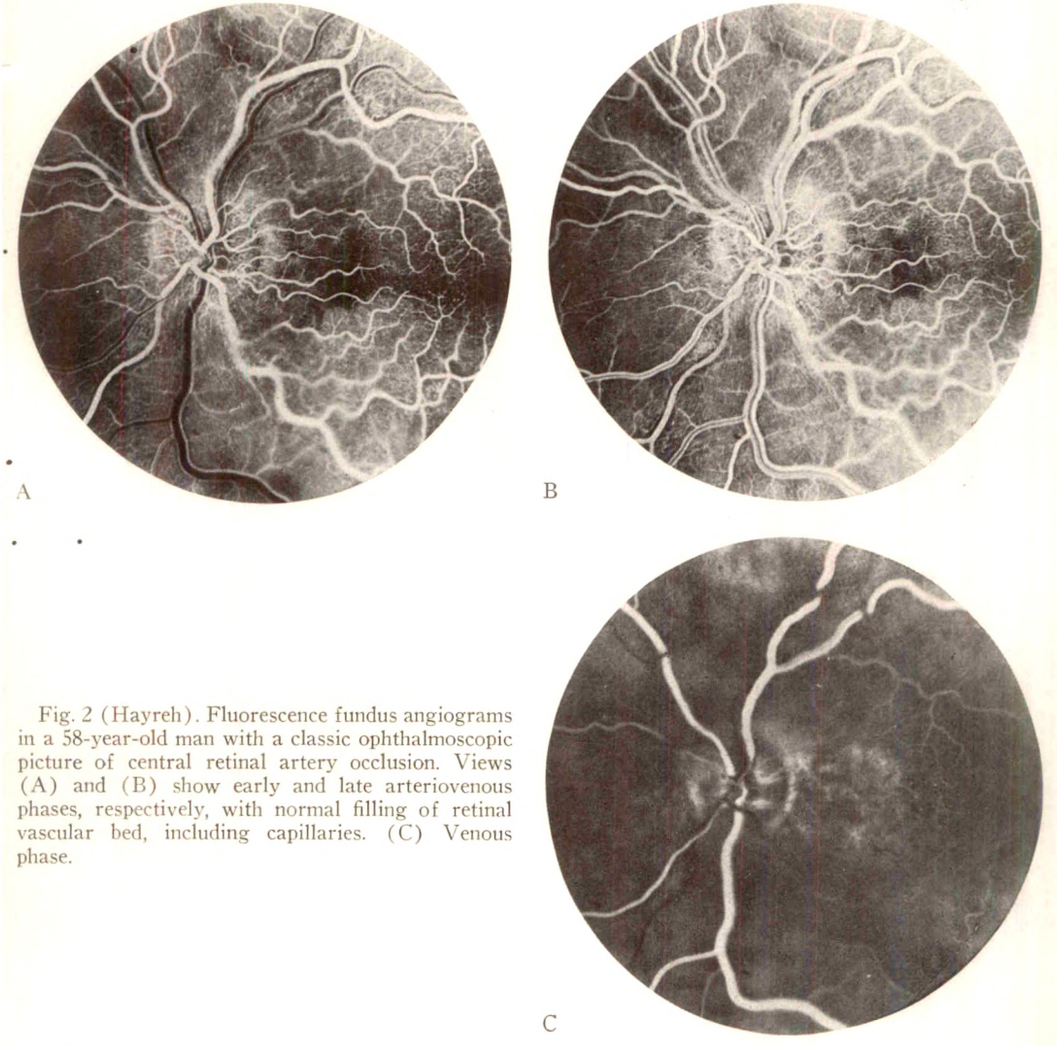
sage of time and, in late cases, returns more or less to normal. The time taken for the retinal arterial circulation to re-establish itself varies in different individuals, depending upon the cause and site of the arterial occlusion, the collateral channels available and, possibly, other factors, which are discussed below.

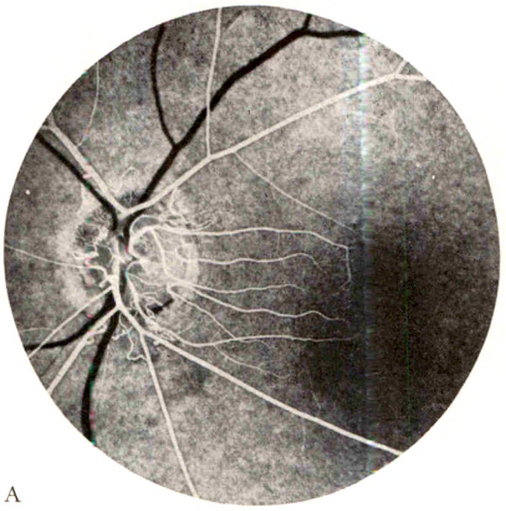
A partial occlusion of the central retinal artery, sufficient to produce the typical ischemic retinal changes, is a possibility in some of the cases where angiography shows the presence of some circulation.

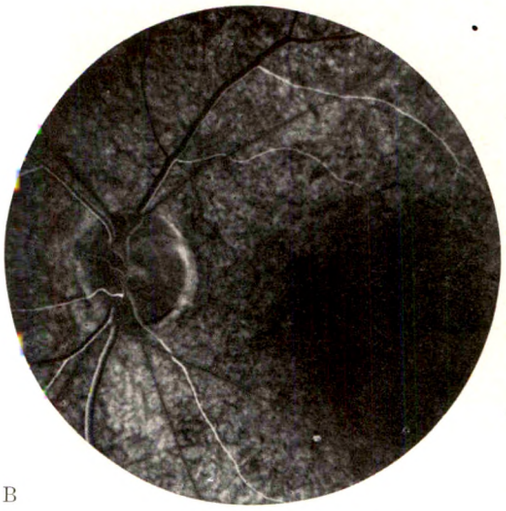
The vascular tissue of the retina is far more resistant to anoxia than the retinal neural tissues.[25] This would produce irreversibly damaged and atrophic neural tissue in the retina with a practically normal-appearing retinal vasculature. The late ophthalmoscopic appearance of the fundus in such cases may be within normal limits or may show optic atrophy with attenuated retinal vessels.[21]

## Mechanism of restoration of arterial circulation in central retinal occlusion

The subject has important implications in







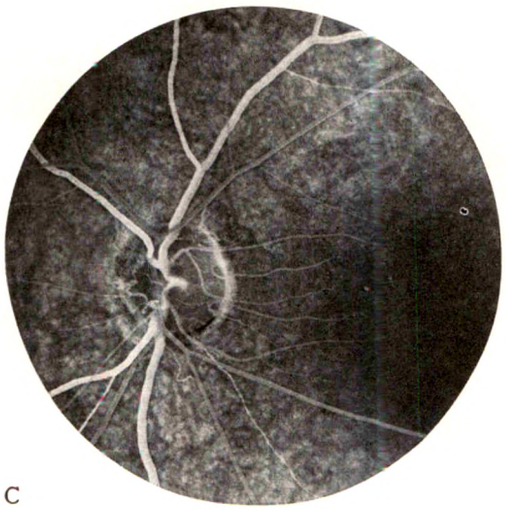


Fig. 2 (Hayreh). Fluorescence fundus angiograms in a 58-year-old man with a classic ophthalmoscopic picture of central retinal artery occlusion. Views (A) and (B) show early and late arteriovenous phases, respectively, with normal filling of retinal vascular bed, including capillaries. (C) Venous phase.

Fig. 3 (Hayreh). Fluorescence fundus angiograms in a 14-year-old girl who had central retinal artery occlusion nine months previously and had a patent cilioretinal artery. (A) Arterial phase, showing cilioretinal anastomoses at the optic disk and adjacent retina. (B) Phase in between the arterial and venous phase showing "hibernation" of the blood in the retina and the start of filling of the retinal veins. No arteriovenous phase was seen. (C) Venous phase.

a consideration of the outcome of treatment and prognosis of cases with such an occlusion. The circulation in the central retinal artery after occlusion may be re-established by any of the following mechanisms:

*Disappearance of spasm of the artery*—In hypertensive arterial disease and in some traumatic cases, occlusion of the central retinal artery may be due to a spasm of the artery. Disappearance of the spasm spontaneously or after the use of vasodilators would restore the circulation. In such cases the circulation is likely to re-establish within a few minutes to a few hours. The second case cited above appears to belong to this category, where the occlusion lasted sufficiently long to give rise to a typical retinal artery occlusion picture and the disappearance of the spasm later on restored the normal retinal circulation.

*Dislodgement of an embolus*—In cases where an embolus in the central retinal artery or one of its branches is responsible for the occlusion, its dislodgement would lead to a restoration of the retinal circulation within a few minutes or a few hours of the occlusion. Such instances are well known to persons familiar with the subject.

*Recanalization of the blocked lumen*—In thrombosis, this may be due to (1) contrac-

tion of the thrombus owing to the fibrin which it contains, leaving a space between it and the vessel wall; this occurs more commonly in venous than in arterial thrombosis. (2) A part of the thrombus may absorb owing to the activity of the leukocytes; and (3) by canalization of a thrombus. The first case mentioned above belongs to this category.

*Establishment of collateral anastomoses*—In any discussion of the subject, I find little mention of the collateral anastomoses available in the event of central retinal artery occlusion. For a proper understanding of the various anastomoses available, a brief account of the anatomy of the central retinal artery is desirable. A detailed study of the anatomy of the artery[26-28] shows that the artery at two sites during its entire course lies in rigid surroundings where it cannot alter its size and shape and shows a constriction in its lumen; these sites are: (1) where it pierces the dura mater of the sheath of the optic nerve to enter the sheath (Fig. 4), and (2) when it passes through the rigid lamina cribrosa.

Of the two constrictions, the narrowest lumen of the central retinal artery seems to be where it pierces the dura mater. The chances of an embolus which enters the central retinal artery from the ophthalmic artery becoming impacted at this site are probably higher than when it passes through the lamina cribrosa. Therefore, it seems most probable that in cases of central retinal artery occlusion due to embolism, the block will be at the first site, and in cases with occlusion due to thrombosis the block could be at either of these or at other sites.

The site of occlusion is very significant because this determines the anastomotic channels available to re-establish the circulation of the central retinal artery. During its intraorbital course, the central artery has practically no anastomoses. During its intravaginal course, it gives out pial branches in 95% of cases. The pial branches in the great majority of cases establish prominent anastomoses with other pial branches arising

Fig. 4 (Hayreh). Transverse section of a human optic nerve at the site of penetration of the dural sheath by the central retinal artery. It shows the artery lying in the dura. CRA = central retinal artery. D = dura mater. ON = optic nerve.

from the peripapillary choroidal vessels, the arterial circle of Zinn and Haller, the main ophthalmic artery, and other orbital arteries. These pial anastomoses of the central retinal artery have been described and illustrated in detail elsewhere.[26,28,29] The pial anastomoses, being prominent, can play a very important role in establishing collateral circulation. During its intraneural course, the central artery establishes in some cases minor anastomoses which are not of significance in establishing a collateral circulation. At the lamina cribrosa, the central artery gives out no branches, hence there are no anastomoses by the artery at this site. Thus, the pia of the optic nerve is the only site where any anastomoses are seeen that are of significance in establishing a collateral circulation. In cases where the site of occlusion in the central retinal artery is somewhere between its origin and its entry into the dura—i.e., before the origin of the pial branches—the pial anastomoses are available to establish some degree of circulation in the majority of cases. In these cases the traditional treatment of the central retinal artery occlusion with vasodilators would help to dilate these collaterals and establish circulation in the artery distal to the block. These cases can easily be confused with cases of spasm of the artery.

On the other hand, when the block occurs

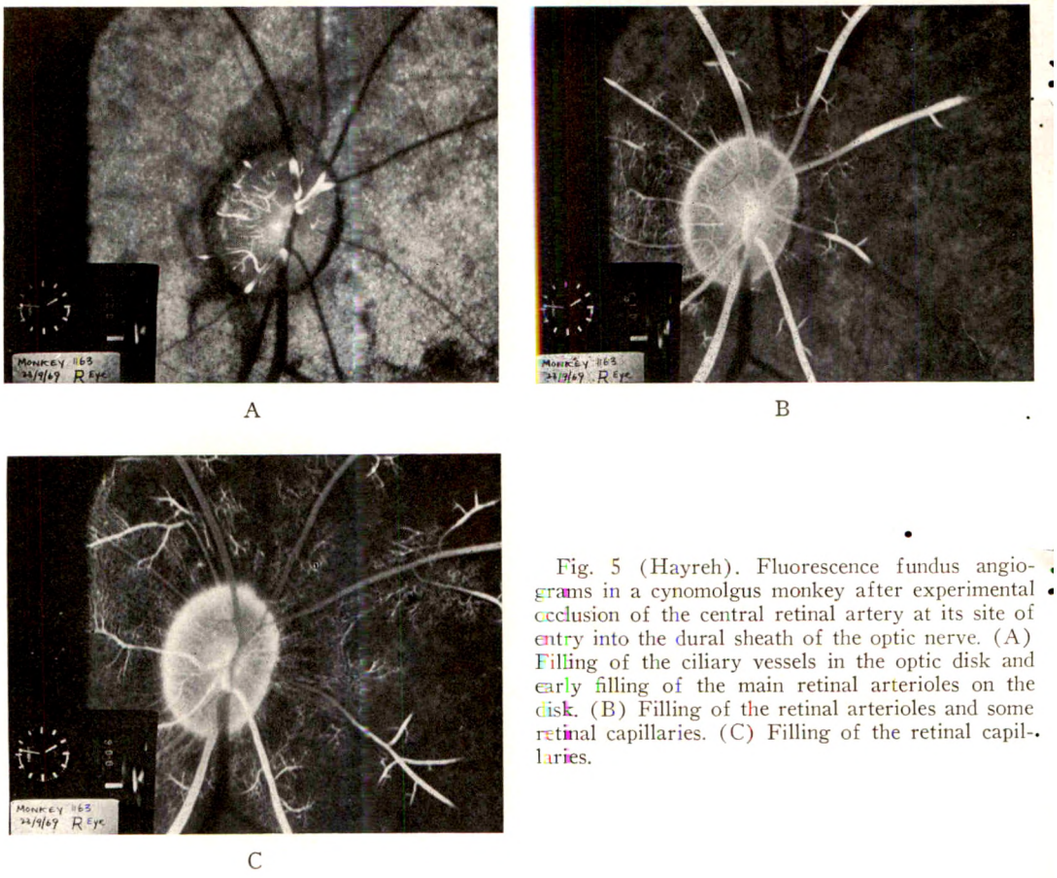

Fig. 5 (Hayreh). Fluorescence fundus angiograms in a cynomolgus monkey after experimental occlusion of the central retinal artery at its site of entry into the dural sheath of the optic nerve. (A) Filling of the ciliary vessels in the optic disk and early filling of the main retinal arterioles on the disk. (B) Filling of the retinal arterioles and some retinal capillaries. (C) Filling of the retinal capillaries.

during the intraneural part or at the lamina cribrosa, the pial collaterals are of no help in establishing the circulation. The prognosis in such cases is grave and no treatment is likely to be of any use. Thus, in any discussion of the prognosis and outcome of the treatment of central retinal artery occlusion, the site of occlusion, which determines the availability of the collaterals, is very important. Treatment with vasodilators, whether by retrobulbar injection or by other routes, is of help only when the occlusion is in the intraorbital part of the artery (up to its site of entry into the dural sheath of the optic nerve) and is useless in cases with intraneural block.

Since, in cases with central retinal artery occlusion, it is impossible to be definite about the site of occlusion, the above discussion may seem theoretical and pointless. The presence of pial anastomoses in the vast majority of cases, however, indicates that it would seem justifiable to try vasodilators in all cases, especially those suspected of being occluded by embolism or spasm.

It is possible that, in some of the cases of central retinal artery occlusion studied by fluorescence angiography by various authors, one of the modes of an early restoration of circulation may be through the pial anastomoses.

Fluorescence angiography in monkeys, after experimental occlusion of the central retinal artery (at the site of its entry into the sheath of the optic nerve) revealed that the retinal arterioles filled to a varying extent at the optic disk from the ciliary vessels supplying the disk via their communications with the surface vessels of the disk (Fig. 5).

Such a phenomenon was also suggested by the cilioretinal anastomoses seen in the third case reported above.

### Central retinal vein occlusion alone

Findings similar to those in experimental studies with central retinal vein occlusion[2-4] alone have been reported in patients. The following patient and Case 5 are cited as examples.

#### Case report

*Case* 4—A 62-year-old man went to his optician for a routine testing of his glasses. The optician noticed abnormal retinal vascular changes in his left fundus and referred him to an ophthalmologist. The patient himself had no symptoms, but he remembered an episode of blurred vision in his left eye about a year previously. He gave a history of ischemic heart disease of 10 years' duration.

On examination, the visual acuity was 6/5 in the right and 6/6 in the left eye with correction. On ophthalmoscopy, the left fundus showed markedly distended and tortuous retinal veins, new vessels on the disk and the adjacent retina, blurred disk margins, and no retinal hemorrhages. The right fundus was normal. He was diagnosed as having "incipient central retinal vein occlusion" on the left side. A thorough physical examination revealed no systemic abnormality. In view of the blurred margins of the left disk, the neurologists considered the possibility of his having an intracranial space-occupying lesion.

Fluorescence fundus angiography revealed markedly sluggish circulation in the left retinal veins as compared to the right side. The left optic disk and the adjoining retina showed dilated vessels and microaneurysms. No evidence of edema of the optic disk was detected. The right fundus showed no abnormality.

Nineteen months later, with the left fundus showing the same ophthalmoscopic and fluorescence angiographic changes, the patient still had no complaint and his visual acuity was normal.

In this patient, an accidental discovery of the retinal venous obstruction by an optician, where there were no visual symptoms and absence of retinal haemorrhages, shows typically the course of events in a pure central retinal vein occlusion. The dilated vessels on the optic disk and adjacent retina most probably short-circuited the retinal blood via the disk vessels to the choroidal circulation without actually developing into prominent retinociliary veins.[30] During the ensuing 19 months there was no change.

This type of case, with pure central retinal vein occlusion behind the optic disk and unassociated with arterial ischemia, is usually considered as incipient central retinal vein occlusion. In these cases, the blood is short-circuited to the choroidal bed via the connections of the central retinal vein with the choroidal circulation at the optic disk. The presence of the prominent retinociliary veins at the optic disk in cases with venous obstruction confirms this view.[30] In fact, one of the major objections raised to my original hypothesis[2-4] was the problem of where the blood from the retinal veins drains to in the pure central retinal venous occlusion unassociated with hemorrhages and other pathology. Fujino and his associates[7] reported that experimental occlusion of the central retinal vein on the optic disk in monkeys resulted in hemorrhagic retinopathy when the above-mentioned collaterals at the disk were also occluded and no collateral channels for shortcircuiting the blood were left. They rightly pointed out that the sequence of events is: increased venous pressure, which is then transferred across the capillary bed to the arterial side, resulting in stoppage of the arterial circulation, which produces ischemia and hemorrhagic retinopathy.

In pure central retinal venous occlusion, there is no visual disturbance or retinal damage. According to Kohner and her associates,[31] the retinal cells can survive venous occlusion because of the presence of arterial inflow, a high pressure head driving collateral flow and more distensible vessels.

### Combined retinal arterial and venous occlusion

The following case is unique in that it provides the missing clinical proof of the important role played by arterial ischemia in the production of the clinical picture of classical so-called retinal venous occlusion.

#### Case report

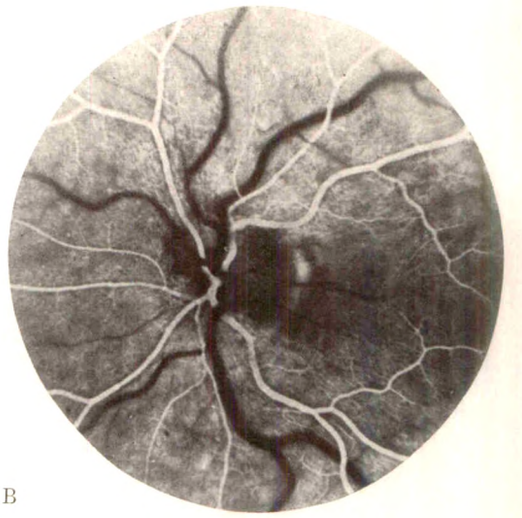
*Case* 5—A 66-year-old man had an attack of blurred vision in the left eye which lasted for about 20 minutes. Nineteen days later he had another similar attack of blurred vision in the same eye lasting for about 15 minutes. On waking up next morning

he found his vision again blurred. When seen four or five hours later, his visual acuity in that eye was 4/60. His fundus showed markedly engorged and turgid retinal veins with new vessels on the disk, normal retinal arterioles, and a few small retinal hemorrhages (Fig. 6-A). A diagnosis of "incipient central retinal vein occlusion" was made by the consulting ophthalmologist.

Fluorescence fundus angiography six or seven hours after he had noticed the defective vision showed a normal filling of the retinal arterioles (Fig. 6-B), the arterial phase being prolonged by four seconds as compared to his normal eye. The area between the optic disk and macula showed a complete absence of retinal capillary filling because of occlusion of the cilioretinal artery supplying that area (Fig. 6-B and C). No arteriovenous phase was seen, i.e., the phenomenon of "hibernation of the blood in the retina" (vide supra) was seen (Fig. 6-C and D). Small retinal veins started to fill 12 seconds after the filling of the arteries, as compared to less than two seconds in the normal eye. The veins did not empty completely even in two minutes, as compared to 30 seconds in his normal eye. Prominent retinociliary veins[30] were seen on the disk which ophthalmoscopically were diagnosed as new vessels (Fig. 6-E). These retinociliary veins evidently acted as collateral channels to drain away the blood from the retinal veins to the choroidal veins.

When the patient was seen two weeks later, his visual acuity was 6/9 in that eye and he had a patch of retinal hemorrhages in the area supplied by the occluded cilioretinal artery (Fig. 6-F), with no change in the rest of the fundus. Visual fields revealed an enlarged blind spot which corresponded to the area of the retinal hemorrhages. Fluorescence angiography three weeks after the first angiography when his visual acuity was 6/6-part, revealed a filling of the cilioretinal artery. His fundus still showed the distended veins and the patch of retinal hemorrhages. When seen three months after the occlusion, his visual acuity was 6/9, the fundus showed no hemorrhages but the engorged veins showed no change. The other eye was normal at all times.

This patient had a chronic central retinal vein occlusion, which produced engorged and tortuous retinal veins with development of collateral retino-ciliary veins on the disk, which shunted the retinal blood to the choroidal circulation, but his visual acuity was not affected. The occlusion of the cilioretinal arteriole in that eye brought on the defective vision and the block was demonstrated angiographically six to seven hours after the onset. At that time no retinal hemorrhages were seen, though some retinal edema in that area was present. At this stage, in view of the retinal venous changes, the patient was erroneously diagnosed as having an "incipient central retinal vein occlusion," and his defective vision was attributed to that. When seen a fortnight later, the area which suffered the arterial insufficiency developed the hemorrhages and the clinical picture of so-called localized venous occlusion, while the rest of the retina showed no similar change, in spite of generalized venous changes. As the localized retinal edema (which also involved the macula) settled, his visual acuity returned to near normal. This eye, thus, provided an ideal experimental model where a localized retinal arterial insufficiency was superimposed by nature on a generalized retinal venous congestion. This resulted in a localized picture of the so-called retinal venous occlusion in the area of arterial ischemia and loss of retinal function localized to that area; in spite of the marked venous engorgement the rest of the fundus showed neither any loss of function nor the changes which are typically described as central retinal vein occlusion. A similar case is reported by Oosterhuis.[6]



These two very instructive cases leave lit-

tle doubt about the mechanism of the so-called retinal venous occlusion, and firmly establish that arterial ischemia, whether transitory or prolonged, is absolutely essential for the production of the clinically identifiable entity of the so-called retinal vascular occlusion. These cases, thus, should be called "retinal vascular occlusion" and not "retinal venous occlusion." On the other hand, patients often diagnosed as having partial or incipient venous occlusion represent cases with true central retinal venous occlusion.

As stated previously, unless the fluorescence fundus angiography is performed during the first few hours of the occlusion in these cases, the chances of seeing an arterial block are remote. This inability to demonstrate the arterial occlusion in such cases [7,20,21] has been a major cause of the confusion created by fluorescence angiography and the doubts cast on the mechanism of retinal vascular occlusions, which has been suggested by experimental studies.[2-4,7] Since most central retinal vein occlusion cases are seen very late and, in the majority, it is not possible to get any definite history of the time of onset, the inability to see the block in the arteries on angiography in no way contradicts the above hypothesis. The other factor to be borne in mind is the presence of a transitory ischemia due to a spasm or transitory embolus or similar process in such cases, which may act as a trigger in the presence of existing venous congestion. Since the retinal venous congestion itself causes no symptoms, the patients seek advice only when the insult of arterial ischemia is superimposed. This transitory ischemia may be a factor in determining recovery of good vision in some cases with central retinal vascular occlusion.

My studies, although they support the views of Rubinstein[5] on the importance of arterial insufficiency in central retinal vein occlusion, do not agree with his conclusion that there is no venous block in such cases. His inability to find a venous block seems to have been due to restoration of the venous circulation by the time fluorescence angiographic studies were performed. Such a restoration of circulation has been reported by Hill.[21] My studies indicate that, for the production of hemorrhagic retinopathy, occlusion of both the artery and vein is essential, though these cases at a later stage may show neither arterial nor venous block on fluorescence angiographies.

## Pathogenesis

Klien and Olwin[32] and Klien[33] postulated the following three occlusive mechanisms involved in occlusion of the central retinal vein: (1) Occlusion by external compression by sclerotic adjacent structures and secondary endothelial proliferation. (2) Occlusion by primary venous wall disease, either degenerative or inflammatory in nature. (3) Hemodynamic disturbances may be produced by a variety of factors, e.g., subendothelial atheromatous lesions in the central retinal artery, arterial spasm, sudden reduction of blood presssure, blood dyscrasias, possible reflex vasoconstriction of the central retinal vein, etc., and further aggravated by arteriosclerosis or unfavorable anatomic relations. These produce stagnation of the flow in the vein and result in primary thrombus formation.

A consideration of Virchow's[34] triad is essential in a discussion on the mechanism of thrombocytosis. The three factors of the triad are as follows:

*Slowing of blood stream*—This is particularly important in venous thrombosis.

*Changes in vessel wall*—The arteries, because of the common occurrence of atheromatous changes, are more commonly affected by this factor. The atheromatous changes predispose to thrombosis because of roughening of the smooth intimal surface and also by producing narrowing of the lumen, which slows the blood stream.

*Changes in the blood*—In thrombocytosis, this is perhaps the most decisive, though least known factor.[35] This may involve stickiness of platelets, viscosity of the blood, or the heparin content.

In cases with combined arterial and venous occlusion in the retina, most probably the sequence of events is: the arterial occlusion (partial or complete, transitory or prolonged) leads to slowing down or stoppage of the circulation in the retinal vascular bed, which, in turn, leads to venous stasis. The venous stasis in a susceptible individual precipitates venous thrombosis. This is further suggested by the fact that most of these episodes come on during sleep when there is a systemic arterial hypotension. Systemic arterial hypotension, with or without arteriosclerotic changes in the central retinal artery, would slow down the retinal circulation. Not only that, but the hypotension could also precipitate central retinal artery thrombosis, because the development of arterial thrombosis in arteriosclerotic individuals with arterial hypotension is well documented in cerebral artery thrombosis. This is further suggested by a large number of reports in the literature establishing a close relationship between central retinal vascular occlusion and arteriosclerotic changes and arterial hypertension.[3]

In any consideration of retinal circulation, the importance of the intraocular pressure must be borne in mind. The retinal vessels are constantly subjected to the intraocular pressure. The venous stasis produced by the fall of pressure in the retinal circulation is further aggravated by the intraocular pressure, particularly when the pressure is raised above normal. This would be an additional important factor in the causation of thrombosis. The commonly observed association between central retinal vein occlusion and glaucoma supports this view. In addition to inducing venous stasis, the raised intraocular pressure may also aggrevate retinal ischemia in cases with low blood pressure in the retinal circulation. An interesting finding in these cases is that the intraocular pressure on the occluded side is usually lower than on the nonoccluded side[2,36-39]; the mechanism of this, however, is obscure.

In some cases, primary retinal venous obstruction in the closed retinal circulation may produce secondary retinal arterial insufficiency,[7] particularly in arteriosclerotic and susceptible individuals, and result in arteriovenous occlusion.

Arterial ischemia damages the vascular wall and produces ischemic capillary changes, so that the capillaries are not able to withstand the blood pressure on restoration of arterial circulation; this leads to hemorrhages, resulting in hemorrhagic retinopathy.

In cases which already have a venous block, as in Case 6, superadded arterial ischemia results in a combined vascular occlusion, and produces the typical hemorrhagic retinopathy.

## Conclusions

Occlusion of the central retinal vein alone produces no retinal damage and, in late cases, is associated with the establishment of collaterals which help to drain the blood away to other patent channels, particularly via the retinociliary connections at the optic disk; the visual acuity is unaffected.

Occlusion of the central retinal artery alone produces white infarct of the retina.

A combined occlusion of the central retinal artery and vein in the retina results in a hemorrhagic infarction of the retina which, in the past, has been erroneously attributed to a simple retinal venous occlusion. In view of this, it is suggested that the term "central retinal vascular occlusion" should be used in these cases.

On fluorescence fundus angiography, the inability to demonstrate an arterial block in cases with central retinal arterial or arteriovenous occlusion does not indicate that the artery was not previously blocked. This is because the arterial circulation re-establishes itself within a few hours or days. The prominent pial anastomoses established by the central retinal artery play an important role in restoration of the circulation; the site of occlusion, however, determines the availability of these anastomoses.

The sequence of events in retinal arterio-

venous occlusion most probably is: arterial occlusion (partial or complete; transitory or prolonged), leading to slowing down of retinal circulation, which, in turn, leads to venous stasis, then venous thrombosis. The arterial occlusion also produces ischemic capillaropathy. Restoration of arterial circulation in the presence of venous thrombosis and capillaropathy results in hemorrhagic retinopathy.

An imbalance between the normal intraocular pressure and the blood pressure in the retinal vascular bed—i.e., a high intraocular pressure and a fall of the blood pressure—would produce venous stasis and ischemia. This may be responsible for the frequent association of central retinal vascular occlusion with glaucoma.

## Summary

Fluorescence fundus angiographic and experimental studies indicate that the hemorrhagic retinopathy seen in occlusive vascular disorders is due to a combined occlusion of the central retinal artery and vein and is not due to venous occlusion; the latter produces no retinal damage. Inability to demonstrate an arterial block, using fluorescence fundus angiography, in cases with central retinal artery or arteriovenous occlusion, does not mean that the artery was not previously blocked. The term "central retinal vascular occlusion" is suggested to replace "central retinal venous occlusion."

# NOTES, CASES, INSTRUMENTS

## DISPOSABLE KERATOME BLADE AND ITS USE IN CATARACT SURGERY

J. Elliott Blaydes, Jr., M.D.
*Bluefield, West Virginia*

Keratomes developed subsequent to the Daviel keratome have undergone wide modification.[1,2] I designed a new and disposable keratome* in order to provide better control of the size of the incision, to eliminate beveling and injuries to the iris and lens capsule, and dulling of the blade.

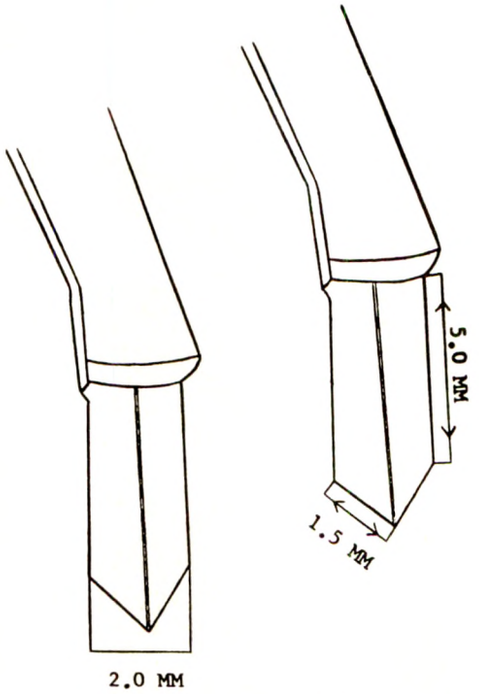

Fig. 1 (Blaydes). New disposable keratome blade.

From the Blaydes Eye Foundation, Bluefield, West Virginia.
Reprint requests to J. Elliott Blaydes, Jr., M.D., 107 Federal Street, Bluefield, West Virginia.
* Available from Rudolph Beaver, Inc., 480 Trapelo Road, Belmont, Massachusetts 02178.

This keratome is made of hard surgical steel and is designed to fit the standard four-inch Beaver chuck handle. The entire blade is 6.5 mm long and 2 mm wide. The leading edge is honed to a tip by the manufacturer, providing two 1.5 mm leading edges ending in a sharp point (Fig. 1). This blade has been used in over 1500 cataract procedures.

I prefer a vertical incision at the 12 o'clock meridian at the posterior one-quarter of the limbus, ending in or near Schwalbe's line; however, other types of incisions are easily carried out with this blade.

### Summary

I have used a disposable keratome in over 1500 cataract extractions. The blade is 2 mm wide, 6.5 mm long, with a 1.5 mm leading edge. The blade is designed to fit the four inch standard Beaver chuck handle.

## NEEDLE WITH WIRE LOOP FOR DRAWING SUTURES THROUGH TISSUE

Clement McCulloch, M.D.
*Toronto, Ontario, Canada*

A small, sharp needle has been devised that carries a loop of fine steel wire (Fig. 1). The needle is stainless steel, 7.14 mm

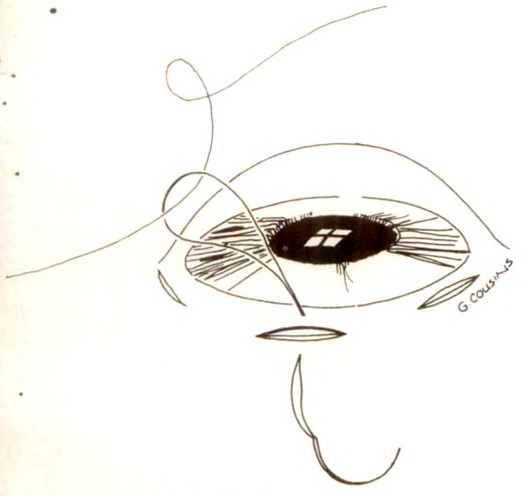

Fig. 1 (McCulloch). Needle with wire loop.

length along the curve, and 0.280 mm in diameter. It is hand-honed, of triangular cross-section, and is reverse cutting. The outside edge of the triangle is rounded except close to the point. The triangle melts to a circle at the base of the needle. The curve of the needle is of 2.38 mm radius, forming an arc of 170 degrees. The wire loop is of stainless steel, fully annealed. It is 32 mm long, and the two ends of the wire are attached to the needle by swaging to its base.

The needle and loop are useful in a number of procedures.[1] Particularly, the loop has value in resolving an emergency during the performance of a penetrating keratoplasty, while using a continuous 9-0 or 10-0 nylon suture. If the surgeon has sewn the nylon suture half or three-quarters of the way around the cornea when the thread breaks, a new suture is usually required. This can be tied to the suture already inserted, leaving an unwanted knot, or the original suture can be removed and the sewing begun afresh. Rather than either poor alternative, the surgeon can continue his sewing, using the wire loop. He merely inserts the free end of the broken, nylon continuous suture through the wire loop and draws the nylon suture through the tissue. This can be done with either end of the broken suture. In this way the surgeon can advance through the remaining steps of the operation, using the original nylon, and without the need of further knots to join broken ends or of removing a length of running suture.

The wire of this loop is very fine and soft. To insert the thread through the loop, the surgeon should use an operating microscope. A sharp instrument is helpful to separate the two sides of the loop, and accuracy is essential to pass a suture through the loop. The loop itself runs easily through the tissues and will draw after it any suture that is likely to be used in microsurgery.

### Summary

A fine, sharp needle that carries a wire loop is described as variously useful in microsurgical procedures, and particularly helpful as an emergency device, permitting the continuation of the single-thread suturing around the cornea when the thread breaks during a penetrating keratoplasty procedure.

## SCLERAL DEPRESSOR

### Marker for Retinal Detachment Surgery

Patrick R. O'Connor, M.D.

*Louisville, Kentucky*

The cryosurgical treatment of retinal detachment, utilizing modifications of the Custodis procedure, requires a precise localization of retinal tears. Localization with the cryosurgical probe is a difficult maneuver for

From the Department of Ophthalmology, University of Louisville, Louisville, Kentucky.

Reprint requests to Patrick R. O'Connor, M.D., 301 East Walnut Street, Louisville, Kentucky 40202.

the inexperienced assistant because no visible lesion remains on the scleral surface after freezing.

Gass[1] introduced a scleral marker in 1966. It resembled the thimble-type scleral depressor with a hollow, stainless steel tube attached to its tip after the cross bar was removed. When applied to the sclera with moderate pressure, a dark, ring-shaped impression remains for 20 seconds. The sclera is then permanently tattooed with a marking pencil. The Gass instrument was found superior to other available markers, but had several disadvantages. Even with rotation of the eye, locating posteriorly positioned tears remains a difficult exercise because the curvature of the instrument prevents its use deep within the bony orbit. The tip of the instrument does not glide smoothly over the scleral surface and is unsatisfactory when dealing with small retinal holes which require scleral indentation and a careful retinal examination prior to marking.

In order to alleviate these two problems, a new instrument was designed which combines a scleral depressor and marker.* The marking portion incorporates the same tip found on the Gass instrument. It is mounted on a flat, straight handle to provide easy access to the posterior sclera without ocular rotation or interference from the orbital rim. Scleral marking of retinal tears is accomplished in the manner described for the Gass design. The smooth, round tip of the opposite end serves as a scleral depressor and avoids tissue damage during the premarking examination.

## Summary

To facilitate scleral marking of retinal tears in surgical treatment of retinal detachments, the Gass scleral marker was mounted on a flat, straight handle. A smooth round tip on the opposite end of the handle serves as a scleral depressor.

## THE 1971 ACADEMY

The 76th annual meeting of the American Academy of Ophthalmology and Otolaryngology, September 20-24, 1971, at the magnificent convention center of Las Vegas, Nevada, was outstandingly successful. With A. Edward Maumenee as president, over 10,000 members and guests (3,300 ophthalmologists and 1,700 otolaryngologists) registered for an exciting meeting. The convention hall was large enough so one could find a seat for the sessions and not have it disappear if one dared to stand up. Instruction courses were popular and the rooms assigned to them were adequate in size.

The meeting opened September 20th with some 25 members receiving honor awards for their contributions to the scientific programs, continuing education, and the instruction program of the Academy. These awards were followed by a symposium on health science liability moderated by George E. Shambaugh, Jr., of Chicago. One came away from this symposium impressed with the variety of viewpoints expressed by the panelists, with few areas of agreement, as ophthalmologists who were attorneys presented their views, and a plaintiff's lawyer

discussed his. Two otolaryngologists then summarized. Underlying the whole discussion was a patient failure to recognize that less than a perfect result did not constitute irresponsibility or lack of expertise on the part of the physician, and that results could never be guaranteed. Conversely, surgeons appear to feel that some type of "no fault" insurance should be available so that patients who incurred hurt could be compensated without the necessity of litigation. Physicians were strongly opposed to contingency fees, but the plaintiff's attorney held that these provided the poor with expert legal talent they would not have if they were called upon to pay for it. The exchange was stimulating and emphasized the need for continuing study, with particular need for communication between attorneys, physicians, and community leaders.

The guest of honor in ophthalmology was Professor Norman Ashton, who discussed the eye in malignant hypertension. He produced hypertensive retinopathy in monkeys by renal ischemia, and showed, in a beautiful electron microscopic preparation, leakage areas of breaks in the endothelium of precapillary arterioles. He postulated that focal constriction of the arterioles causes muscle degeneration, with the opening of the arteriole and rupture of the endothelium as it is exposed to the full force of the blood pressure. Leakage of plasma and fibrin into and through the damaged blood vessel wall causes intramural deposition of fibrin, providing the histologic picture, of fibrinoid necrosis and retinal exudates. The lecture was magnificently illustrated and delivered with the grace and style we all expect from Professor Ashton.

President Maumenee designated six colleagues as honor guests and their lectures were scattered throughout the program. Joaquin Barraquer of Barcelona presented a beautifully prepared film of management of dislocated lenses. In children, the lens was aspirated through an 18-gauge needle, while the adult lens was extracted through a large incision. David Cogan presented three families with congenital ocular motor apraxia in which the mode of transmission appeared as either an autosomal dominant or an autosomal recessive. He showed striking pictures of the inability of the children to move their eyes voluntarily, giving rise to characteristic jerky head movements when attempting to fix upon a moving object or to read. With labrynthine stimulation by rotation of the head, the eyes moved to extreme positions of gaze.

Michael J. Hogan presented a beautiful example of electron microscopy of the retinal pigment epithelium and choriocapillaris. He related these to changes occurring in macular degeneration. Irving H. Leopold discussed problems in ophthalmic drug therapy, with particular attention to the interaction of drugs, the inborn capacity of an individual to handle drugs, and the systemic effects of topically applied agents. Frank W. Newell discussed the clinical and histologic correlations of drusen and fundus flavemaculatus. Lorenz E. Zimmerman indicated the value of reprocessing paraffin-prepared material for re-examination with the electron microscope. Additionally, he indicated the unusual value of preparing small specimens (such as corneal buttons) immediately for electron microscopy although the tissue is destined for light studies; thus if the tissue proved of unusual interest, good preparations for electron microscopy are possible.

The XXVIII Edward Jackson Memorial Lecture was presented by Enrique S. Malbran of Buenos Aires, Argentina, who provided unique pathologic material of cornea dystrophies studied mainly by means of histochemistry. The lecture was in the grand tradition of the Jackson lecturers, and it will appear in an early issue of the JOURNAL.

Two major symposia were presented. Robert Shaffer moderated one on microsurgery of the outflow channels. The speakers included Doctors Krasnov of Moscow, Dannheim of Germany, Cairns of (Cam-

bridge) England, Spencer of (San Francisco) California, Grant of (Boston) Massachusetts, and Podos of (St. Louis) Missouri. It seemed evident that this type of surgery is most effective in congenital anomalies of the angle and that its value in open-angle glaucoma is not precisely established.

Morton F. Goldberg moderated a symposium on genetics as applied to ophthalmology. Speakers included Doctors David Yi-Yung Hsia, Edward Cotlier, John M. Opitz, and Harold E. Cross. Once again, the key position of the ophthalmologist in recognizing and distinguishing congenital and genetic defects was emphasized. In addition to these presentations, there was an additional 38 papers and films presented with accompanying discussions.

A major change in the direction of the Academy occurred at the annual business meeting. Howard P. House, an otolaryngologist of Los Angeles, was named president to succeed A. Edward Maumenee. Kenneth L. Roper, Chicago, was named president-elect after having served as secretary for ophthalmology for nearly 20 years. He was succeeded as secretary for ophthalmology by Frederick C. Blodi of Iowa City. Edward W. D. Norton of Miami was named first vice-president and Webb Chamberlain of Cleveland, third vice-president. David Shoch of Chicago was named secretary for instruction in ophthalmology, succeeding Glen Gibson of Philadelphia, who served some 17 years in this post and is responsible for establishing the current pattern of instruction courses. Bradley R. Stratsma continues as secretary for continuing education for ophthalmology, an enormous enterprise involving the self-assessment examination and continuing education for residents and members. Clair M. Kos, Iowa City, was re-elected executive secretary-treasurer and Wesley Bradley, Syracuse, an otolaryngologist from Syracuse, New York, was elected councillor.

An enormous number of additional meetings surrounded the main meeting. There were breakfast, lunch, and dinner meetings of innumerable special committees, ophthalmic and otolaryngologic societies and alumni groups. With these meetings combined with the usual scientific program and instruction courses, the conscientious ophthalmologist was involved from breakfast meetings at 7:30 in the morning to the conclusion of a scientific program at 10:30-11:00 o'clock at night. Many ophthalmologists attended the following public gatherings: American Society of Ophthalmic and Otolaryngologic Allergy; Eye Bank Association of America; American Society of Ophthalmic Plastic and Reconstructive Surgery; Ocular Microbiology and Immunology Society; American Society of Ocularists; a contact lens medical seminar; Association for Research in Vision and Ophthalmology, a stimulating program chaired by David Cogan discussing misdiagnosis in neuro-ophthalmology; a joint meeting of the Association of the National Society for the Prevention of Blindness and the Association for Research in Vision and Ophthalmology concerning glaucoma; Ophthalmic Photographers Society; a joint session of the Academy and the committee on drugs and the Association for Research in Ophthalmology and Vision concerning the pathologic effects of light upon the eye; the American College of Veterinary Ophthalmologists; a film program of the International Eye Film Library; a joint meeting of the American Orthoptic Council and the American Association of Certified Orthoptists; the American Association of Ophthalmology public affairs workshop; the Reconstructive and Plastic Surgery in Ophthalmology evening meeting; the scientific meeting of the American Association of Certified Orthoptists.

There were over 21 purely scientific exhibits in ophthalmology, combined with an additional 12 instructional exhibits. For the first time this year, those whose scientific exhibits were winners were awarded beautiful medallions appropriately named the William L. Benedict awards. First award was

for "Fluorescein angiography of the anterior segment," by Pierre M. Amalric, Edward W. D. Norton, Johnny Justice, Jr., and Mizuo Matsui. Second award was for "Time curves of the effect of miotics on intraocular pressure and outflow facility," by Paul C. Barsam, and the bronze award was for "Retinopathy in experimental diabetes," by Ronald L. Engerman, Matthew D. Davis, and James M. B. Bloodworth.

It was a tired group that left the Academy this year convinced of the extraordinary educational impact of this meeting. The next meeting is scheduled for September 24-28 in Dallas, Texas.

Frank W. Newell

## IN MEMORIAM

### Clarence H. Graham

Professor Clarence H. Graham of Columbia University died July 26, 1971, at the age of 65 years. He was renowned for his contributions to visual science and for his training of over 70 recipients of the doctor of philosophy degree.

Dr. Graham received his A.B., M.A., and Ph.D. degrees from Clark University in Worchester. His doctoral disertation (1930) concerned binocular summation. Thereafter, he collaborated with Dr. R. Granit and later with Dr. H. K. Hartline in the recording of nerve impulses in single cells of Limulus. From 1934 through 1941, he and his students at Brown University used psychophysical techniques to study threshold interactions of intensity, time, and area. During and after World War II, he was interested in space perception. At Columbia in the 1950s, he turned his attention to color vision and, in collaboration with Dr. Yun Hsia, investigated some fundamental characteristics of color blindness. In recent years he turned again to space perception, and he and his students studied movement perception.

Professor Graham was the recipient of many honors and awards including the Warren Medal of the Society of Experimental Psychologists (1941), the Presidential Certificate of Merit (1948), The Tillyer Medal of the Optical Society of America (1963), and the distinguished Scientific Contribution Award at the American Psychological Association (1966). Dr. Graham was elected to the National Academy of Sciences, the American Philosophical Society and the American Academy of Arts and Sciences.

Dr. Graham's living memorial is the many graduate students he trained during his career. His students hold him in respect and affection, exemplified by the fact that they call themselves his "academic family."

Joel Pokorny

## CORRESPONDENCE

### Protective moist dressing

Editor,
American Journal of Ophthalmology:

At the time we submitted our manuscript entitled "Protective moist chamber eye dressing" (Am. J. Ophth. 71:1333, 1971), we were unaware that the method had been previously described by Dr. Stanley Golden, M.D., of Redwood City, California (Am. J. Ophth. 55:384, 1963). We wish to acknowledge his prior report.

Robert W. Hollenhorst
Charles F. MacCarthy

## BOOK REVIEWS

The Endothelium of the Cornea and its Clinical Implications, 2nd ed. By Frederick W. Stocker, Springfield, Charles C Thomas, 1971. Clothbound, 250 pages, table of contents, bibliography, 124 black and white figures. $14.25

This is an important and extremely readable book by a clinician and researcher of great experience and maturity. In this brief work, Dr. Stocker reviews in perspective the enormous literature available on the endo-

thelium, and interprets it with judgment and balance. He summarizes the necessary concepts of endothelial anatomy and physiology in a way that is valuable to both basic scientists and clinicians, and presents in detail many important clinical manifestations of corneal endothelial disease.

In some areas Dr. Stocker could be considered to overly stress his own work and concepts, and in others he emphasizes certain controversial and unproven therapies (e.g., rutin and vitamin A therapy for corneal edema, full thickness lamellar keratoplasty for bullous keratopathy). These areas are minimal, however, and do not spoil the generally well-rounded presentation of an important subject.

This book is highly recommended for students of ophthalmology as well as basic scientists and clinicians.

Herbert E. Kaufman

THE CONTROL OF EYE MOVEMENTS. Edited by Paul Bach-Y-Rita, Carter C. Collins, and Jane E. Hyde. New York, Academic Press, 1971. Clothbound, 560 pages, table of contents, index, 322 black and white figures. $14.50

This book records the proceedings of a symposium held under the auspices of the Smith-Kettlewell Institute of Visual Sciences of the Pacific Medical Center in San Francisco at the time of dedication of a new building of that institute in November, 1969. The purpose of the symposium was to assemble visual scientists and clinicians for an exchange of views on physiological aspects and clinical correlation of eye movement control. Participants included physiologists, pharmacologists, bioengineers, physiologists, and neuro-ophthalmologists. Indeed, the list of contributors reads like a "who's who" in the field of eye movement studies.

The first part of the book deals with physiological aspects of eye movement controls and contains original contributions and comprehensive reviews on the probable role of muscle spindles and tendon organs on the control of eye movements, the pharmacology of extraocular muscles, central oculomotor pathways, vestibular ocular reflexes, and other related subjects. In this section, a paper by Hoyt and Daroff, "Clinical Anatomical and Physiological Correlations of Supranuclear Disorders of Ocular Control Systems in Man," is especially noteworthy. It provides a superb review of the supranuclear ocular motor syndromes and signs in terms of current physiological concepts. It also points up the many opportunities for interdisciplinary investigation of eye movement anomalies.

Perhaps because of the intriguing interdependence between its sensory and motor functions, the visual system has held a great fascination for bioengineers and other scientists engaged in the modeling of system behavior. This is reflected in the second part of this book in which we find the latest (and often brilliant) work on orbital mechanics, the dichotomy of the saccadic and the pursuit movement system, the version and vergence systems, and vestibulo-ocular functions. Undoubtedly, some of this work will eventually have direct clinical implications, whereas other aspects, such as the independence of the saccadic and the pursuit system, provide the experimental basis for what has been clinically observed for the past 50 years.

The most exciting aspect of this book is that it points to numerous possibilities of a fruitful interdisciplinary approach in the study of eye movement anomalies by combining the talents of various types of visual scientists and clinicians. This should not only enhance the efficiency of neuro-ophthalmic diagnosis, but also ultimately lead to better insight into the physiology and pathophysiology of the oculomotor system.

Acquisition of this book is a "must" for anyone interested in the field of normal or abnormal eye movements, and the scientific community is indebted to the organizers of this symposium for making this information available.

Gunter K. von Noorden

VIRUS ET UVEITES. By A Catherine Martenet. Paris, Doin Editeurs, 1971. Paperback, 136 pages, table of contents, bibliography, 27 black and white figures and 11 color figures. 65.00 F.

This short monograph details the biology of viruses which have been implicated in ocular disease. Subsequently, it covers the clinical aspects of viral uveitis with particular emphasis on diagnostic procedures in viral uveitis and cites the author's own experience.

An important section is devoted to experimental viral uveitis together with the presentation of Madam Martenet's experiments in inducing uveitis in rabbits.

A necessarily limited section on therapy of ocular viruses considers the possible theoretical approaches for the future. A valuable bibliography is appended.

Marcel Frenkel

THE SECOND CONFERENCE ON THE CLINICAL DELINEATION OF BIRTH DEFECTS. PART VIII. EYE. Edited by Daniel Bergsma. Baltimore, William and Wilkins, 1971. Clothbound, 213 pages, table of contents, index, 316 black and white figures. $17.00

The second conference on the clinical delineation of birth defects was held at Johns Hopkins Hospital in 1969, and was devoted to the eye. Happily, the volume is dedicated to that gentle scholar, Frank Burton Walsh, who continues his active teaching, research, and consultation.

The book consists of generalized discussions of corneal dystrophies and chorioretinal disorders with additional chapters on Norrie's disease, oculocutaneous albinism, Rieger's syndrome, and microphthalmia. Many of the discussions are devoted to classification and textbook description of the various disorders. The authors are experts with much clinical awareness, and the text is richly illustrated. The book concludes with 23 illustrated case reports.

The text provides interesting information for the ophthalmologist who is involved more and more in the recognition of genetic disorders.

Frank W. Newell

CORRECTION OF SUBNORMAL VISION, 2nd ed. By Norman Bier. New York, Appleton-Century-Crofts, 1970. Clothbound, 287 pages, table of contents, bibliography, index, 170 black and white figures. $14.00

The second edition of this book has been revised and expanded. The section on multifocal systems and magnifiers have each been made into a chapter and a chapter on visual efficiency has been added. The chapters on clinical procedures have been rearranged.

This book merits a place in the library of the ophthalmologist who is particularly interested in the correction of subnormal vision. It contains a fairly complete, if somewhat confusing description of various types of lenses and magnifiers and therefore might serve as a reference.

The chapter on visual efficiency is perhaps the most useful part of the book. Everyone who works with patients with subnormal vision has certain favorite devices which he prescribes under certain circumstances. Mr. Bier gives no hint of which devices have proved most helpful to him. Many clinicians will not approve of the emphasis on telescopic lenses.

Since Mr. Bier is an optometrist, it is not surprising that the sections on clinical procedures and the case reports would seem to be of greater interest to optometrists than to ophthalmologists.

Daniel Snydacker

TEACHING THE VISUALLY LIMITED CHILD. By Virginia E. Bishop. Springfield, Illinois, Charles C Thomas, 1971. Clothbound, 214 pages, table of contents, index, 21 black and white figures. $9.50

This book represents the ideas and theories of the author gained from extensive research and personal experience in working with the visually handicapped. The author's

stated purpose in writing this book is to provide workable ideas for efficient teaching in this field.

The book contains 10 chapters. The first three chapters discuss eye disease and suggested classroom adaptations to meet these handicaps. Included here is a brief chapter on visual perception. Chapters 4 through 6 deal with actual classroom teaching. Objectives and specific activities are outlined for teaching required subject matter and other valuable skills such as typing. These chapters are very good and could be a great aid to the teacher of visually handicapped children. Many suggestions are applicable to the teaching of the normally sighted child as well. Chapters 7 through 10 are excellent sources of information for anyone dealing with the visually limited, most especially those involved in instituting or coordinating special programs for the visually handicapped. These chapters stress Resources, special services, specialized programs and sources of professional assistance available to those interested.

This book does contain, however, a number of inaccuracies in regard to eye disease and the adaptive measures that should be taken in the classroom, e.g., ". . . 18-20 inches reading distance should be encouraged and sensible limits should be set up for the amount of close work required, to avoid eye fatigue in the farsighted child" (page 8). Nor does evidence support the statement that "the farsighted child may be subject to severe headaches and/or nausea during periods of close work" (page 8).

In discussing strabismus, the author has confused suppression with arrested vision, stating that when suppression occurs vision is permanently lost (page 11). Page 25 contains a misinterpretation as to the meaning of 10/200 vision.

The strength of this work lies in the educational content, which is very well done. Perhaps the chapter on visual perception might better have been deleted by the author, however, since the material is of such a controversial nature.

The parts of the book dealing with ophthalmology reflect significant deficiencies which seriously compromise the value of these sections. This appears to be due to lack of sufficient consultation with an ophthalmologist.

This book is well written and can certainly be of value to the teacher entering this field. Any teacher can well benefit from the author's experience and her obvious enthusiasm for teaching the visually handicapped.

EDITED BY DAVID SHOCH, M.D.

## ACTA OPHTHALMOLOGICA

ON THE PROGNOSTIC VALUE OF INTRAOCULAR PRESSURE IN TREATMENT OF RETINAL DETACHMENT. Ehlers, N. and Osterby, E. (Arhus Kommunehospital, 800. Arhus C, Denmark), Acta Ophth. 48:181-185, 1970.

Among 102 cases of retinal detachment the intraocular pressure was found to be lower in the detachment eye than in the contralateral eye. No significant difference was found between pressures in the reattached and non-reattached cases. There was a significantly lower frequency of reattachment ($P < 0.05$) among cases with a pressure reduction of more than 2 mm Hg than among the remaining cases of the material. (3 tables, 8 references)—Authors' abstract

LEBER'S DISEASE. Seedorff, T. (Rigshospitalet, University of Copenhagen, Denmark), Acta Ophth. 48:186-213, 1970.

The author studied 20 pedigrees with Leber's optic neuritis. In four of these families there were numerous descendants so that some accuracy was obtainable to evaluate the type of inheritance. Two of the pedigrees were particularly valuable since they had enormous number of descendants. In these two pedigrees, both followed through 8 generations and representing 229 and 116 persons respectively, it was not possible to demonstrate mothers who could be said with certainty to be free of the trait. The results of studying these two pedigrees support the assumption that all women born in the pure female lineage are carriers. This result cannot be disproved by the study of the other 18 pedigrees. Thus the study has demonstrated that a carrier-rate of 100% does occur. It has made probable, but not definitely proven, that this is a general rule. (8 figures, 12 references)—David Shoch

DENDRITIC KERATITIS. II. FOLLOW-UP EXAMINATION OF CORNEAL OPACITY. Norn, M. S. (Kommunehospitalet, Copenhagen, Denmark), Acta Ophth. 48:214-225, 1970.

A series of 109 patients who had had dendritic keratitis (the first attack on the average 13 years previously) have been followed up. Corneal opacity was seen in 85%, most often localized centrally. It was ramified in no more than one-fourth of the cases and covered on an average 10% of the corneal area. Blood-vessel invasion was found in half of the affected eyes. The size of the opacity (area and depth) and the vascularization was seen to become aggravated with increasing length of the observation period, as well as after some relapses, after treatment with steroids, and probably also after IDU treatment. The result of the present investigation suggested that iodine cauterization gives the least opacity. Hudson-Stahli's line was found in 52%, apparently equally often in the different age groups, and more frequently than in a normal series, where the line is a fairly rare phenomenon especially in the young age classes. Signs of previous iritis were seen in 21%. (1 figure, 3 tables, 9 references)—Author's abstract

LOCALIZATION OF BACTERIA ON SINGLE EYELASHES. Norn, M. S. (Kommunehospitalet, Copenhagen, Denmark), Acta Ophth. 48: 237-244, 1970.

A total of 153 single eyelashes epilated from 33 eyes of 17 patients have been subjected to bacteriological examination. Staphylococci were detected in all the patients. . . . Staphylococcus albus were found on 56% and Staphylococcus aureus on 5% of the lashes. . . . Practically all the S. albus strains were susceptible to erythromycin. . . . The bacteria were most often situated in or around the root of the lash, more rarely at the tip. (2 tables, 14 references)—Author's abstract.

FLUORESCEIN ANGIOGRAPHY OF THE OPTIC DISC AND PERIPAPILLARY AREA IN CHRONIC GLAUCOMA. Raitta, C. and Sarmela, T. (Helsinki University Eye Hospital, Finland), Acta Ophth. 48:303-308, 1970.

A fluorescein study of the papillary and peripapillary region in 12 patients with chronic wide angle glaucoma and cupping of the disc is presented. Diminished vascularity of the disc and circumpapillary choroidal atrophy was a constant finding in the series. In advanced glaucoma with severe functional loss a peripapillary atrophic area was typical. Severe vascular changes not only of the disc but of

the juxtapapillary and peripapillary zone indicated that a zonular arrangement of the choriocapillaris might exist. (4 figures, 1 table, 6 references)—Authors' abstract

MEDIASTINOSCOPY WITH LYMPH NODE BIOPSY CARRIED OUT IN PATIENTS WITH ENDOGENOUS UVEITIS OF UNKNOWN ETIOLOGY. Nordentoft, V. and Moller, P. M. (Odense County and City Hospital, Odense, Denmark), Acta Ophth. 48:331-344, 1970.

Of 108 patients with endogenous uveitis, sarcoidosis was found to be the etiological factor in 13%. However, in the bilateral cases sarcoid was the etiologic factor in 20%. Mediastinoscopy was performed in 77 of these patients and in 14 giant cell granuloma was demonstrable. No serious complications followed the mediastinoscopy, which was performed under general anesthesia by the chest surgeons. X-ray of the chest showed definite normal conditions in five of the patients in whom mediastinoscopy with biopsy demonstrated sarcoidosis. (2 figures, 5 tables, 29 references)—David Shoch

DENDRITIC KERATITIS. IV. FOLLOW-UP EXAMINATION OF CORNEAL SENSITIVITY. Norn, M. S. (Kommunehospitalet, Copenhagen, Denmark), Acta Ophth. 48: 383-395, 1970.

A series of 96 patients who had had their first attack of unilateral dendritic keratitis not less than five years previously—on an average 13 years previously—had their corneal sensitivity measured. In 81% the sensitivity was markedly impaired, compared with that of the contralateral eye. The average pressure required for the touching to be recognized was four times higher on the keratitis-affected eye than on the contralateral. In 12% the hypesthetic region was localized centrally, in 14% peripherally, being sector-formed, while in 22% it comprised half of the cornea, and in the remainder it was diffuse. Declining corneal sensitivity was found to be positively correlated to rising number of relapses, presence of opacity, blood-vessel invasion of the cornea, stainability of the cornea, reduced wetting time, defects or absence of Fischer-Schweitzer' fluorescein pattern, previous iritis, and increasing impairment of vision. It is possibly correlated to increasing depth of corneal opacity. The corneal sensitivity seems not to be correlated to the length of the observation period nor to present of Hudson-Stahli's line and hardly to herpes of the lip. Sequelae of dendritic keratitis (opacity, pathological Fischer-Schweitzer's fluorescein pattern, impaired sensitivity) were not visible in three of the 96 corneae. (1 figure, 6 tables, 12 references)—Author's abstract

SIDE EFFECTS FROM USE OF LONG-ACTING CHOLINESTERASE INHIBITORS IN YOUNG PERSONS. Axelsson, U. and Nyman, K. (Sabbatsberg Hospital, Stockholm, Sweden), Acta Ophth. 48:396-400, 1970.

A group of 18 young persons with various types of accommodative convergent deviations and treated with Fluropryl or Phospholine Iodide, was studied with regard to side effects. Transient lens clouding was observed in two cases and iris cysts appeared in seven patients. On re-examination six to ten months after discontinuance of treatment iris cysts persisted in three patients and in two, a patchy depigmentation of the pipillary border and the surrounding iris was observed. (4 references)—Authors' abstract

PSEUDOEXFOLIATION OF THE LENS CAPSULE. III. OCULAR TENSION IN EYES WITH PSEUDOEXFOLIATION. Hansen, E. and Sellevold, O. J. (Namdal Hospital, Namsos, Norway), Acta Ophth. 48:446-454, 1970.

In 65 men and 177 women with unilateral pseudoexfoliation and otherwise normal eyes, a significantly higher level of tension was found in eyes with pseudoexfoliation compared with those in which this condition was not present. The average difference in which this condition was not present. The average difference in tension was 2.15 mm Hg in the men and 1.46 mm in the women. In 59 men and 88 women with bilateral pseudoexfoliation but otherwise normal eyes, the average difference in tension between the two eyes was much less. There were significantly more patients with unilateral pseudoexfoliation in whom tension in the eye with pseudoexfoliation was clearly higher than in the other eye than there were patients in the group with bilateral pseudoexfoliation in whom a clear difference in tension between the two eyes was observed. In a group of patients with unilateral pseudoexfoliation who had not developed glaucoma during the period of observation, a record was kept of deviations in the ocular tension over a number

of years. No tendency for the ocular tension to increase in eyes with pseudoexfoliation was observed. Findings indicate that the essential changes which affect ocular tension take place during an early phase of the exfoliation process. (3 figures, 1 table, 1 reference)—Authors' abstract

ORBITAL PNEUMOTOMOGRAPHY. Bertelsen, T. I. (University of Bergen, Bergen, Norway), Acta Ophth. 48:616-624, 1970.

Seventeen patients with primary tumors of the orbit were examined by pneumotomography. This method gives the best results in benign, encapsulated tumors where the air can spread over the tumor surface. Tumors of the optic nerve seem to be the growth which is most easily demonstrated. (7 figures, 6 references)—Author's abstract

LONG-TERM PROGNOSIS IN MALIGNANT EXOPHTHALMOS. Riise, R. (Kommunehospilet, Copenhagen, Denmark), Acta Ophth. 48:634-643, 1970.

Ten patients with severe symptoms were followed for 5 to 15 years. The author concludes the disease is self-limited. After periods of months or years, some remission may occur, followed by a stationary stage, characterized by exophthalmos and disturbances of motility. During critical phases, brief treatment with large doses of steroids is recommended. (2 tables, 32 references)—Author's abstract

OPHTHALMODYNAMOMETRY IN APOPLECTIC PATIENTS WITH HEMISPHERICAL INFARCTION OR TRANSITORY HEMISPHERICAL SYMPTOMS. Kjer, P., Eiken, M. and von Wowern, F. (Gentofte Hospital, Copenhagen, Denmark), Acta Ophth. 48:700-709, 1970.

The results of ophthalmodynamometry and carotid angiography are compared in 123 apoplectic patients with hemispherical infarction or transitory hemispherical symptoms. Ophthalmodynamometry showed a significant difference between the two sides in half of the patients with severe stenosis of the carotid artery and in about two-thirds of the patients with carotid occlusion. (5 tables, 18 references)—Authors' abstract

CAROTID-CAVERNOUS FISTULAE. A STUDY OF 18 CASES. Madsen, P. H. (Arhus Kommunehospital and Amts og Bys Sygehus, Denmark), Acta Ophth. 48:731-751, 1970.

A study on a series of 18 patients with carotid-cavernous fistula is presented. Of the cases, 16 were of traumatic origin, while two were of spontaneous onset. . . . Thirteen patients were treated with ligation of the carotid vessels, and two with ligation and muscle emvolization. Lasting effect on the pulsating exophthalmos was obtained in 11 patients; in two the effect was incomplete in spite of repeated operations. . . . Owing to the numerous possibilities of anastomoses, ligation of vessels had to be repeated in five cases in order to obtain an acceptable result. Accordingly, it is desirable to perform a direct operation on the fistula at once. (8 figures, 2 tables, 36 references)—Author's abstract

DIFFERENTIATION OF PAPILLEDEMA FROM PSEUDO-PAPILLEDEMA BY FLUORESCEIN OPHTHALMOSCOPY. Bynke, H. G. and Aberg, L. (University Hospital, Lund, Sweden), Acta Ophth. 48:752-758, 1970.

In 16 cases with papilledema and nine with pseudo-papilledema the optic discs were studied by blue filter ophthalmoscopy after intravenous injection of fluorescein. The deep disc fluorescence was found to be much more marked in the majority of the cases with edema than in the cases with pseudo-edema. However, in four cases with edema it was faint and of the same order of size as in some cases with pseudo-edema. It was concluded that fluorescein ophthalmoscopy is valuable for a differentiation of the two conditions but that the method is not entirely reliable. (1 table, 8 references)—Authors' abstract

CORNEAL SENSITIVITY BY LOW TEMPERATURES. Kolstad, A. (University of Oslo, Norway), Acta Ophth. 48:789-793, 1970.

Exposure to ambient temperatures common in Norway during the winter is found to decrease the corneal sensitivity as measured by an esthesiometer. It is thought that this may explain the higher tolerance to contact lenses experienced during the cold season. (12 references)—Author's abstract

VARIABILITY OF THE ELECTRO-OCULOGRAM (EOG). Van Lith, G. H. M. and Balik, J. (Medical Faculty, Rotterdam), Acta Ophth. 48:1091-1096, 1970.

Variability of the EOG has been determined by making ten EOGs in each of 15 normal subjects. The mean value and standard deviation of the experiments was respectively 2.15 and 0.25. From the results two conclusions have been drawn. Firstly, values lower than 0.25 in the same person has particular meaning. (4 figures, 1 table, 8 references)—Authors' abstract

MESODERMAL DYSGENESIS OF THE CORNEA AND IRIS (RIEGER'S ANOMALY). Zetterstrom, B. (Karolinska Sjukhuset, Stockholm, Sweden), Acta Ophth. 48:1102-1106, 1970.

A case of mesodermal dysgenesis of the cornea and iris is reported in which the anomaly was suspected in the first week of life, its presence being confirmed in the seventh month, and the clinical course of the condition has been followed up for four years at the time of writing. Interesting features of the case were that the bilateral congenital opacity cleared sufficiently for details of the anterior chamber to be photographed and that there was objective evidence of improvement of vision. (5 figures, 7 references)—Author's abstract

BILATERAL HOMONYMOUS HEMIANOPSIA FOLLOWING VENTRICULOGRAPHY. Rasmussen, K. E. (Arhus Kommunehospital, Arhus, Denmark), Acta Ophth. 48:1174-1184, 1970.

Eight cases of bilateral homonymous hemianopsia were found following ventriculography on a material of 335 patients. In five of these cases the vision returned to normal in less than 10 days, in one it had been restored at follow-up six months later, while in two cases no improvement had occurred at discharge from the hospital one and two months after the ventriculography. (12 references)—Author's abstract

THE VALUE OF OCULAR FINDINGS IN THE DIAGNOSIS OF ANGIOKERATOMA CORPORIS DIFFUSUM (FABRY'S DISEASE). Lou Christensen, H. V., Heidensleben, E. and Larsen, H. (Kovwnhavns Amts Syeghus i Gentofte, Denmark), Acta Ophth. 48: 1185-1194, 1970.

In this study of Fabry's disease, 11 out of 15 members of one family presented symptoms and signs of this disorder. It is pointed out that corneal opacities are of great diagnostic value in both heterozygote females and young males presenting only slight general manifestations. The presence of marked focal varicosities and ampulliform or saccular dilatations of the conjunctival vessels together with tortuosity of the vessels may also be of great diagnostic value in this disease. Retinal vascular tortuosity is considered to be of no diagnostic value if not present together with other manifestations of the disease. (6 figures, 1 table, 21 references)—Authors' abstract

DEMODEX, FOLLICULORUM. INCIDENCE AND POSSIBLE PATHOGENIC ROLE IN THE HUMAN EYELID. Norn, M. S. (Kommunehospitalet, DK-1399, Copenhagen K, Denmark), Acta Ophth. Suppl. 108:1-85, 1970.

On the basis of examination of 400 patients the author comes to the following conclusions. Demodex can be found in about 50% of all patients. However, the author does not feel that Demodex folliculorum is the cause of blepharitis. A cylindric formation around the base of the lash suggests presence of Demodex. The cylinder (cuff, collaring around the ciliary root) is an epithelial proliferation of the hair follicle, presumably caused by Demodex movements and metabolic waste products in the follicle. Demodex play a role in the ecology of the skin. The mite can spread S. albus from one hair follicle to another. Demodex can be demonstrated in nearly all people, aged over 70 years. The incidence rises with increasing age. The mite is also found in the younger age classes (e.g. in about 25% of teenagers). (21 figures, 11 tables, 52 references)—Author's abstract

A CLINICAL STUDY OF THE NORMAL HUMAN CENTRAL CORNEAL THICKNESS. Hansen, F. K. (Kommunehospitalet, University of Arhus, 8000 Arhus C., Denmark), Acta Ophth. 49:82-89, 1971.

Central corneal thickness was measured in 150 normal eyes with the Haag-Streit pachometer. A mean value of 0.520 ± 0.018 was found in 76 right eyes, whereas the value of 74 left eyes was 0.004 mm higher due to the angle kappa. A normal frequency distribution is demonstrated. Central corneal thickness is found to increase significantly with increasing intraocular pressure within normal range, and possible to decrease with increasing body height. No correlation between age, refraction and anterior corneal curvature was found. No

sex difference was found. (2 figures, 4 tables, 12 references)—Author's abstract

HUMAN RETINAL VASCULAR OBSTRUCTIONS. Nilsson, S. E. (Karolinska Sjukhuset, 10401 Stockholm 60, Sweden), Acta Ophth. 49:111-133, 1971.

The author examined six patients with central retinal vein obstructions and four patients with central retinal artery obstructions with fluorescein angiography and electroretinography. They found that both these modalities were useful prognostic indicators. Generally in those patients who recovered vision the b waves remained normal while in those who went on to suffer deprivation of vision there was a markedly reduced b wave. Further, the mean retina circulation time for cases with return of vision was 4.2 seconds (as against a normal of 2.2 seconds) while in those cases where the vision did not return the mean retinal circulation time ranged from 7 to 330 seconds. (14 figures, 3 tables, 33 references)—David Shoch

IRIDENCLEISIS. Tarkkanen, A. and Eskelin, L. (Helsinki University Eye Hospital, Finland), Acta Ophth. 49:143-150, 1971.

Iridencleisis was performed on 124 eyes over a five year period. Tensions were controlled in 89% but visual deterioration took place in 23% of these. Persistent hypotony developed in 10%. (6 tables, 12 references)—David Shoch

MODIFIED GONIOPUNCTURE IN THE TREATMENT OF CONGENITAL GLAUCOMA. Vannas, S. and Pohjola, S. (Helsinki University Eye Hospital, Finland), Acta Ophth. 49: 159-164, 1971.

Good ocular tension control was obtained by means of modified goniopuncture in nine eyes of 13, and there were no postoperative complications in these cases. In two eyes a spontaneous cure occurred. Goniopuncture can be recommended as the primary operation in the treatment of congenital glaucoma because of the slight risk of complications and the encouraging results obtained. In addition it should be taken into account that goniopuncture does not preclude a subsequent goniotomy or trabeculotomy, should it prove necessary. (2 tables, 10 references)—Authors' abstract

THE FREQUENCY OF FIBRILLOPATHIA EPITHELIOCAPSULARIS (SO-CALLED SENILE EXFOLIATION) IN PATIENTS WITH OPEN-ANGLE GLAUCOMA. Aasved, H. (University of Bergen, Norway), Acta Ophth. 49: 194-210, 1971.

A total of 444 patients with open-angle glaucoma has been examined to determine the incidence of pseudoexfoliation. The most important factor appears to be the severity of glaucoma. The frequency was considerably higher among patients with optic nerve damage than among patients with normal optic discs and visual fields. Different patient groups collected from the same geographical area but with varying degrees of severity showed an increasing frequency of fibrillopathy in the same sequence as the serverity. . . . These findings seem to concur well with the clinical experience that capsular glaucoma is a more serious condition than ordinary simple glaucoma. Among patients with open-angle glaucoma in Norway as a whole it is assumed that the frequency of fibrillopathy is in the range of 20 to 30% and thus probably not higher than in other countries. (7 tables, 42 references)—Author's abstract

SYNKINESIS OF UPPER LID ELEVATION OCCURRING IN HORIZONTAL EYE MOVEMENTS. Ticho, U. (Hadassah Medical Center, Jerusalem, Israel), Acta Ophth. 49:232-238, 1971.

The motility of the upper eyelid was investigated in 133 subjects with normal eye motility during horizontal movements of the eyes. Elevation was found to be present in abduction in 49% of the cases, in adduction in 15% and during both abduction and adduction it occurred in 14%. . . . Six cases with abducens palsy and three cases with Duane's syndrome presented exaggerated elevation of the eyelid in abduction. The presence of physiologic synkinesis between the lid elevators and the horizontal muscles of the eye is suggested. In cases of 6th nerve palsy and Duane's syndrome the exaggerated nerve impulses to the levator palpebrae muscle could be the cause for the exaggerated lid retraction on abduction. (8 figures, 2 tables, 8 references)—Author's abstract

THE SAGITTAL GROWTH OF THE EYE. I. ULTRASONIC MEASUREMENT OF THE DEPTH OF THE ANTERIOR CHAMBER FROM BIRTH TO PUBERTY. Larsen, J. S. (University of

Bergen, Norway), Acta Ophth. 49:239-262, 1971.

Ultrasonographic measurements of the depth of the anterior chamber were carried out in 80 full-term newborns (43 boys and 37 girls) and in 465 boys and 381 girls aged 6 months to 13 years. Both eyes were measured in all subjects. From birth to the age of 13 the mean value of the anterior chamber depth increased from 2.37 to 3.70 mm for boys and from 2.39 to 3.62 mm for girls, having then reached the same value as in young adults (20 to 40 years). It therefore appears that the increase in the depth of the anterior chamber terminates at the age of 13, or is minimal after this age. The increase in the depth of the anterior chamber takes place in three growth phases: a rapid postnatal phase from birth to the age of one and a half years, with an increase of approximately 0.9 to 1.0 mm, a slower infantile phase from 1 to 7 years with an increase of 0.3 to 0.4 mm and a slow juvenile phase from 8 to 13 years with an increase of barely 0.1 mm. During the whole of the growth period there appears to be a real sex-determined difference in the depth of the anterior chamber of about 0.1 mm, the deepest anterior chamber being found in boys. A negative correlation between the depth of the anterior chamber and refraction develops at an early stage of the growth period, and has in this study been found to be established from the second year of life. (7 figures, 9 tables, 48 references)—Author's abstract

LATE RESULTS OF SURGERY ON EYES WITH PRIMARY GLAUCOMA AND CATARACT. Laatikainen, L. (University of Helsinki, Finland), Acta Ophth. 49:281-292, 1971.

The effect of lens extraction on intraocular pressure in glaucomatous eyes was studied. The material comprised 98 glaucomatous eyes operated on for cataract in the years 1960 to 1968 in the University Eye Clinic, Helsinki. In cases with previous antiglaucomatous surgery, lens extraction had no distinct effect on the intraocular pressure or on the need for antiglaucomatous medication. Only in one eye was loss of filtration found postoperatively. In cases were cataract extraction was the primary procedure, the beneficial effect on glaucoma control was seen in about 70% of eyes with open-angle glaucoma. In 50% of eyes with open-angle glaucoma the pressure was adequately controlled without any postoperative medication. In the more difficult cases of chronic open-angle glaucoma, and in most cases of chronic angle-closure glaucoma, the effect of lens extraction alone seem insufficient to control the glaucoma. (8 tables, 42 references)—Author's abstract

THE FREQUENCY OF RUBEOSIS IRIDIS IN DIABETIC PATIENTS. Ohrt, V. (Aalborg Sygehus, 9000 Denmark), Acta Ophth. 49: 301-307, 1971.

Rubeosis iridis occurs in about 5% of Danish diabetics. . . . As, however, rubeosis is closely connected with proliferative retinopathy, it is more relevant to consider the frequency in this connection and rubeosis was found in 64% of these patients. . . . However, rubeosis is also seen in a smaller number of patients with retinopathy, but without proliferations. Therefore, one arrives at the final conclusion that the frequency of rubeosis in a diabetes material can be considered to be about 60% of the number of the proliferative cases in the series. (5 tables, 13 references)—Author's abstract

## AMERICAN ORTHOPTIC JOURNAL

THE NATURAL COURSE OF ESOTROPIA. Moore, S. (Columbia-Presbyterian Medical Center, New York), Am. Orthoptic J. 21:80-83, 1971.

A child with a moderate degree of esotropia has a 59% chance of his deviation decreasing as he grows up. One out of 10 will become exotropic and neither the change in refractive error nor the presence of amblyopia will influence its development. (3 tables)—Author's abstract

## ARCHIVES OF OPHTHALMOLOGY

AQUEOUS DYNAMICS OF PILOCARPINE-TREATED EYES. THE INFLUENCE OF TOPICALLY APPLIED EPINEPHRINE. Harris, L. S., Mittag, T. W. and Galin, M. A. (New York Medical College, 1249 Fifth Ave., New York), Arch. Ophth. 86:1-4, July, 1971.

Solutions of levoepinephrine borate were prepared in concentrations of 0.6%, 0.12%, 0.25%, 0.50%, 1.00% and 2.00%. These solutions were applied to the right eye only for four to six weeks in a series of open-angle

glaucomatous patients who were receiving 4% pilocarpine to both eyes. Although a small effect was noted with lower doses, no meaningful additional hypotensive response from epinephrine was noted until the concentration reached 0.50%. The maximal additive response occurred with 2.00% levoepinephrine. Although the combined effect of pilocarpine and epinephrine was greater than the maximal effect of either drug alone, it was less than the additive effects of both drugs. Parallelism of the epinephrine and pilocarpine/epinephrine dose-response curves suggests that both drugs act by similar mechanisms. (3 tables, 3 references)—Authors' abstract

THE FIXED DILATED PUPIL. Thompson, H. S., Newsome, D. A. and Loewenfeld, I. E. (University of Iowa, Iowa City), Arch. Ophth. 86:21-27, July, 1971.

Isolated iridoplegia or internal ophthalmoplegia may be due to impairment of the effector muscles in the eye, defective parasympathetic innervation, or the presence of atropinic substances in the eye. Pharmacologic blockade can be identified by the pupil's failure to constrict to pilocarpine drops. Because of its clarity and technical simplicity, this test should be in general use as an office procedure. (6 figures, 12 references)—Authors' abstract

## DEVELOPMENTAL MEDICINE AND CHILD NEUROLOGY

VISUAL ACUITY OF A NATIONAL SAMPLE (1958 COHORT) at 7 YEARS. Alberman, E. D., Butler, N. R. and Sheridan, M. D. (National Children's Bureau, 1 Fitzroy Square, London W.1.), Develop. Med. Child. Neurol. 13:9-14, Feb., 1971.

Of 14,197 children at the age of seven, 79% had a visual acuity of 6/6 in both eyes, and in 96% at least one eye had an acuity of 6/9 or better. (5 tables, 6 references)—Joel G. Sacks

## INTERNATIONAL OPHTHALMOLOGY CLINICS

SOME IATROGENIC OCULAR DISEASES FROM SYSTEMATICALLY ADMINISTERED DRUGS. Bernstein, H. N. (Washington Hospital Center, D.C.), Int. Ophth. Clin. 10:553-619, 1970.

An excellent review article that discusses the documented side-effects of various medications. For example, systemically administered steroids have been reported to cause glaucoma, cataracts and papilledema. The antimalarials cause retinal degeneration and keratopathy. The phenothiazine tranquilizers cause retinal degeneration, keratopathy and cataracts. Chloramephenicol has been implicated in optic neuritis as has penicillamine and ethambutol. Triparanol, which is no longer on the market, is known to produce cataracts. These and other drugs are described and the pertinent literature references given. (21 figures, 7 tables, 195 references)—David Shoch

## INVESTIGATIVE OPHTHALMOLOGY

"STEROID-INDUCED" MYDRIASIS AND PTOSIS. Newsome, D. A., Wong, V. G., Cameron, T. P. and Anderson, R. R. (National Institutes of Health, Bethesda, Md.), Invest. Ophth. 10:424-429, June, 1971.

It has been noted clinically that commercial preparations of dexamethasone induce a mydriasis and ptosis. The authors used the usual commercial preparation available (Decadron), the vehicle alone and a solution of dexamethasone in saline to evaluate the relative importance of each constituent. When either Decadron or the vehicle was used to irrigate the anterior chamber of rabbits, mydriasis resulted. No pupil changes were observed after perfusion with dexamethasone in saline. Similarly perfusion with Decadron or the vehicle mixture produced marked to moderate ptosis. However the use of dexamethasone in saline did not cause any ptosis. Therefore, the mydriasis and ptosis reported from the use of steroids appears to be caused by a direct myopathic effect of the vehicle. (3 figures, 1 table, 9 references)—David Shoch

FURTHER STUDIES SUPPORTING THE IDENTITY OF CONGENITAL TRITANOPIA AND HEREDITARY DOMINANT OPTIC ATROPHY. Krill, A. E., Smith, V. C. and Pokorny, J. (Eye Research Laboratories, University of Chicago, Illinois), Invest. Ophth. 10:457-465, June, 1971.

Dominant inherited optic atrophy is usually a stationary disorder with typical findings of temporal optic nerve pallor, abnormal distance acuity, minimal visual-field defects, and char-

acteristic color confusions in the blue-green region of the spectrum. Variability in the severity of these abnormalities is common, even within the same family. In patients with minimal disease, distance acuity may be close to normal and optic pallor may be so subtle that a definitive diagnosis cannot be made unless other obviously affected members of a family are seen. Our studies indicate that patients with dominantly inherited optic atrophy have similar color vision to that previously reported for subjects with congenital tritan defects. In fact, the almost identical color-vision profiles and pattern of inheritance of the two conditions lead us to question the existence of congenital tritan defect as an independent entity. Criteria are suggested for distinguishing the two conditions. It is emphasized that the utmost care should be taken to rule out dominant optic atrophy in future subjects in whom congenital tritanopia is suspected, both because of the strikingly similar characteristics of the two conditions, if these are indeed separate entities, and because the diagnosis of hereditary dominant atrophy may be easily missed. (4 figures, 29 references)—Authors' abstract

RETINAL COLLATERAL VESSEL FORMATION. Klein, R., Klein, B., Henkind, P. and Bellhorn, R. (Albert Einstein College of Medicine, Bronx, New York), Invest. Ophth. 10:471-480, July, 1971.

Retinal vessels of 18 adult domestic cats were successfully embolized with graded glass microspheres, and the resultant vascular changes were monitored clinically by ophthalmoscopy. . . . While collaterals were ophthalmoscopically evident within 24 hours of occlusion, none were identified histologically until seven days after occlusion. These collaterals developed from the pre-existing retinal capillary bed and often attained the same caliber as the occluded vessel. (7 figures, 2 tables, 10 references)—Authors' abstract

CHARACTERIZATION AND INHIBITION OF CORNEAL COLLAGENASE. Hook, C. W., Brown, S. I., Iwanij, W. and Nakanishi, I. (New York Hospital-Cornell University Medical College, 525 E. 68th St., New York, N.Y.), Invest. Ophth. 10:496-503, July, 1971.

This investigation shows that corneal collagenase operates optimally at a physiologic pH and not at 4.0 or above 8.4, and that the enzyme cleaves the collagen molecule into ¾ and ¼ length fragments. Studies on the dynamics of collagenase inhibition show that the enzyme is calcium dependent. Many potential inhibitors were tested. The collagenase inhibitors sodium and calcium ethylenediaminetetraacetic acid (EDTA) probably inhibit collagenase by removing the essential calcium. They were found to be completely reversible. The inhibition of corneal collagenase by cysteine was partially reversible by the addition of calcium, indicating that part of its inhibition is due to chelating. However, more than 50% of cysteine's inhibition is irreversible. Dithiothreitol was also found to inhibit collagenase. Iodoacetate was added to dithiothreitol to alkylate in sulfhydryl groups, and then it did not inhibit collagenase. These results indicate that in addition to inhibiting by chelating calcium, cysteine irreversibly inhibits by reducing a disulfide bond in the enzyme molecule. Finally, guanidinium-extracted corneal proteoglycan was shown to prevent collagenase from breaking down collagen. (4 figures, 5 tables, 21 references)—Authors' abstract

MECHANISM OF DEVELOPMENT OF HEREDITARY CATARACT IN MICE. Iwata, S. and Kinoshita, J. H. (Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, Mass. 02114), Invest. Ophth. 10:504-512, July, 1971.

The biochemical evidence regarding a recessively transmitted cataractous trait in mice suggests that an apparent deficiency of Na-K ATPase may be involved in the initiation of this type of cataract. The enzyme defect leads to inefficiency of the cation pump mechanism. This abnormality was demonstrable in 13-day-old mice. At this stage the lens was clear and the electrolyte levels were normal. However, by the twentieth day it became apparent that the defective lens was no longer able to extrude sodium efficiently, therefore sodium content increased. The sudden increase in electrolytes drew water into the lens and an osmotic change occurred. These events preceded the appearance of a "pin-head" nuclear opacity. (8 figures, 17 references)—Authors' abstract

STUDIES OF AQUEOUS HUMOR DYNAMICS IN MAN. II. MEASUREMENTS IN YOUNG NORMAL SUBJECTS USING ACETAZOLAMIDE AND L-EPINEPHRINE. Kupfer, C., Gaasterland,

D. and Ross, K. (National Institutes of Health, Bethesda, Md.), Invest. Ophth. 10:523-533, July, 1971.

The short-term effects on aqueous humor flow dynamics of single doses of acetazolamide and L-epinephrine, alone and combined were studied in selected young, normal men. Analysis of aqueous flow before and after medication was facilitated by graphic representation of flow versus intraocular pressure, the flow curve. Acetazolamide reduced intraocular pressure and $P_k$ of Goldmann without affecting true facility or pseudofacility. A pattern of pressure-independent reduction of flow occurred. L.-epinephrine reduced intraocular pressure and pseudofacility. A pattern of pressure-dependent change of aqueous flow occurred with reduction of flow at intraocular pressures below approximately 30 mm Hg. When acetazolamide was combined with epinephrine, additive effects were noted, with an additional decrease of intraocular pressure associated with significant increase of true facility. No change of true facility occurred after epinephrine or acetazolamide alone in these subjects. (5 figures, 8 tables, 16 references)—Authors' abstract

## Johns Hopkins Medical Journal

TEACHING OPHTHALMOLOGY TODAY AND TOMORROW. Paton, D. (Dept. of Ophthalmology, Baylor College of Medicine, Texas Medical Center, Houston, Texas 77025), Johns Hopkins Med. J. 128:208-233, Apr., 1971.

There is an urgent need in ophthalmology to increase the efficiency and effectiveness of teaching.

Lectures that are repeated frequently should be available as single-concept, audio visual recordings so that their repeated delivery will not lessen the effectiveness and stifle the enthusiasm of the lecturer. The simultaneous use of three slide projectors along with the use of a "guest lecturer" from another department is highly successful. Training can be made more efficient with the use of such aids as model eyes, enucleated animal eyes for teaching surgery and movie films. (8 figures, 31 references)—Joel G. Sacks

## Journal of Neurology, Neurosurgery and Psychiatry

CLINICAL SPECTRUM OF OCULAR BOBBING. Susac, J. O., Hoyt, W. F., Daroff, R. B. and Lawrence, W. (Letterman General Hospital, San Francisco), J. Neurol. Neurosurg. Psychiat. 33:771-775, 1970.

Ocular bobbing is a distinctive movement disorder occurring in a variety of related forms herein classified as "typical," "monocular," and "atypical." "Typical" ocular bobbing occurs in patients with paralysis of horizontal conjugate eye movements and consists of abrupt, spontaneous downward jerks of the eyes with a slow return to the mid position. The "monocular" type reflects co-existing unilateral third nerve paresis in addition to the bobbing. The "atypical" type includes either a variation unexplained by associated oculomotor palsy, or bobbing with intact spontaneous or reflex horizontal eye movements. The clinical spectrum of ocular bobbing, its varied causes, and its prognostic significance are exemplified in a report of nine cases. (1 table, 14 references)—Authors' abstract

## Klinische Monatsblätter für Augenheilkunde

PHOTOCOAGULATION IN RETINAL PERIPHLEBITIS. (German) Lemke, L. and Jutte, A. (Univ.-Augenklinik Jena), Klin. Mbl. Augenh. 158:8-15, Jan. 1971.

Twenty patients with a retinal periphlebitis of the haemorrhagic type were treated by photocoagulation, the vascular defects being identified as prestages of haemorrhages in the fluorescence-angiogram. The disease could be brought to a standstill in 18 cases. Under fluorescence-angiographic control, the relapse-free observation period lasted for 1 to 5 years, on the average to 3 years. (2 figures, 1 table, 10 references)—Authors' abstract

SYNDROME OF DANCING EYES WITH MYOCLONIC ATAXIA. (German) Brune, G., Hertel, G. and Gruninger, W. (Univ.-Klinik Wurzburg), Klin. Mbl. Augenh. 158:41-48, Jan., 1971.

A case of dancing eyes with myoclonic ataxia is reported. The syndrome appeared after ex-

posure to infection, showed sudden onset and protracted course. A viral infection or immunopathological mechanisms are suggested to play a role in the pathogenesis of the disease. In addition, it is assumed that irritative lesions within the cerebellar vermis and the brainstem represent the pathomorphological base of the clinical symptomatology. (2 figures, 9 references)—Authors' abstract

ELECTRORETINOGRAPHY, A METHOD OF EXAMINATION TO DETERMINE THE PROGNOSIS IN JUVENILE DEGENERATION OF THE MACULA. (German) Hammerstein, W. (Univ.-Augenklinik, Dusseldorf), Klin. Mbl. Augenh. 158:72-75, Jan., 1971.

While the early stage of a juvenile degeneration of the macula (son) showed a degeneration process which was still restricted to the macula region, the subnormal ERG already indicated a progression of the disease. After a course for decades (father) a degeneration of the entire central area of the retina was seen ophthalmoscopically, with a disappearance of the electroretinal potential. In the initial stage the electroretinogram already gave information on the prognosis of the disease. (4 figures, 12 references)—Author's abstract

TREATMENT OF PROLIFERATING DIABETIC RETINOPATHY WITH DIATHERMY-COAGULATION. (German) Wessing, A. and Bockenhoff, I. (Augenklinik am Klinikum Essen der Ruhruniversitat Bochum), Klin. Mbl. Augenh. 158:212-220, Feb., 1971.

The results are obtained by the examination of 92 treated eyes. In approximately half of the cases diathermy-coagulation results in the arresting of intravitreal proliferation of vessels. Furthermore, diathermy leads to a very rapid absorption of massive hemorrhages in the vitreous body. (1 figure, 3 tables, 23 references)—Authors' abstract

CLINICAL CONSIDERATIONS AND INHERITANCE OF VITELLIFORM DEGENERATION OF THE MACULA. (German) Thiel, H. J. and Behnke, H. (Univ.Augenklinik, Kiel), Klin. Mbl. Augenh. 158:235-246, Feb., 1971.

In three family branches with vitelliform degeneration of the macula, with a total of 565 genealogically related persons, 98 members of the family were available for ophthalmological examination. The disease is transmitted dominant autosomally. Cysts were found and particularly in older persons, scarred stages. (13 figures, 40 references)—Authors' abstract

THE RIGHT-LEFT PROBLEM OF RETINAL TEARS. (German) Jager, A. (51 Aachen, Goethestr. 27/29, Augenklinik), Klin. Mbl. Augenh. 158:272-273, Feb., 1971.

A statistical comparison between patients in one German and three Persian eye hospitals has shown that retinal tears, independently of the direction of reading—in German from left to right and from right to left in the Arabic script—appear more frequently in right eyes than in left eyes. (2 references)—Author's abstract

INITIAL CLINICAL EXPERIENCE OF TREATMENT WITH ADHESIVES IN OPHTHALMIC SURGERY. (German) Muller-Jensen, K. (Augenklinik der Universitat München, Germany), Klin. Mbl. Augenh. 158:573-577, Apr., 1971.

The tissue adhesive butylcyanoacrylate was used in man in three cases of perforating injuries of the cornea and in ten cases of corneal incision for cataract, following extensive animal experiments. Small, smooth perforations of the cornea or incisions by lancet adhered without difficulty. When larger wounds of the cornea or corneal incisions for cataract were treated with the adhesive, it was frequently necessary to use additional sutures for adaptation. The strong adhesion of the adhesive material to the suture may then cause delay for several weeks until the adhesive membrane has been shed spontaneously. This in turn may produce severe keratitic reactions. In lacerated corneal injuries the monomeric adhesive easily enters the wound clefts and polymerises in the parenchyma of cornea. Disorders of wound healing resulted and toxic kerato-iritis with vascular infiltration into the cornea occurred. Altogether the usefulness of adhesive substances in corneal surgery is limited. (3 figures, 4 references)—Author's abstract

ON THE IMPORTANCE OF BLOOD FACTORS IN KERATOPLASTY. (German) Meyer, H. J. (Univ.-Augenklinik Gottingen), Klin. Mbl. Augenh. 158:780-785, June, 1971.

The author studied 250 keratoplasties and subdivided the patients into various prognostic

groups. No dependence of healing on blood factors of the corneal donor could be demonstrated in any group. (5 figures, 1 table, 16 references)—David Shoch

## Scientific American

EYE MOVEMENTS AND VISUAL PERCEPTION. Noton, D. and Stark, L. (University of Colorado), Sci. Amer. 224:35-43, June, 1971.

Angles and other informative details are the features selected by the brain for remembering and recognizing an object. It is hypothesized that as a subject views an object for the first time and becomes familiar with it he scans it with his eyes and develops a scan path for it. During this time he lays down the memory traces of the feature ring, which records both the sensory activity and the motor activity. When he subsequently encounters the same object again, he recognizes it by matching it with the feature ring, which is its internal representation in his memory. (12 figures)—Joel G. Sacks

## Transactions of the American Academy of Ophthalmology and Otolaryngology

OCULAR FINDINGS FOLLOWING RADICAL MAXILLECTOMY. Wilder, L. W., Beyer, C. K., Smith, B. and Conley, J. J. (New York), Tr. Am. Acad. Ophth. Otolaryng. 75:797-801, July-Aug., 1971.

Malignant tumors of the nasopharynx and paranasal sinuses are frequently present with epiphora as the primary complaint. Following radical maxillectomy, ocular ptosis and enophthalmos are common results. Visual acuity and binocular visual function are not often affected. Despite the partial removal of the nasolacrimal duct, dacryocystorhinostomy is seldom necessary. (4 figures, 1 table, 2 references)—Authors' abstract

ORBITAL FLOOR FRACTURES: FOLLOW-UP OF CASES WITH AND WITHOUT SURGICAL REPAIR. Emery, J. M., von Noorden, G. K. and Schlernitzauer, D. A. (Wilmer Institute, Johns Hopkins Hospital, Baltimore), Tr. Am. Acad. Ophth. Otolaryng. 75:802-812, July-Aug., 1971.

Hypocycloidal polytomography appeared to be the most accurate roentgenographic technique currently available for the diagnosis of orbital floor fractures. An analysis of patients who were operated on for orbital floor fractures and were followed for an average period of 3.4 years revealed that 24 of 49 patients had persistent diplopia despite surgical repair. Patients who were operated on within the first week after injury had late diplopia just as frequently as those who were operated on during the second week after injury. A follow-up examination of 18 patients with roentgenographically proved orbital floor fractures which were not operated on revealed that in a significant number diplopia would disappear permanently within two weeks after injury even when surgery was not performed. Thus, patients with orbital floor fractures, who initially either have no diplopia or who lose the diplopia within 14 days after injury should not undergo surgery unless roentgenograms show evidence of an extensive defect of the orbital floor that may cause enophthalmitis if left untreated. (3 figures, 8 tables, 28 references)—Authors' abstract

VITRECTOMY: A PARS PLANA APPROACH. Machemer, R., Buettner, H. and Norton, E. W. D. (Bascom Palmer Eye Institute, University of Miami, Florida), Tr. Am. Acad. Ophth. Otolaryng. 75:813-820, July-Aug., 1971.

An instrument has been described which is introduced into the vitreous cavity through the pars plana. Simultaneously, vitreous is destroyed, aspirated, and replaced by a balanced salt solution. The instrument allows the surgeon to eliminate gel-like vitreous of any consistency and also to cut vitreous strands. With the exception of the vitreous base, almost all vitreous can be removed. The action of this vitreous infusion suction cutter in the eye is observed through a fundus contact lens with the operating microscope. The pars plana approach avoids the common complications in the anterior segment involved in the open-sky technique. Long-standing vitreous hemorrhages, vitreous membranes in diabetic retinopathy, complicated detachments with strong vitreous pull and giant retinal tears have been treated successfully with this technique. (6 figures, 12 references)—Authors' abstract

## TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY

CATARACT EXTRACTION AFTER FILTERING PROCEDURES. Regan, E. F. and Day, R. M. (Edward Harkness Eye Institute, Columbia University, New York), Tr. Am. Ophth. Soc. 68:96-104, 1970.

The authors removed cataracts from 70 eyes with filtering blebs at the 12 o'clock position. They made no attempt to avoid the bleb but made their incisions directly through it. They found that in 60 of the 70 cases, ocular tension control was just as good after the surgery as before. In 10 of the cases control ranged from fair to poor after the surgery. Therefore, the authors conclude there is no need to make special incisions for cataract surgery after filtering procedures since in most cases filtration will continue to work after the surgical procedure. (1 table, 19 references)—David Shoch

LONG-TERM COMPLICATIONS OF BETA-RADIATION THERAPY IN OPHTHALMOLOGY. Barrón, A., McDonald, J. E. and Hughes, W. F. (Illinois Eye and Ear Infirmary, Chicago), Tr. Am. Ophth. Soc. 68:113-128, 1970.

After re-examining 71 patients 5 to 21 years following beta radiation therapy for external ocular conditions, it has become evident that the doses used in the early stages of development of this treatment were unnecessarily high and led in many instances to late complications. However, most of these were tolerable, including development of lens vacuoles in the equatorial region of the lens which then usually migrated posteriorly to the subcapsular region. This rarely caused any diminution of vision and the opacities tended to be stationary, perhaps because of the highly localized nature of the irradiation. It would therefore seem reasonable not to discard this mode of therapy in conditions where it is superior to other methods or in conditions where other methods have failed. Reduction of the size of the dose and greater fractionation of doses can be expected to reduce the incidence of late changes caused by radiation. (9 figures, 4 tables, 16 references)—Authors' abstract

MARSUPIALIZATION OF INOPERABLE ORBITAL DERMOIDS. Kennedy, R. E. (University of Rochester School of Medicine, Rochester, New York), Tr. Am. Ophth. Soc. 68:146-164, 1970.

The best management of deep orbital dermoids is complete surgical removal. If this can not be accomplished without damage to the orbital contents, partial removal is indicated with or without cauterization of the residual cyst. These lesions frequently recur. Marsupialization of deep orbital dermoids may then be justified as an attractive alternative to extensive orbital surgery or neurosurgery with possible complications. The functional eye with good vision and fusion is well worth the cosmetic deficit of proptosis and the annoyance of intermittent discharge from the fistula. (17 figures, 25 references)—Author's abstract

DRUSEN OF THE OPTIC DISK-HEMORRHAGIC COMPLICATIONS. Sanders, T. E., Gay, A. J. and Newman, M. (Washington University School of Medicine, St. Louis, Mo.), Tr. Am. Ophth. Soc. 68:186-218, 1970.

Drusen of the optic nerve head are associated with three types of hemorrhage complications. One is the splinter hemorrhages in the substance of the disk. These apparently are asymptomatic, but theoretically they may play a role in the field loss associated with drusen. The main problem they present is in the differentiation of drusen from papilledema. The location of the hemorrhages in the disk and the characteristic fluorescein angiography should serve to clarify the diagnosis. The second type is the disk hemorrhage that is severe enough to rupture into the vitreous body. This results in blurred vision but usually resolves without complication. It is important to realize that drusen of the optic nerve can be a cause of vitreous hemorrhage. Third is the deep peripapillary hemorrhage lying beneath the retina, with associated blurred vision. It apparently resolves, leaving a peripapillary pigment atrophy similar to that occurring after inflammatory juxtapapillary processes. This type may also form a localized hematoma simulating melanoma. A central field defect is usually present in both forms. (13 figures, 21 references)—Authors' abstract

RESTRICTION IN UPWARD GAZE WITH ADVANCING AGE. Chamberlain, W., Tr. Am. Ophth. Soc. 68:234-244, 1970.

A progressive symmetrical limitation in upward gaze with advancing years has been

documented. This limitation of elevation is most apparent in the elderly, but is a measurable restriction, which can be demonstrated even in young adults. The symmetrical restriction of upward gaze simulates a supranuclear paralysis. When there is a marked inability to elevate either eye, it is not possible to test the function of the individual muscles that elevate the globe. In evaluating older patients it is important to recognize that symmetrical limitation of upward gaze may be a "normal" finding related to the age of the individual. The normal upward rotation in young children in the 5 through 14-year decade is 40°, but in elderly patients in the 75 to 84-year bracket the average is only 16° with many scarcely able to elevate 10°. It would seem that the relative ineffectiveness of upward gaze may relate to the reduced use of the eyes in the upper field with advancing years. (5 figures, 2 tables, 9 references)—Author's abstract

HYDRATION OF THE CORNEA. Manchester, Jr., P. T., Tr. Am. Ophth. Soc. 68:425-461, 1970.

There are variations in corneal hydration as evidenced by changes in its thickness, curvature, and transparency. The cornea becomes thicker and flatter during sleep, although it does not seem to vary during pregnancy, with birth control drugs, or during the phases of the menstrual cycle. Removal of the precorneal oily film by irrigation, then exposure of the eye during surgery may cause considerable thinning of the cornea. Contact lenses cause very slight reversible thickening of the cornea. They also mould and warp the surface of the cornea and they produce superficial cloudiness which can be seen grossly by scleral shatter technique. They may cause alteration of the protective pre-corneal oily film with resultant development of dry spots and ulceration. (18 figures, 13 tables, 54 references)—Author's abstract

## TRANSACTIONS OF THE PACIFIC COAST OTO-OPHTHALMOLOGICAL SOCIETY

FILTERING CONJUNCTIVAL BLEBS AS A COMPLICATION OF CATARACT EXTRACTION. Christensen, R. E. and Rundle, H. L. (Jules Stein Eye Institute, Los Angeles), Tr. Pac. Coast Oto.-Ophth. Soc. 51:137-156, 1970.

In a consecutive series of 710 cataract extractions, unintentional postoperative filtering blebs occurred in 18 eyes. Seventeen of the 18 blebs (90%) appeared within seven months after surgery. Filtering blebs after limbus based conjunctival flaps occurred seven times more frequently than after fornix based conjunctival flaps. Postoperative complications were the most common etiologic factor associated with the production of the filtering blebs. Site of suture placement, incision site into the anterior chamber, use of enzymatic zonulysis, or operative complications could not be correlated either with the development, size, or location of the blebs. Seven of the 18 eyes had hypotony, yet the size of the blebs could not be correlated with the degree of hypotony. In this series, hypotony did not appear to affect visual acuity adversely. Indications for operative bleb closure include foreign body sensation, tearing, persistent leakage of aqueous, interference with contact lens wear, and macular edema. (7 figures, 4 tables, 14 references)—Authors' abstract

SURGICAL TREATMENT OF JAW-WINKING PTOSIS. Berke, R. N. (Palo Alto, California), Tr. Pac. Coast Oto.-Ophth. Soc. 51: 215-216, 1970.

The author performed 55 operations of various kinds for surgical correction of jaw-winking ptosis. He concludes that the best results follow a Crowell Beard operation in which both levator muscles were myectomized and both lids suspended from the brows by autogenous fascia lata. (7 references)—David Shoch

PHOTOCOAGULATION OF EXUDATIVE SENILE MACULOPATHY. Cleasby, G. W., Fung, W. E. and Fiore, Jr., J. V. (San Francisco, Calif.), Tr. Pac. Coast Oto.-Ophth. Soc. 51:233-258, 1970.

Sixty-two cases are described in which photocoagulation treatment of ESM was employed. The results have been generally encouraging. The authors believe that carefully directed photocoagulation by presently available techniques, in selected cases, can be useful in preserving vision for these unfortunate patients. (18 figures, 11 references)—David Shoch

# NEWS ITEMS

EDITED BY THOMAS CHALKLEY, M.D.
*700 North Michigan Avenue, Chicago, Illinois 60611*

For adequate publicity, notices of postgraduate courses, meetings and lectures must be received *at least* three months prior to the date of occurrence.

### FIRST PAN AMERICAN SYMPOSIUM ON STRABISMUS

The First Pan American Symposium on Strabismus, sponsored by the Pan American Association on Ophthalmology, will be held at the Shands Teaching Hospital, University of Florida, Gainesfille, Florida, on March 30-31, 1972. This meeting immediately precedes the Ninth Pan American Association of Ophthalmology Meeting in Houston, Texas.

It will consist of presentations by a distinguished panel, followed by round table discussions.

The moderators will be Alberto Ciancia (Argentina), John Pratt-Johnson (Canada), Guilllermo Velez Restrepo (Colombia), and Gunter K. von Noorden, Edward Dunlap, and Marshall M. Parks (U.S.A.).

For further information regarding this meeting, please write to Jorge Ferrer, M.D., Department of Ophthalmology, Medical College, University of Florida, Gainesville, Florida 32601.

### DOMINICAN REPUBLIC RECEIVES GRANT FROM INTERNATIONAL EYE FOUNDATION

As part of a continuing program of assistance to the Dominican Republic, the International Eye Foundation has sent $10,000 worth of examining and surgical equipment to the Doctor Luis E. Aybar Hospital in Santo Domingo. All of this equipment was donated to thte IEF by pharmaceutical houses and individual ophthalmologists.

In addition to the Dominican Republic, the IEF is presently conducting assistance programs in Puerto Rico, El Salvador, Honduras, and Haiti. The Foundation is planning additional projects throughout Latin America. As part of its Latin American Fellowship program, the IEF arranges annually for 20 resident eye surgeons to attend the University of Puerto Rico's basic science course in ophthalmology.

### EIGHT STUDENT FELLOWSHIPS AWARDED: FIGHT FOR SIGHT

Eight Student Fellowships have been awarded for 1971 by Fight For Sight, Inc., it was announced by Charles A. Perera, Chairman of the organization's Scientific Advisory Committee. Recipients are Walter E. Bundy, Department of Ophthalmology, Virginia Commonwealth University, Richmond, Virginia (Direct supervisor: Walter J. Geeraets; project title: The effect of vitamin A on the healing of experimental corneal lesions; Amount: $600). Wei-Mei Ching, Department of Chemistry, Natural Science II, University of California, Santa Cruz, California (Direct supervisor: Edward A. Dratz; project title: Structure and function of the visual membrane; amount: $750). Joseph Eichenbaum, Bascom Palmer Eye Institute, University of Miami, Miami, Florida (Direct supervisor: Duco I. Hamasaki; project title: Response of normal and visually deprived neurons of cats to moving stimuli; amount: $600). Stephen Finger, Department of Ophthalmology, Columbia University, New York, New York (Direct supervisor: Emil Wirostko; project title: Is there an infectious agent in the etiology of diabetic retinopathy? amount: $600). Laurence Franklin, Department of Chemistry, Natural Science II, University of California, Santa Cruz, California (Direct supervisor: Edward A. Dratz; project title: The mechanism of visual excitation; amount: $750). Robert P. Goodman, Department of Biochemistry, Virginia Commonwealth University, Medical College of Virginia, Richmond, Virginia (Direct supervisor: James M. Collins; project title: Alteration of DNA during lens cell differentiation; amount: $875. Susan Bagley Johnson, The Marine Biological Laboratory, Woods Hole, Massachusetts (Direct supervisor: Seymour Zigman; project title: Near ultraviolet effects on visual cell biochemistry: Amount: $750). Charles L. Murphy, Department of Biochemistry, University of Georgia, Augusta, Georgia (Direct supervisor: John Lee; project title: Photoenzymes; amount: $750).

### OPHTHALMOLOGY SELF-EDUCATION PROGRAM

Fellows of the American Academy of Ophthalmology and Otolaryngology are offered an ophthalmology self-education program without charge. It provides an outline containing the essential core of ophthalmic knowledge and provides select areas for study in accordance with the personal needs or preferences of the ophthalmologists. It provides two major study guides, reading lists, and self-assessment procedures each year. It is conducted under the auspices of Bradley R. Straatsma and the Academy Group in Continuing Education in Ophthalmology.

The new program is designed primarily to assist the practicing ophthalmologist in maintaining a continuing process of education throughout his professional life.

Applications and further information may be obtained from C. M. Kos, M.D., Executive Secretary-Treasurer, American Academy of Ophthalmology and Otolaryngology, Continuing Education in Ophthalmology, 15 Second Street SW, Rochester, Minnesota 55901.

### Short course tuition fees: Armed Forces Institute of Pathology

The Board of Governors at the Armed Forces Institute of Pathology Washington, D.C., decided a tuition fee of $25 per day will be charged to each civilian attending postgraduate short courses in continuing education. The action is effective as soon as possible, following modification of the wage-price policy.

A five-day course in ophthalmic pathology is scheduled for February 28 to March 3, 1972. Further information is available from the Armed Forces Institute of Pathology, Washington, D.C. 20305.

### Spring Meeting: West Virginia Academy of Ophthalmology and Otolaryngology

The National Spring Meeting of the West Virginia Academy of Ophthalmology and Otolaryngology will be held April 26-29, 1972, at the Greenbrier Hotel, White Sulphur Springs, West Virginia.

The ophthalmology program will be highlighted by Miles A. Galin, New York; Louis J. Girard, Houston; Frank W. Newell, Chicago; John T. Simonton, New York; and Frederick Stocker, Durham.

Hotel reservations should be made directly with the Greenbrier Hotel. The registration fee of $60 should be made payable to the West Virginia Academy of Ophthalmology and Otolaryngology and sent to J. Elliott Blaydes, Jr., M.D., 107 Federal Street, Bluefield, West Virginia.

### Symposium: University of Louisiana School of Medicine

The Department of Ophthalmology of the Louisiana State University School of Medicine announces a symposium on glaucoma, to be held at the L.S.U. Medical Center in New Orleans, Louisiana, on January 21-22, 1972. Guest participants at the symposium will be W. Morton Grant of Harvard University, Robert N. Shaffer of the University of California, H. Dunbar Hoskins, Jr., of the University of California, David Walton of Harvard University, David Apple of the University of Illinois, and William H. Coles of the University of South Carolina. Registration fee, payable to the Eye Foundation of America, is $100. For further information, contact George M. Haik, M.D., Department of Ophthalmology, L,S.U. Medical Center, 1542 Tulane Avenue, New Orleans, Louisiana 70112.

### Journal of Ophthalmic Surgery

The Journal of Ophthalmic Surgery is being reorganized under the editorship of George W. Weinstein, Head of the Division of Ophthalmology of the University of Texas Medical School at San Antonio. Members of the editorial board include Walter R. Gilbert, Jr., Jacksonville, Florida; Morton F. Goldberg, Chicago; Eugene Helveston, Indianapolis; Steven Ryan, Baltimore; Charles R. Leone, Jr., San Antonio; Margaret F. Obear, New York; Richard Keates, Columbus, Ohio; David Paton, Houston; Richard C. Troutman, New York; and George L. Spaeth, Philadelphia. The Journal appears bi-monthly and includes articles on basic and clinical aspects of surgery, instrumentation techniques, and related aspects of this field.

### Annual ophthalmology department meeting: Hermann Hospital

The third annual meeting of the department of ophthalmology of Hermann Hospital of Houston, Texas, will be held December 11, 1971. The guest speaker is Charles L. Schepens of Boston, Massachusetts.

### Postgraduate seminar: Cleveland Clinic

The annual postgraduate seminar of the ophthalmology department of the Cleveland Clinic Foundation will be held December 8-9, 1971. The guest faculty includes Morton F. Goldberg, Thomas R. Hedges, Eugene M. Helveston, and John R. Lynn. F. A. Gutman is chairman of the seminar.

For further information write to the Education Office, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

### Contact lens course: Baylor College of Medicine

The contact lens course of the department of ophthalmology of Baylor College of Medicine, Houston, Texas, will be held December 9-11, 1971. The course is open to all ophthalmologists, residents in ophthalmology, and technicians sponsored by an ophthalmologist. Classes will be conducted so that each ophthalmologists will be given individual instruction by members of the staff of the department of ophthalmology and guest lecturers.

For further information contact David Paton, M.D., Professor and Chairman, Department of Ophthalmology, Baylor College of Medicine, 1200 Moursund, Houston, Texas 77025.

### Technicians course: International Eye Foundation

The International Eye Foundation established a three-month course for ophthalmic technicians in Indonesia, beginning in October, 1971. Katherine Burkhard, a graduate of Georgetown University's school for ophthalmic technicians, will teach the course. Technicians who complete the course will be qualified to assume much of the responsibility of the treatment and diagnosis of minor eye diseases. This will permit the 12 ophthalmologists in Djakarta to concentrate on more technical aspects of ophthalmology and treating patients in need of immediate care.

In addition, Suzanne Veronneau and Richard C. Troutman of New York will serve as a medical teaching team in Indonesia from late October through November.

### Presidents' Meeting: Puget Sound Academy

The annual presidents' meeting of Puget Sound Academy of Ophthalmology will be held January 14 and 15, 1972, at the Wahington Plaza Hotel,

Seattle. The theme of the program will be complications of ophthalmic surgery. Speakers include Benjamin F. Boyd, Milton Boniuk, and Jerome W. Bettman. Management of office problems will be discussed in a seminar.

Further information is available from William P. Mulligan, M.D., 4615 35th Avenue S.W., Seattle, Washington 98126.

### Coming meetings

Research Study Club Mid-Winter Clinical Convention at Los Angeles Hilton Hotel, January 23-28, 1972. Information: 1136 West 6th Street, Los Angeles, California 90017.

Third Mid-Winter Ophthalmological Conference at St. Mary's Hospital nad Medical Center, January 22, 1972. Information: 2200 Hayes Street, San Francisco, California.

The 58th Annual Colorado Ophthalmology Conference at Broadmoor Hotel, July 3-6, 1972. Information: University of Colorado Medical School, Office of Postgraduate Medical Education, 4200 East Ninth Avenue, Denver, Colorado 80220.

Ophthalmic Plastic and Corneal Symposium at Diplomat Hotel, Hollywood, March 26-31, 1972. Information: Bascom Palmer Eye Institute, Box 875, Biscayne Annex, Miami, Florida 33152.

Ninth Annual Neuro-Ophthalmology Course at Americana Hotel, Miami Beach, January 4-7, 1972. Information: Bascom Palmer Eye Institute, Box 875, Biscayne Annex, Miami, Florida 33152.

Florida Midwinter Seminar at American Hotel, Miami Beach, January 30 to February 5, 1972. Information: Bascom Palmer Eye Institute, Box 875, Biscayne Annex, Miami, Florida 33152.

Clinical Conference of Chicago Ophthalmological Society at Drake Hotel, Chicago. Information: 950 East 59th Street, Chicago, Illinois 60637.

Ophthalmology meeting of the University of Kansas School of Medicine, Department of Postgraduate Medical Education, from April 10-12, 1972. Information: 39th and Rainbow Blvd., Kansas City, Missouri 66103

Wilmer Residents Meeting at Turner Auditorium, April 13-15, 1972. Information: Johns Hopkins University School of Medicine, 725 N. Wolfe, Baltimore, Maryland 21205.

Neuro-Ophthalmology meeting at Massachusetts Eye and Ear Infirmary April 24-29, 1972. Information: Department of Continuing Education, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115.

Ophthalmology for the Internist, Pediatrician, and General Practitioner at Massachusetts Eye and Ear Infirmary, May 4-5, 1972. Information: Department of Continuing Education, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115.

Diseases of the Cornea at Massachusetts Eye and Ear Infirmary, June 8-10, 1972. Information: Department of Continuing Education, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115.

Ophthalmology Conference, University of Michigan May 11-13, 1972. Information: Towsley Center for Continuing Medical Education, University of Michigan Medical Center, Ann Arbor, Michigan 48104.

Ophthalmology for Specialists at Nolte Center for Continuing Education, May 1-2, 1972. Information: Health Sciences Center, University of Minnesota Medical School, Box 193, Minneapolis, Minnesota 55455.

Ophthalmic plastic surgery, Brooklyn Eye and Ear Hospital, April 26-28, 1972. Information: 29 Greene Avenue, Brooklyn, New York 11238.

Annual Spring Meeting and Postgraduate Course in Ophthalmology and Otolaryngology, University of Oklahoma Medical Center, March 16-17, 1972. Information: University of Oklahoma Medical center, 800 Northeast 13th Street, Oklahoma City, Oklahoma 73104.

Postgraduate Convention, Oregon Academy of Ophthalmology and Otolaryngology, March 3-4, 1972. Information: Oregon Academy of Ophthalmology and Otolaryngology, 1216 SW Yamhill Street, Portland, Oregon 97205.

Fourth Annual Seminar of the Department of Ophthalmology, New York Medical College, Dorado Beach Hotel, Puerto Rico, January 14-22, 1972. Information: Department of Ophthalmology, New York Medical College, 1249 Fifth Avenue, New York, New York 10029.

Annual Residents Conference, Medical University of South Carolina, April 6-8, 1972. Information: Department of Ophthalmology, Medical University of South Carolina, 80 Barre Street, Charleston, South Carolina 29401.

### Personals

#### Trustees' award: Research to Prevent Blindness

The Research to Prevent Blindness Trustees' award for outstanding achievement was awarded to David H. Hubel and Torsten N. Wiesel September 22, 1971, during the annual meeting of the American Academy of Ophthalmology and Otolaryngology. Both are professors of neurobiology at Harvard University Medical School. The award was made by Jules C. Stein, Chairman of Research to Prevent Blindness, Inc. It consists of a plaque and a $25,000 honorarium from personal contributions of the board of trustees of Research for the Prevention of Blindness. Previous recipients of the award are Frank B. Walsh (1966); Charles L. Schepens and Gard Meyer-Schwickerath (1967); and Toichiro Kuwabara (1969).

Doctors Hubel and Wiesel (Fig. 1) studied extensively the electrical activity of individual neurons of visual centers in the brain of kittens and monkeys. They have studied the effects of visual deprivation and the morphologic and physiologic properties of visual cells, as well as the processing of information concerning the directions center intensity of stimuli of the eyes.

#### Samuel Schwartz

Samuel Schwartz has been appointed Deputy Associate Director for Extramural Programs, Na-

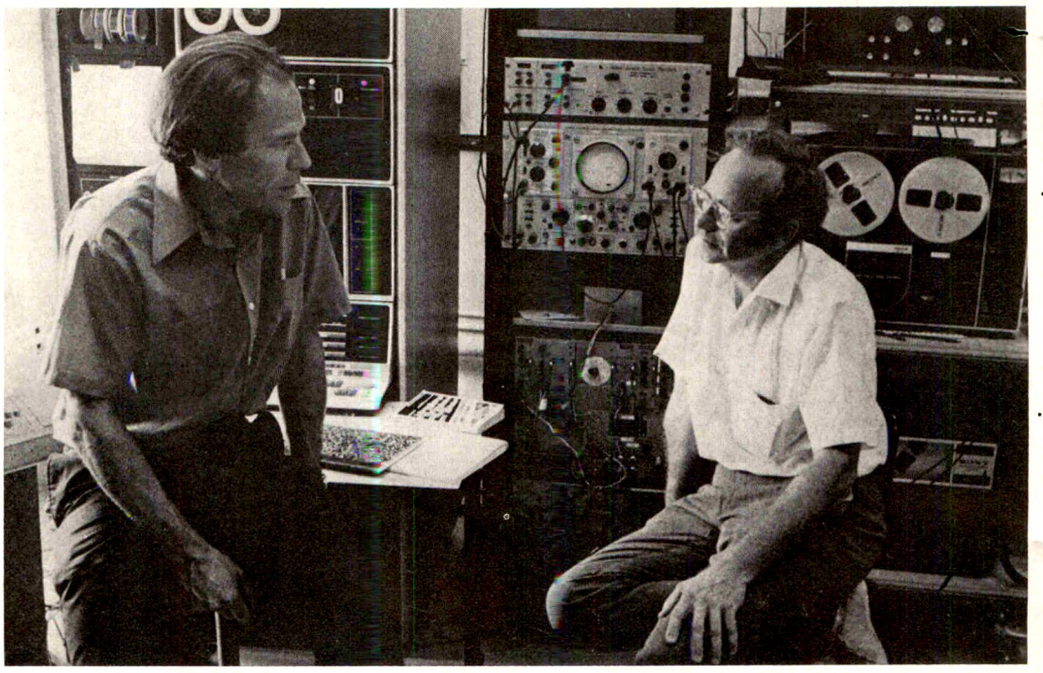

Fig. 1 (Hubel and Wiesel). Drs. Torsten N. Wiesel (left) and David H. Hubel (right), recognized for outstanding achievement in ophthalmology by Trustees of Research to Prevent Blindness.

tional Eye Institute, by Dr. Carl Kupfer, NEI Director.

Dr. Schwartz will also serve as Chief, Scientific Programs Branch of the NEI Extramural Programs, succeeding Dr. Samuel Price. In both capacities, Dr. Schwartz will assist Dr. George Brooks, newly appointed Associate Director for Extramural Programs, in directing the over-all scientific and administrative management of NEI's research and training programs.

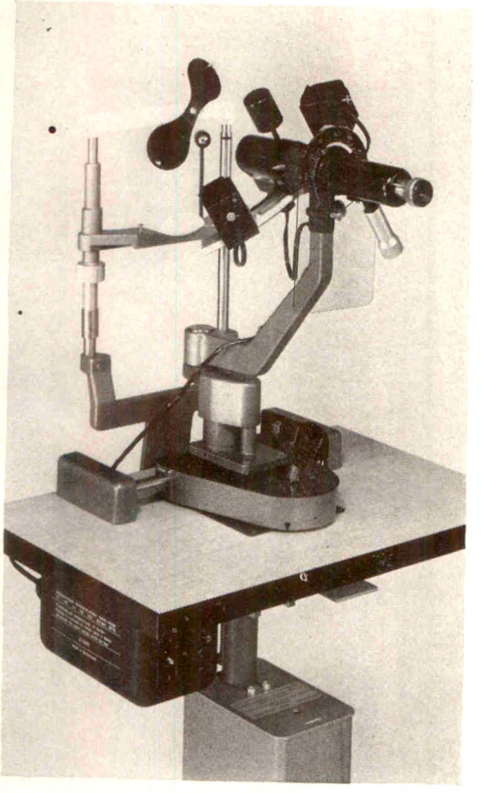
A native of Winnipeg, Canada, Dr. Schwartz earned a B.Sc degree from the University of Manitoba in 1952 and a Ph.D. degree from the University of Minnesota in 1956, majoring in medicinal chemistry with a minor in biochemistry. He served for eight years on the faculty of the George Washington University.

Dr. Schwartz brings to NEI a varied background in NIH extramural activities beginning in 1964 with the National Cancer Institute. In January, 1965, he was appointed Executive Secretary of the Medicinal Chemistry Study Section, Division of Research Grants (DRG) and served in that capacity until November, 1968. As Assistant Chief for Referral, Research Grants Review Branch, DRG, he then assumed responsibility for the DRG Research Referral Office and held that position until his present appointment.

### Arthur H. Wolintz

Arthur H. Wolintz, Clinical Assistant Professor of Ophthalmology at State University of New York, Downstate Medical Center, Brooklyn, has been named Associate Director of Neurology, Coordinator in Ophthalmology and Neuro-Ophthalmologist at the Kingsbrook Jewish Medical Center. Dr. Wolintz, who resides in Brooklyn, attended New York University. He was graduated Summa Cum Laude from the State University of New York, Downstate Medical Center College of Medicine in 1962. He served his internship and one year of medical residency at Maimonides Medical Center. He was a resident in neurology in the Medical Neurology Branch of the National Institute of Neurological Disease and Blindness and served as senior and chief resident in neurology at Mount Sinai Hospital. He was awarded a special fellowship in neuropathology at the College of Physicians and Surgeons, Columbia University. He completed training in ophthalmology and neuro-ophthalmology at Downstate Medical Center in 1971.

### More volunteers for Project HOPE



Ophthalmologists Robert James Davis, Patrick D. Moore, and Brooks Poley are now serving short-term tours of service on the hospital ship SS HOPE, beginning October 1. The good ship HOPE is now in Kingston in the West Indies on a 10-month medical teaching and treatment mission.

Dr. Davis is in private practice in Spokane, Washington. Dr. Moore is a resident at Wills Eye Hospital in Philadelphia. Dr. Poley is an instructor in ophthalmology at the University of Minnesota School of Medicine in Minneapolis.

# JAVAL-SCHIOTZ OPHTHALMOMETER —HAAG-STREIT

The Javal-Schiotz Ophthalmometer is in great demand for the fitting of contact lenses. It provides quick and accurate measurements of the corneal radius of curvature, the refractive power, and the direction of the principle meridians. Its range extends from 5.5 to 11 mm., or from 30 to 60 diopters. Two readings—the radius of curvature in millimeters and the refractive power in diopters — can be made on the two graduated scales of the arc. The use of complementary colors, which when superimposed on each other produce white light, enables the observer to focus very accurately. If desired, color glasses can be removed for work with white images.

Unusual luminous fixation point can be easily seen even by patients with poor vision. New dual-purpose "joystick" focusing control simplifies and speeds up positioning of the instrument in all directions.

**H5500-950** — Javal-Schiotz Ophthalmometer on spring-balanced table #1000, with head and chin rest, transformer, 7.5 mm. testing ball, chin rest papers, 10 bulbs 6V, breath shield and cover. . . . . $940.00

**H5500-951** — Javal-Schiotz Ophthalmometer, Unit Model. . . . . $705.00

# TWENTY-FOURTH ANNUAL CLINICAL CONFERENCE

## February 3-5, 1972

at the

BELLEVUE STRATFORD HOTEL
BROAD AND WALNUT STREETS
PHILADELPHIA, PA.

*SPECIAL HIGHLIGHTS*

THE ARTHUR J. BEDELL LECTURE
by
LORENZ E. ZIMMERMAN, M.D.,
WASHINGTON, D.C.

SYMPOSIA:
"CAUSES OF FAILURE IN CATARACT SURGERY AND HOW TO AVOID THEM"

"RETINAL VASCULAR OCCLUSIVE DISEASE"

WORKSHOPS:
ANESTHESIA, NEUROLOGY, MOTILITY, REFRACTION, RETINAL DISORDERS AND PLASTIC SURGERY

Address inquiries to:
ROBERT D. MULBERGER, M.D.,
Chairman
Annual Clinical Conference Committee
Wills Eye Hospital
1601 Spring Garden Street
Philadelphia, Pa. 19130

## INDIRECT OPHTHALMOSCOPY OF THE PERIPHERAL RETINA

Purpose: To teach this new technique—the normal anatomy of the peripheral retina to residents and ophthalmologists.

Contents: Demonstrates and discusses normal anatomy of the equatorial and oral region of the retina as viewed during indirect ophthalmoscopy and scleral indentation. All normal anatomy and variations are discussed, and presented in views of post mortem eyes and shown in scenes taken with the Stenstrom cine. This technique demonstrates the actual views of the fundus as seen during clinical examinations.

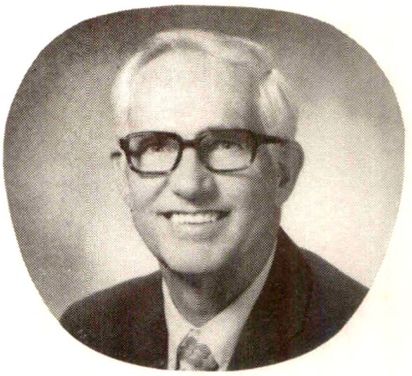
Running Time: 41 minutes—16 mm sound

Cost: Rental $25.00 per week
Purchase price $300.00

For information contact: Retinal Service
Department of Ophthalmology
University of Iowa College of Medicine
Iowa City, Iowa 52240

## THE UNIVERSITY OF TEXAS MEDICAL SCHOOL AT HOUSTON BASIC SCIENCE COURSE IN OPHTHALMOLOGY

**January 3 through February 25, 1972**
**Texas Medical Center, Houston, Texas**



This course consists of 270 hours of lectures and demonstrations by an experienced faculty of forty ophthalmologists and basic scientists. It is directed toward the requirements of residents and prospective residents in ophthalmology.

The curriculum includes:

| | |
|---|---|
| Anatomy | Pharmacology |
| Physiology | Optics |
| Pathology | Refraction |
| Biochemistry | Glaucoma |
| Neuro-ophthalmology | Motility |
| Embryology and Genetics | Visual Fields |
| Microbiology | External Disease |
| Medical Ophthalmology | Surgery |

Tuition is $600.00. For further information and application forms please write to Whitney G. Sampson, M.D., Coordinator of Basic Science Programs, Department of Ophthalmology, The University of Texas Medical School, 530 West 20th Street, Houston, Texas 77008.

# Tillyer Topics

E. WILLIAM TILLYER

## Aspheric Cataract Lenses

Of all the work done in optics for the betterment of vision, perhaps the most spectacular is the development of aspheric cataract lenses. Nowhere can I recall such dramatic improvement in the quality of vision as that which occurs when properly developed aspheric curves are used in place of spherical curves in the aphakic patient's prescription.

The patient's reaction, of course, is the ultimate criterion. But the advantages of the aspheric curves can be proved mathematically.

For instance, a +14.00 sphere, if made up in a spherical curve with a —3.00 D inside curve, has the following Rx at 15mm away from the center of lens:

$$+14.16 = +2.14$$

The aspheric lens of the same power has an Rx at 15mm away from the center of:

$$+14.31 = -.75$$

This is quite a dramatic reduction in the marginal error. It is no wonder so many patients are extremely pleased with their new aspheric lenses!

But just being an aspheric lens does not make all the difference. One cannot use the same aspheric curve for all Rx's and still get these same results. The marginal effects of each power of sphere combined with each cylinder must be computed. Then a determination can be reached of the best aspheric curves for the individual power required.

We use 29 different base curves in the range from plus 8.00 D to plus 20.00 D. Only with this minimum can we achieve what we consider the ultimate results.

This seems like a lot of changes—more than one for every half diopter change in Rx power. But it gives the patient better vision every time.

There are other areas where improvements have been made in lens design which are extremely important. But I, personally, still believe that none are as dramatic as the vision given the aphakic patient—by the use of a true aspheric series of cataract lenses.

## Announcement of
## TWELFTH ANNUAL INSTRUCTIONAL COURSE IN CONTACT LENS FITTING BY THE OPHTHALMOLOGIST

**April 8-9, 1972**

Sponsored by
The Rudolph Ellender Medical Foundation, Inc.

Co-ordinated with the
New Orleans Academy of Ophthalmologist's Meeting on "Contact Lenses"
April 9-14, 1972

PLACE

Roosevelt Hotel, New Orleans, La.

TUITION

$85.00 ($40.00 Out of State Residents and M.D.'s Technicians)

PANEL MEMBERS

Colonel Budd Appleton, M.D., Walter Reed Hostp., Washing. D.C.
Jos. A. Baldone, M.D., New Orleans, Louisiana
Antonio R. Gassett, M.D., Gainesville, Florida
Herbert L. Gould, M.D., White Plains, New York
G. Peter Halberg, M.D., New York, New York
Jack Hartstein, M.D., St. Louis, Missouri
Frank Hoefle, M.D., New York, New York
Whitney G. Sampson, M.D., Houston, Texas
Keith Whitham, Buffalo, New York

TOPICS

Practical technics of fitting of hard and soft gel lenses will be actually demonstrated, audience participation in handling of lenses.

Full description of the Series System (Inventory System) fitting technic of hard lenses.

Didactic lectures will be held to a minimum (in co-operation with the New Orleans Academy's Program which follows).

WORKSHOP

For M.D.'s Technicians in evening

LADIES DAY

Saturday, April 8, 1972 with planned activities.

# Halberg is quick...

At $20, the Halberg clips could save you a lot of time and trouble. These inexpensive monocular units clip over adults' or children's frames. Uses include checking presbyopic addition to know prescriptions, verification of cylindrical correction, retinoscopy and muscle balance tests and post-cataract refractions while the problems of fitting trial frames to children can be minimised. Fill in the coupon below; let the Halberg trial clips help to speed your daily routine.

**KEELER OPTICAL PRODUCTS INC.**

Announces a Symposium on

## OPHTHALMIC PLASTIC AND CORNEAL SURGERY

To be held at the Diplomat Hotel,
Miami Beach (Hollywood), Florida

March 26-31, 1972

Faculty for the course will include:

| | |
|---|---|
| Dr. Crowell Beard | Dr. J. H. King |
| Dr. Jorge Buxton | Dr. James Major |
| Dr. Ramon Castroviejo | Dr. A. E. Maumenee |
| Dr. Claes Dohlman | Dr. Gordon Miller |
| Dr. Max Fine | Dr. Edward W. D. Norton |
| Dr. Richard Forster | Dr. Frank Polack |
| Dr. J. Donald M. Gass | Dr. Marvin Quickert |
| Dr. Russell Harner | Dr. Norman Sanders |
| Dr. Danny Jones | Dr. Byron Smith |
| Dr. A. Dalma Kende | Dr. David Soll |

Dr. Richard Tenzel

This symposium will cover the corneal and ophthalmic plastic field. Multiple lectures will be given with ample time for panel discussion and questions from the registrants.

Afternoons will be set aside for recreation including tennis and golf tournaments. There will be planned entertainment for most evenings.

Tuition will be $175, breakfasts included. Special rate of $75 available for residents upon application from their Department Head. Checks should be made payable to "Bascom Palmer Eye Institute" and mailed to Ophthalmic Plastic and Corneal Surgery Symposium, Bascom Palmer Eye Institute, P.O. Box 875, Biscayne Annex, Miami, Florida 33152.

## Muro
## Ointment
## Sodium Chloride 5%

*MURO OINTMENT NO. 128 / SUPPLIED 1/8 OZ.*

An ointment of hypertonic sodium chloride solution in a base of lanolin, liquid petrolatum and white petrolatum.

Apply to conjuctiva at bedtime.

# TO REDUCE CORNEAL EDEMA

## Murocoll Methylcellulose
## 4000 cps 0.9%
## with Sodium Chloride 5%

*MUROCOLL PRODUCT NO. 4 / SUPPLIED 15cc and 30cc*

A hypertonic solution of sodium chloride with methylcellulose. Preservatives - methylparaben and propylparaben.

TO REDUCE CORNEAL EDEMA: 1 or 2 drops in affected eye 3 times a day or as directed by the physician.

MURO preparations are available to all pharmacies and hospitals through their drug wholesaler.

Complete ophthalmologic formulary available on request.

Federal law prohibits dispensing without prescription.

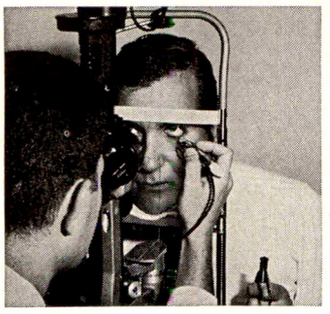
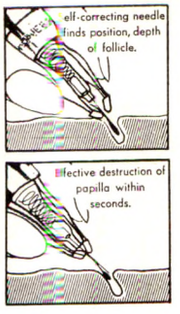
7-year-old boy with severe gunpowder burns on both corneas, treated 24 hours with lactated Ringer's solution administered via medi-FLOW device. Right, two weeks after patient discharged.

*medi-FLOW*™



battle-proved in Viet Nam* . . . now amplifying the armamentarium of civilian ophthalmology.



The medi-FLOW device delivers controlled medication to the cornea and conjunctiva either rapidly or slowly, as you desire.

It is a uniquely designed clear plastic scleral lens with a polyethylene tube and Luer-lock adaptor for attaching either a syringe or I.V. set. The lens incidentally protects the cornea from eyelid trauma, reduces discomfort rapidly, and aids in the prevention of symblepharon formation—all outstandingly valuable assets of medi-FLOW.

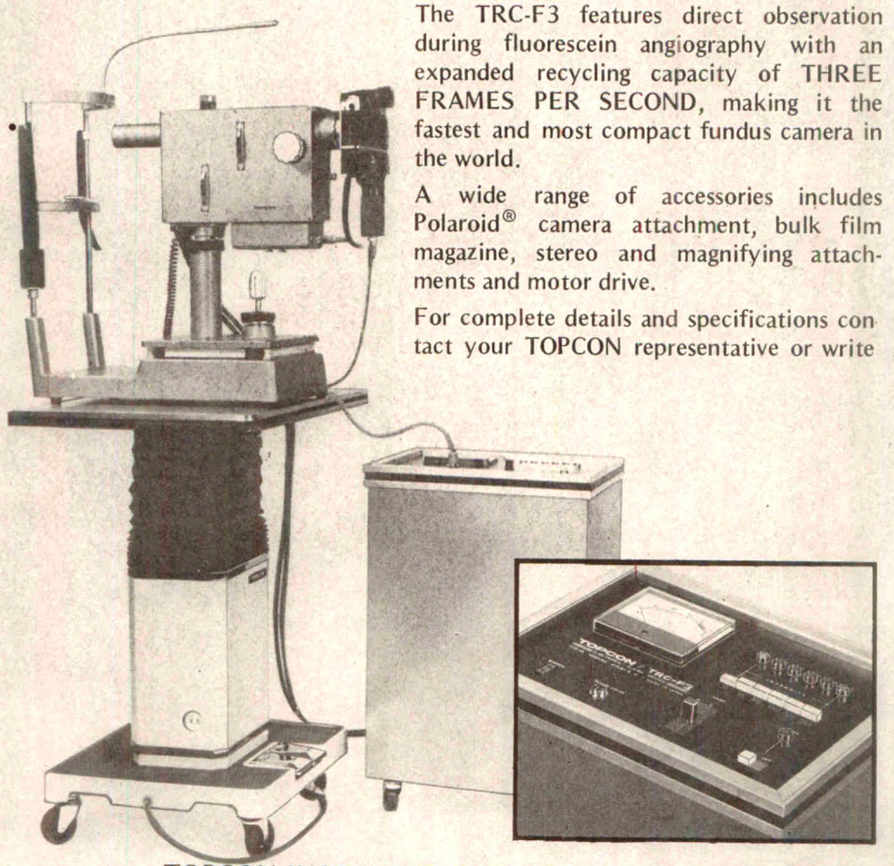
# IMPACT RESISTANT LENSES

An impact-resistant lens is one which withstands the impact of a ⅝-inch steel ball, weighing 0.56 ounces, dropped from a height of 5 inches upon the horizontal upper surface of the lens within a ⅝-inch circle located at the geometric center of the lens. Each finished impact-resistant glass lens (including each impact-resistant laminated glass lens) for prescription use shall be subjected to the impact test.

Impact lenses are mainly heat-hardened glass, plastic, or laminated glass. A scratched heat-hardened glass lens tends to shatter more readily than ordinary glass.

Notched and drilled glass lens cannot be made impact-resistant. Rimless glasses should be prescribed in plastic.

Glass lenses exceeding +7.00 diopters or —6.00 diopters in sphere, or —3.00 diopters in cylinder, cannot be reliably heat-hardened. Lenses outside these limits should be made in plastic.



Impact-resistant lenses are not safety glasses, are not shatter-proof, are not unbreakable. They are lenses which have withstood the impact test described above.

NEWEST, FASTEST

# THE TOPCON SYSTEM

TRC-F3 (3FPS) RETINAL CAMERA

Like the TRC-F1, the Model F3 is a superior instrument, ideal for obtaining distinct 35 mm color or black & white photographs of the anterior ocular structures and fundus.

The TRC-F3 features direct observation during fluorescein angiography with an expanded recycling capacity of THREE FRAMES PER SECOND, making it the fastest and most compact fundus camera in the world.

A wide range of accessories includes Polaroid® camera attachment, bulk film magazine, stereo and magnifying attachments and motor drive.

# Apollo Space Flight Veteran: Methulose, for dry eyes!

Methulose artificial tears lubricate sensitive ocular tissues to provide comfortable, soothing relief from eye dryness and irritation without blurring vision. Little wonder it is a big item on Apollo flights where dry eyes could present serious problems.

Meanwhile, back on earth, Methulose might be the simple solution to the dry-eye problems of many of your patients. A non-irritating buffered aqueous solution containing Methylcellulose U.S.P. preserved with Benzalkonium Chloride 1:25,000, it is available in 15cc and 30cc direct application plastic containers. Write for a generous supply of 5cc starter samples.

(chloramphenicol) *

# ALL CHLOROPTIC PRODUCTS ARE STERILE.. GUARANTEED STERILE.

## WHY ACCEPT LESS?

3 JUN 1972

*The mark of guaranteed sterility.

In 1968, CHLOROPTIC® (chloramphenicol) brought ophthalmic chloramphenicol out of the dark ages with the introduction of the first ready-to-use solution. For the first time, physicians and patients were offered guaranteed sterility, laboratory-controlled potency, greater stability, and greater convenience. We didn't stop there...In 1970, Allergan introduced the first ophthalmic ointments guaranteed sterile with a tamperproof seal... CHLOROPTIC® (chloramphenicol) and CHLOROPTIC®-P (chloramphenicol-prednisolone). The potential risk of contaminated chloramphenicol ophthalmic ointments has been eliminated.

ADD
NIGHT
TO
DAY
Isopto Carbachol 3%
controls
diurnal variation
without
risking lens opacities

**One drop of Isopto® Carbachol 3% keeps IOP down for 8 hours.** Administer it at bedtime and control IOP through the early morning hours—without the side effects of the more potent cholinesterase inhibitor. Consider Isopto Carbachol, also, for extended IOP control *during the day*, in cases where the patient no longer responds to pilocarpine.

One recent study* in glaucoma patients showed Isopto Carbachol 3% effective for a full 8 hours. A single instillation of the solution was administered in one eye; the fellow eye served as a control. IOP in the treated eye was still significantly lower than the control at 8 hours. Use it for assured all night glaucoma control.

**Variation in IOP after instillation of a single dose of Carbachol 3%**

An increase in the log value corresponds to a drug induced fall in IOP

| | | | |
|---|---|---|---|
| Mean Log | Baseline outflow pressure treated eye | X | Outflow pressure control eye at same time after instillation as treated eye. |
| | Baseline outflow pressure control | X | Outflow pressure treated eye at same time after instillation as control eye. |

*Drance, S. M. and Flindall, R. J.; Canad. J. of Ophth. *1*:#4:292-296, Oct. 1966

**Contraindicated** in presence of corneal abrasion or when constriction is undesirable, as in acute iritis. **Precaution & Side Effects:** Avoid overdose. Transient ciliary and conjunctival injection, headache and ciliary spasm with resultant temporary decrease of visual acuity may occur. Systemic symptoms of cholinesterase inhibitors may occur even when epithelium is intact. **Available:** Isopto Carbachol 0.75%, 1.5%, 2.25%, 3%. **Supplied** in 15cc and 30cc Drop-Tainer® Dispensers. Rx only.

# the xonix stereoscope

## THE PRECISION MICROSCOPE THAT'S AS MANEUVERABLE AS YOU ARE

Your delicate movements during surgery require you to **move about freely.** So you've passed up table or floor mounted microscopes to retain your mobility.

Now, the XONIX STEREOSCOPE* — the quality binocular microscope **you control like a loupe.** To bring a subject into focus, you merely move your head. A glance below the oculars gives you an unobstructed, unmagnified view of the field. **Your hands are completely free** — no fiddling with adjustments during surgery.

**Self-contained coaxial light system** pinpoints the subject with 1500 foot-candles of **cool illumination,** which you'll find particularly useful when operating in cavities.

Interchangeable oculars provide various magnifications, such as 6X, with exceptional optical clarity and resolution. The optical system was **computer-designed** specifically for this instrument.

Comfortable headpiece is **chamois-lined** to absorb moisture and **foam-padded** to provide a soft cushion. You can even wear the XONIX STEREOSCOPE **with your regular glasses** without sacrificing field size.

**THE XONIX STEREOSCOPE — DESIGNED FOR THE SURGEON WHO WANTS THE SAME MANEUVERABILITY WITH HIS MICROSCOPE AS HE HAS WITH HIS HANDS.**

## GENERAL

Address manuscripts and other scientific communications to Frank W. Newell, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Manuscripts must be original material submitted solely to the AMERICAN JOURNAL OF OPHTHALMOLOGY. Two original typed copies must be submitted. The entire manuscript, including case reports, footnotes and references, must be typed in double space, with wide margins, on 8½ by 11-inch heavy white bond paper. See Suggestions to Authors (Am. J. Ophth. 70: Advertising pages 85–88, December, 1970). Receipt of manuscript is acknowledged immediately.

Author's proofs must be corrected and returned within 48 hours to Manuscript Editor, 160 East Grand Avenue, Chicago, Illinois 60611.

Fifty reprints of each article will be supplied to the senior author without charge. Additional reprints may be obtained from Ophthalmic Publishing Company, 160 East Grand Avenue, Chicago, Illinois 60611, if ordered at the time proofs are returned.

Address news items and society proceedings to Thomas Chalkley, M.D., 700 North Michigan Avenue, Chicago, Illinois 60611.

Exchange copies of medical journals should be sent to David Shoch, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Subscriptions, requests for single issues, notices of changes of addresses, advertising and other communications should be sent to 160 East Grand Avenue, Chicago, Illinois 60611.

Change of address notices must be received at least 60 days in advance and must include both old and new addresses.

Claims for copies lost in the mail must be received within 60 days from the date of issue.

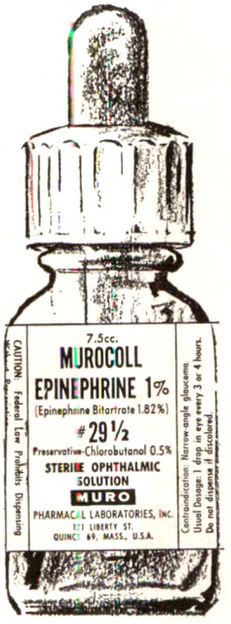
Advertisement insertion orders and copy must be received before the first day of the preceding month for which the advertisement is scheduled.

# At her age, she's entitled to see.

One of the most tragic infirmities of age is that of failing vision. It is a precious gift to an oldster when the services of ophthalmologist and dispenser can be combined to enable her to read once again . . . to sew, perhaps . . . to see the faces of her family and friends.

Here, the dispensing optician serves a vital function, for the ophthalmologist's prescription must be perfectly interpreted in order to provide the patient with as much vision as possible.

The Guild Optician, by the very nature of his excellent capabilities in this area, is well qualified to handle subnormal vision cases. If he didn't have these capabilities, he wouldn't be a Guildmember.



This is one of the reasons we believe a Guild Optician is best qualified to serve the ophthalmologists' dispensing needs.

# MUROCOLL EPINEPHRINE 1%

**As (L-Epinephrine Bitartrate 1.82%)** **PRODUCT #29½**

- Effective in maintaining lowered intraocular pressure in certain cases of open angle glaucoma by reducing the rate of aqueous formation.
- Improves the facility of outflow after prolonged therapy in more than 50% of eyes with open angle glaucoma.*
- Aids in breaking posterior synechiae in uveitis.

Murocoll Epinephrine 1% (as Bitartrate 1.82%) with Chlorobutanol 0.5% as a preservative and bacteriostatic agent is also available as Murocoll Epinephrine 2% (as Bitartrate 3.64%), Product #29.

Both solutions also have Sodium Bisulfite as preservative; Sodium Chloride and distilled water as inactive ingredients.

Above solutions are contraindicated in narrow angle glaucoma.
Use with caution in presence of hypertension.

Available: 7.5 cc. glass bottle with plastic dropper. ℞ only

Patient does not have to refrigerate above solutions.

# CONFORM-A-SPHERIC™ *and* ELLIP-SEE-CON™

## ASPHERIC CORNEAL LENSES

**ARE WE NUTS?** Imagine . . . we're advertising a NEW corneal lens design when everyone's interested in soft lenses!

**WE HAVE OUR REASONS!** First, soft lenses are in a transition phase. (It may be 12 to 18 months before everyone may fit soft lenses.) Also, the new soft lens materials are not expected to solve **all** contact lens needs nor to completely replace the hard lens.

**THE PUBLIC MUST BE SATISFIED!** Aspheric designs will challenge soft materials for future comfort and fitting simplicity. In fact, aspheric lenses will:

1) Eliminate peripheral flare without gimmicks. They furnish a wider, brighter peripheral field of vision.

2) Assured reproductibility! A distinct advantage over convential sperical curves.

3) Their gentle, more evenly distributed bearing areas minimize corneal changes and spectacle blur problems.

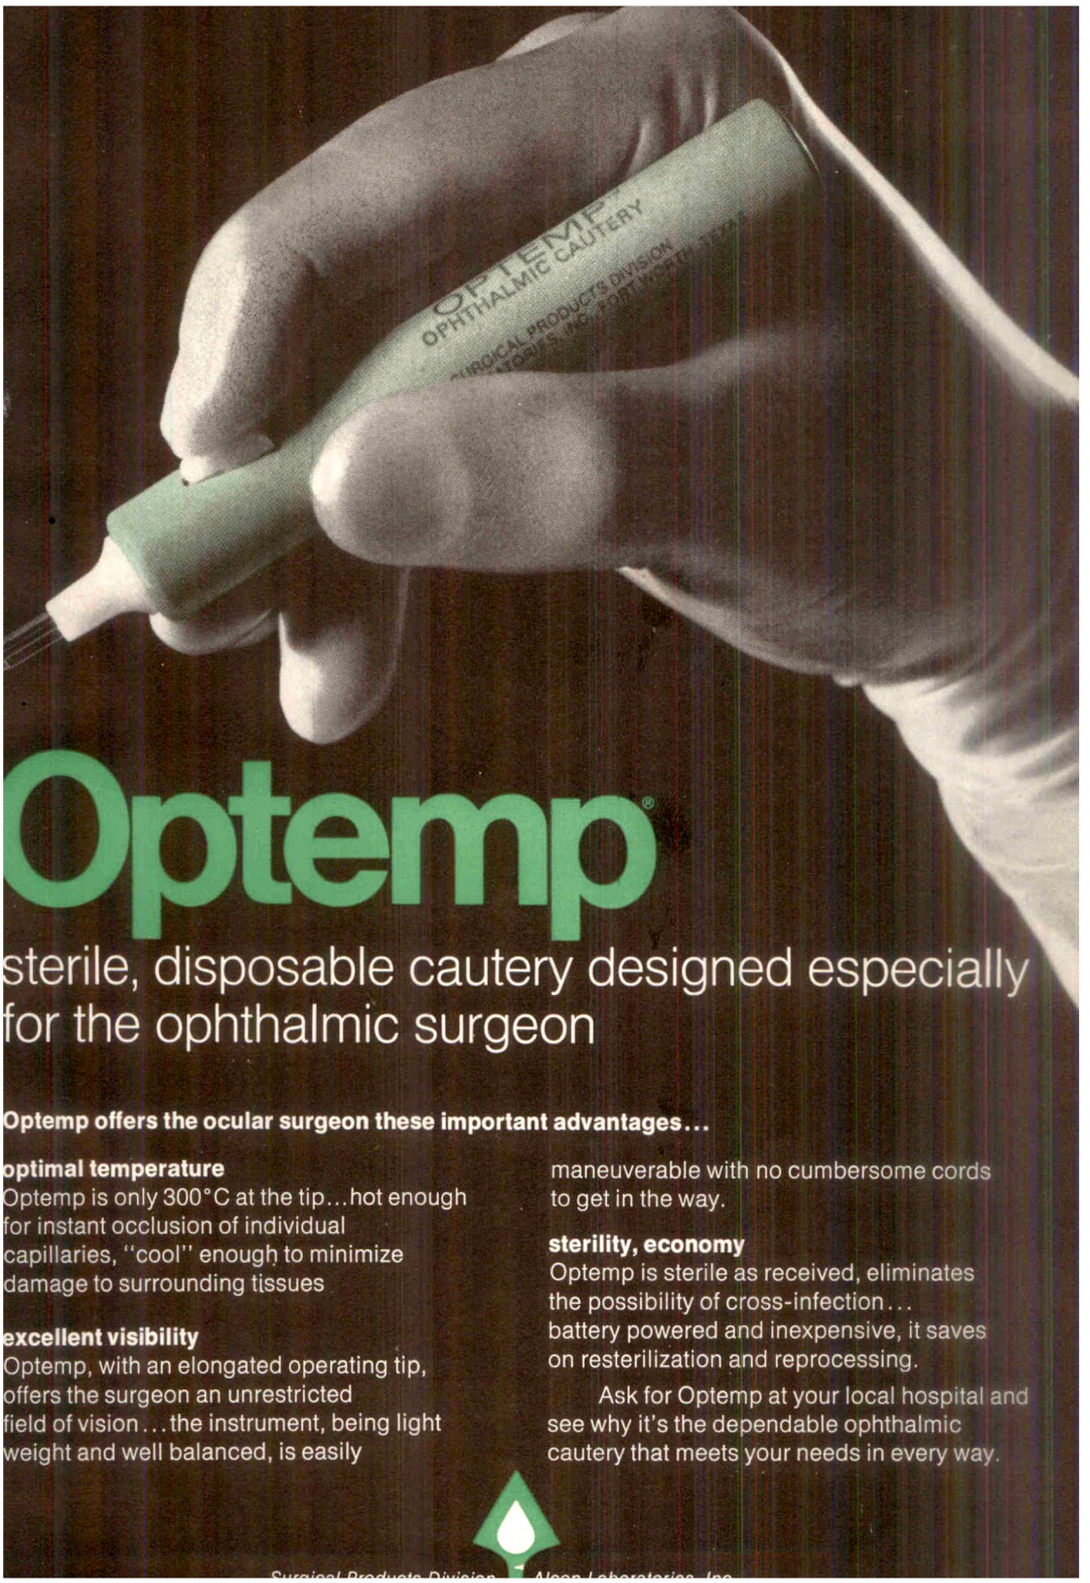
When properly managed, aspheric lenses will increase patient comfort and decrease fitting time.

**ASPHERIC LENSES COST LESS!** Aspheric lenses cost less than soft lenses. And, in these inflationary times, you'd better believe that this is meaningful.

**ASPHERIC LENS VERSATILITY** We have two aspheric corneal lens designs:

1) CONFORM-A-SPHERIC™—aspheric values replace the conventional spherical peripheral curve (s). Can be used with any existing fitting philosophy (spherical or toric base curves).

2) ELLIP-SEE-CON™—an ellipsoidal central curve and an aspheric bevel.



**LEARN HOW** to use Aspheric Corneal Lenses.

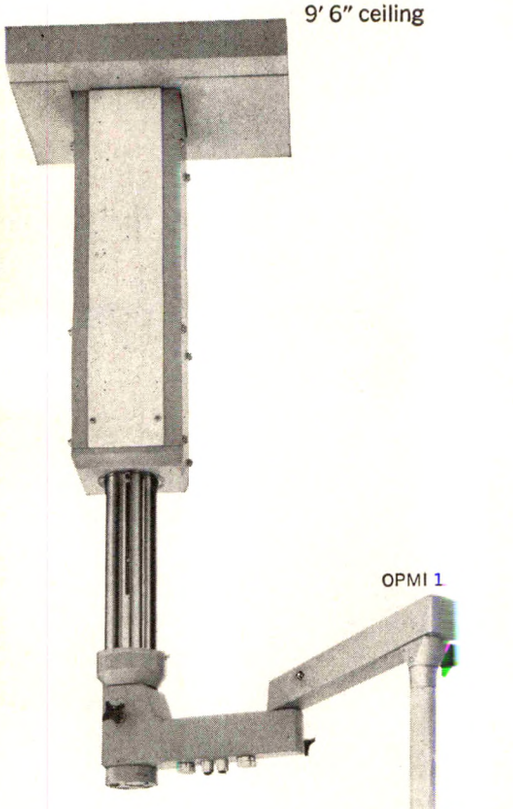
# Optemp®

## sterile, disposable cautery designed especially for the ophthalmic surgeon

**Optemp offers the ocular surgeon these important advantages...**



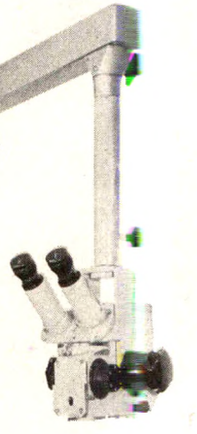
**optimal temperature**
Optemp is only 300°C at the tip...hot enough for instant occlusion of individual capillaries, "cool" enough to minimize damage to surrounding tissues

**excellent visibility**
Optemp, with an elongated operating tip, offers the surgeon an unrestricted field of vision...the instrument, being light weight and well balanced, is easily maneuverable with no cumbersome cords to get in the way.

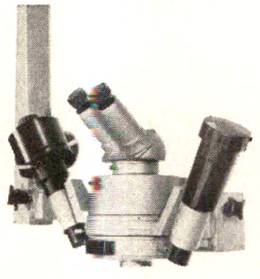
**sterility, economy**
Optemp is sterile as received, eliminates the possibility of cross-infection... battery powered and inexpensive, it saves on resterilization and reprocessing.

Ask for Optemp at your local hospital and see why it's the dependable ophthalmic cautery that meets your needs in every way.

Surgical Products Division — Alcon Laboratories, Inc.

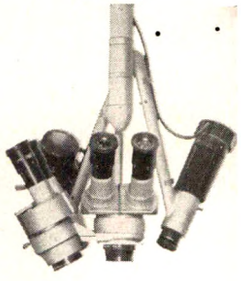


Now any of the seven great Zeiss Operation Microscopes can be suspended from the ceiling of the operating room, providing an unmatched combination of the world's finest optics and the utmost in convenience.



The versatile and precision-engineered Zeiss Electro-Hydraulic Ceiling Suspension System is the device that makes it possible. Since Zeiss operation microscopes are the standards for microsurgery in operating rooms worldwide, the Zeiss engineers have been able to draw upon the broadest base of experience in designing a system to meet both the requirements of the surgeon and the practicalities of the hospital. Let's consider some of the main features of the system—leaving the best for last.

1. Adaptability to any operating room height. Standard equipment for ceilings 9′6″ up to 13′; cus-



OPMI 1

OPMI 2

OPMI 3

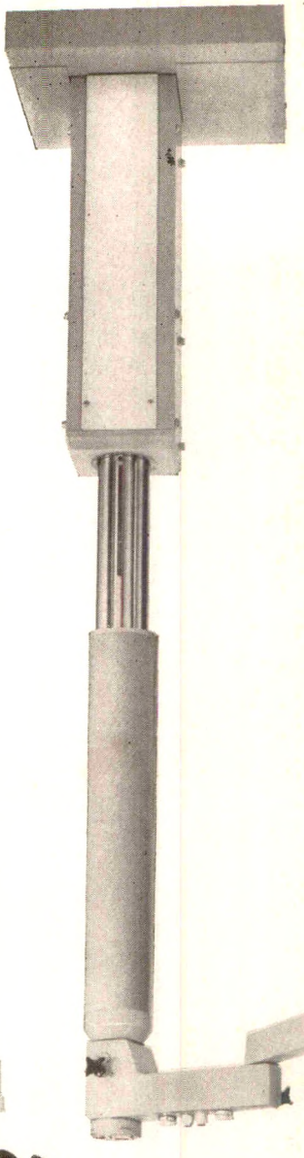
# 7-UP

**OPMI 1**

The microscope that has been used in the development of most currently employed microsurgical procedures. Magnifications from 2.5X to 50X; working distances from 4″ to 16″; direct, internal, shadow-free illumination. Still, motion picture, and television cameras can be attached.

**OPMI 2**

Fully motorized. *Zoom* magnification operated by foot or hand remote control panels. OpMi 2 provides a stereo image of unequalled brightness and edge-to-edge sharpness with continuous magnification. All photographic attachments available.



**OPMI 3 after Barraquer**

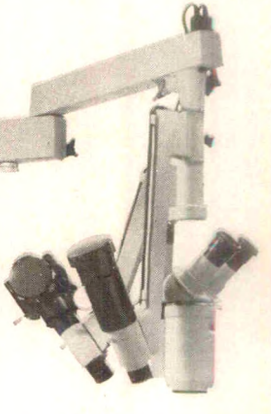
Designed exclusively for ophthalmological surgery, OpMi 3 is the easiest-to-operate microscope made. The exclusive 150/200mm tele-lens provides an unmatched depth of focus and flatness of field. All attachments available, including a special assistant's stereo-microscope with optics of the same high quality as the main one.

**OPMI 4**

A specialized instru-

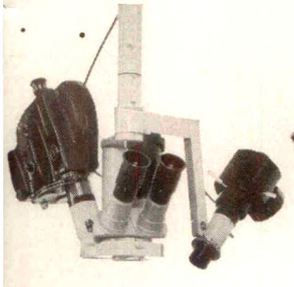
13'ceiling or higher •

tom fittings for higher ceilings. (See illustration.)



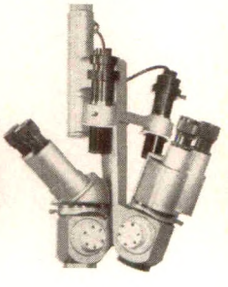
2. Telescoping action through a range of 21" (530mm) to permit surgical fields to be cleared fully and freed when the microscope is not in use.

3. Two telescoping speeds—one for rapid positioning of the microscope along the vertical axis and one for precise positioning. Speeds can be set anywhere up to 30mm/sec.

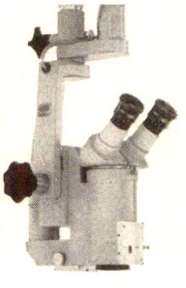


4. Automatic electro-hydraulic control by either hand or foot control panels or both simultaneously.

5. And, most important, the system is fully compatible with any of the seven great Zeiss operation microscopes you may presently own or with any you may add in the future. This feature alone means unequalled versatility. A brief review of the instruments will prove it.



OPMI 7



OPMI 4

OPMI 5

OPMI 6

ment for taking 16mm motion pictures during eye surgery. Adaptable for Urban, Beaulieu or Bolex 16mm movie cameras. Special cine objective for high-resolution close-up work.

**OPMI 5 after Harms**

A double microscope that provides simultaneous binocular observation in the positions most convenient to the tasks at hand—side-by-side, opposite, or anywhere in between. Illumination from two homogeneous illuminators.

**OPMI 6**

A new, versatile operating microscope with coaxial illumination, motorized *zoom* optics and motorized fine focusing. Especially compatible to the requirements of hospitals where the Ear, Nose and Throat Dept. and the Ophthalmology Dept. must both use the same instrument.

**OPMI 7**

A new instrument designed specifically for ophthalmic microsurgery. The vertical microscope body has a built-in *zoom* magnification system with a ratio of 1:5. In addition to all the regular Zeiss accessories, several special ones are available, including an assistant's microscope and a scanning prism.

ZEISS

THE GREAT NAME IN OPTICS

CARL ZEISS WEST GERMANY

ATLANTA, BOSTON, CHICAGO, COLUMBUS, DENVER, HOUSTON, KANSAS CITY, LOS ANGELES, PHILADELPHIA, SAN FRANCISCO, SEATTLE, WASHINGTON, D.C.

Probably not. The repeated washing away of medication residue can cause irritation, too.

But if he's using Vasocidin, there is no medication residue. It's a true solution. Free of irritating particles that crust on the lids and must be washed off.

Vasocidin is an antibacterial, steroid, decongestant combination that works fast because it disperses fast. Helps relieve nonpurulent blepharitis and conjunctivitis more effectively. It's no washout.

**Vasocidin**

Smith, Miller & Patch, Inc., New York

## If he has to keep washing out what you gave him to control nonpurulent blepharitis, is it controlling nonpurulent blepharitis?

**VASOCIDIN**
**ANTIBACTERIAL/STEROID/**
**DECONGESTANT**

**INDICATIONS:** Relief and management of nonpurulent Blepharitis and Conjunctivitis.

**DOSAGE:** Initially, 1 or 2 drops placed in the conjunctival sac every hour until improvement occurs.
Thereafter, 1 or 2 drops 2 to 4 times daily.

**COMPOSITION:**

| | |
|---|---|
| Prednisolone-21-phosphate sodium (Equivalent to Prednisolone 0.2%) | 0.25% |
| Sulfacetamide sodium | 10.0% |
| Phenylephrine HCl | 0.125% |
| Methylparaben | 0.02% |
| Propylparaben | 0.005% |

In a stabilized aqueous solution containing sodium thiosulfate and °SMP-68 (a combination of polyoxyethylene polyoxypropylene compound and polysorbate 80).

**EFFECTIVENESS:** The antibacterial spectrum of Vasocidin is particularly effective against the gram positive pyogenic cocci; E. coli, N. gonorrhoeae, Koch-Weeks bacillus and other bacteria susceptible to sulfacetamide. Because Vasocidin is a true solution, dosage is uniform and each drop is free of any irritating particles. The Vasocidin vehicle enhances the dispersion of active components. Sulfacetamide combats a wide range of pathogens; prednisolone reduces inflammatory reaction; phenylephrine relieves hyperemia. Local effects of active therapeutic agents appear to be prolonged by phenylephrine-induced vasoconstriction.

**CAUTION:** Federal law prohibits dispensing without prescription.

**CONTRAINDICATIONS:** Steroids are contraindicated in dendritic ulcers (herpes simplex), vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, as well as in fungal and tubercular ocular disease. Contraindicated in the treatment of purulent conjunctivitis or blepharitis. Should not be used by persons with narrow-angle glaucoma or those sensitive to sulfonamides. If irritation persists or increases, discontinue use and consult physician.

**SIDE EFFECTS:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.

Vasocidin is sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area with the dropper tip of bottle. Keep container tightly closed.

**SUPPLIED:** Plastic dropper-tipped vials, 5 cc.

# *Kowa* SL
## slit lamp microscope

*The new portable approach to ophthalmic examination.*

The Kowa SL has removed all limitations placed on the use of the slit lamp microscope by conventional, bulky, fixed instrumentation.

Hand-held and fully portable, the Kowa SL permits ophthalmic examination at any time, any place: before or after surgery, at the patient's bedside, in the nursery . . . anywhere.

Yet for all its compactness, light weight, moderate price, and remarkable versatility, it has sacrificed nothing in the way of performance or reliability.

The Kowa SL's optics are the finest; its mechanics and electronics are state-of-the-art; it offers an image bright enough for use in a fully illuminated room.

In short, the Kowa SL is one of the most sophisticated slit lamp microscope systems there is . . . and the *only one* that's fully portable.

For the details on the *new portable approach* to ophthalmic examinations, the Kowa SL, contact the representative in your area.

# Before you buy a $25,000 argon laser photocoagulator, invest 

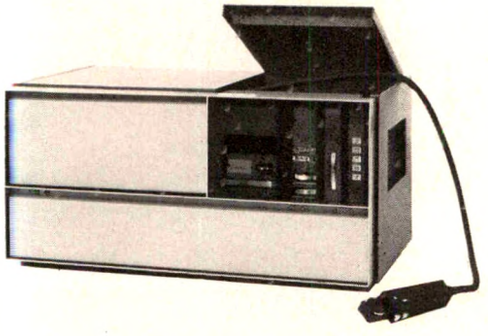
in research.

For such a small investment, you'll discover that our new instrument, with its fiber optics transmission system, is uniquely designed for effective retinal photocoagulation. Here are just a few of the reasons why.

By using fiber optics to transmit argon laser energy, you get significant improvement in operating freedom. The fiber optics cable is lightweight, flexible and reliable. It replaces heavy, rigid, mirror transmission systems.

Fiber optics also results in delivery instrument flexibility. You can now choose the delivery technique best suited to your particular needs, whether it be a slit lamp; a direct viewing, hand-held ophthalmoscope; or an erect image, indirect ophthalmoscope. And changing from one to another only takes a few minutes.

You're also concerned with economy. The simple adapter allows you to attach or detach your slit lamp to the laser quickly and accurately. This means that you don't have to purchase an additional slit lamp for permanent dedication to photocoagulation. And most important for economy, our unit is priced at less than $25,000.



We can't tell you the whole story here, so invest 8¢ in postage and send for the data. And if you're interested in learning more about argon laser photocoagulation, check the box on the coupon. We'll tell you about our regional seminars, clinical discussions to back up your 8¢ investment.

Specific for
Herpes Simplex Keratitis

**STOXIL®**
**brand of IDOXURIDINE**

the only brand of IDU
available in two forms:
Solution—Ointment

Both now available in Canada

# The choice is yours

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.

**Indications:** Only in the treatment of herpes simplex keratitis.

**Description: 'Stoxil' Ophthalmic Solution** contains idoxuridine (5-iodo-2'-deoxyuridine) **0.1% (1 mg./ml.)** in distilled water; sterile when packaged. Preserved with thimerosal, 1:50,000. **'Stoxil' Ophthalmic Ointment** contains idoxuridine **0.5% (5 mg./gram)** in a petrolatum base. (White petrolatum and liquid petrolatum are inactive ingredients.)

**Contraindications:** Contraindicated in patients with known or suspected hypersensitivity to any of its components.

**Precautions:** Some strains of herpes simplex appear to be resistant. If there is no response in *epithelial infections* after 7 or 8 days of treatment, other forms of therapy should be considered.

The recommended frequency and duration of administration should not be exceeded.

'Stoxil' is not effective in corneal inflammations in which the virus is not present.

Corticosteroids are usually contraindicated in herpes simplex keratitis.

Boric acid should not be used during the course of therapy.

'Stoxil' Ophthalmic Solution should not be mixed with other medications.

**Adverse Reactions:** Occasionally, irritation, pain, pruritus, inflammation, edema of the eye or lids and, rarely, allergic reactions have been reported. Photophobia has occurred. Occasionally corneal clouding, stippling and small punctate defects in the corneal epithelium have been observed. The punctate lesions may be a manifestation of the infection.

**How Supplied:** 0.1% Ophthalmic Solution (1 mg./ml.), in 15 ml. bottles with dropper; 0.5% Ophthalmic Ointment (5 mg./gram) in 4 gram tubes.

**Stability:** The Solution should be stored in refrigerator until dispensed. The Ointment does not require refrigeration.

SK&F Smith Kline & French Laboratories

"to make it perfectly clear–"

# Neosporin®

## Ophthalmic Solution, Sterile

polymyxin B–neomycin–gramicidin

Each cc. contains: Aerosporin® brand Polymyxin B Sulfate 5000 units; Neomycin Sulfate 2.5 mg. (equivalent to 1.75 mg. of neomycin base); Gramicidin 0.025 mg., in aqueous saline solution isotonic with tears, containing the inactive ingredients alcohol (0.5%), propylene glycol, polyoxyethylene polyoxypropylene compound, sodium chloride, and purified water (preservative: thimerosal 0.001%). Bottles of 10 cc. with sterile dropper.

## eradicates bacterial conjunctivitis and other eye infections due to susceptible organisms–

- highly effective against almost all pathogens which invade the eye, including *Pseudomonas* and *Staphylococcus aureus*
- bacterial resistance rarely develops on repeated or prolonged use
- low allergenicity
- also available: Neosporin® Ophthalmic Ointment—Each gram contains: Aerosporin® brand Polymyxin B Sulfate 5000 units; Zinc Bacitracin 400 units; Neomycin Sulfate 5 mg. (equivalent to 3.5 mg. neomycin base) in special white petrolatum q.s. In ⅛ oz. tubes with ophthalmic tip.

*Precaution:* As with other antibiotic preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs. Articles in the current medical literature indicate an increase in the prevalence of persons allergic to neomycin. The possibility of such a reaction should be borne in mind.

*Contraindications:* This product is contraindicated for subconjunctival or intraocular injection, or for irrigation of fistulous tracts. This product is also contraindicated in those individuals who have shown hypersensitivity to any of its components.

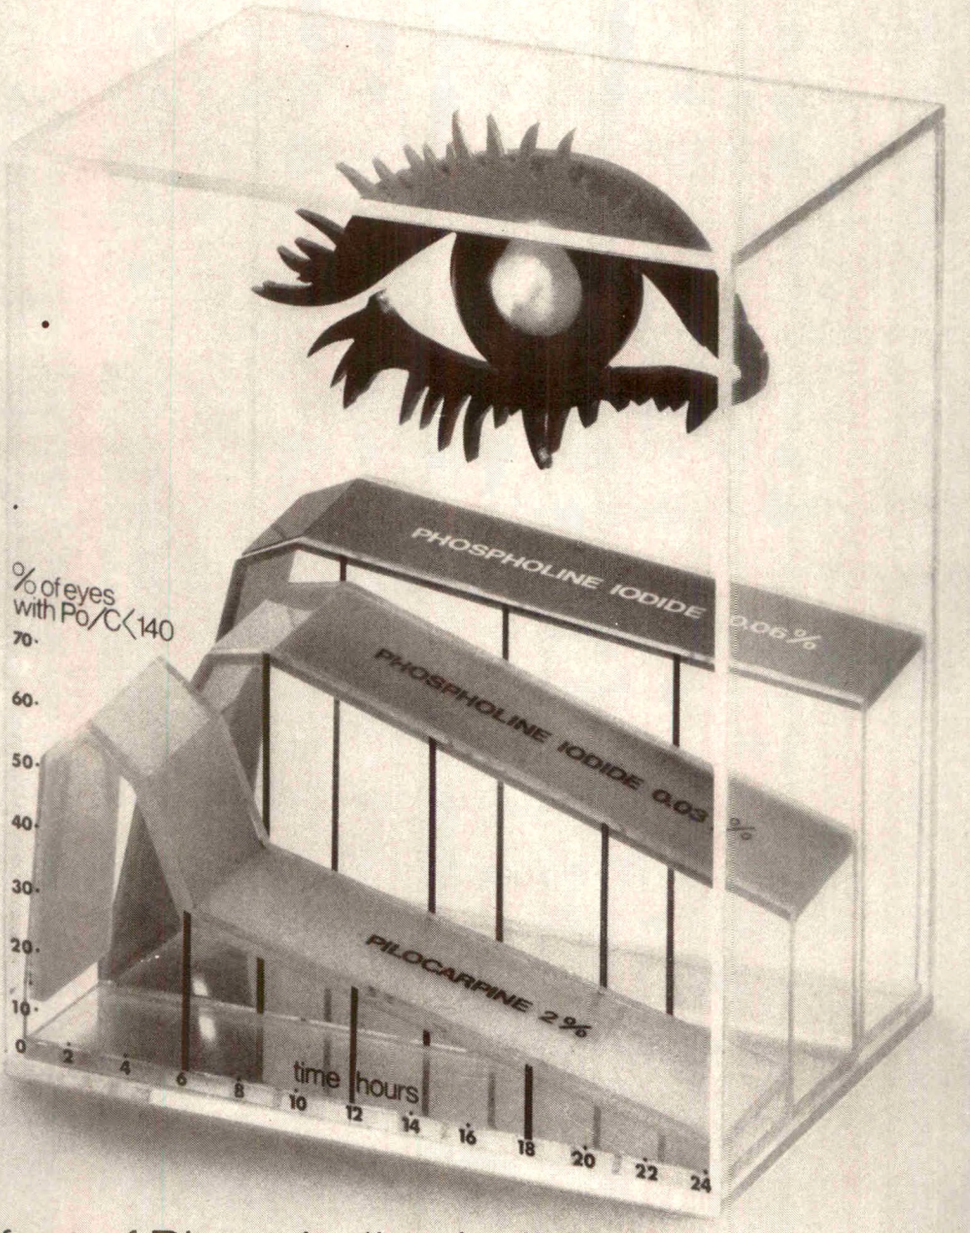
# Not more potent, but longer acting...*

PHOSPHOLINE IODIDE 0.03% and 0.06% were compared with pilocarpine 2% in a study of the time course of changes in outflow facility and intraocular pressure after single dose administration in patients with open-angle glaucoma. While Phospholine Iodide 0.06% showed little diminution in effect on intraocular pressure after 24 hours, the effect of pilocarpine 2% declined markedly in the first few hours, and was almost completely dissipated after 24 hours. The action of Phospholine Iodide 0.03% was intermediate between that of pilocarpine 2% and Phospholine Iodide 0.06%.

## An important consideration in the management of glaucoma



When treated with short acting miotics, the patient with open-angle glaucoma runs the risk of an undetected intraocular pressure buildup during the night—a "silent emergency."

The longer acting Phospholine Iodide® (echothiophate iodide) may protect against this nightly insult. A single instillation of the 0.03% or 0.06% strength before retiring will act through the critical hours, and is especially recommended when you have found pilocarpine to be inadequate.

When initiating therapy... Phospholine Iodide 0.03% can often maintain 24 hour control of intraocular pressure with a single instillation at bedtime. It provides a smooth transition to the higher strengths—0.06%, 0.125%, 0.25% —when necessary. When indicated, epinephrine or carbonic anhydrase inhibitors may be prescribed with any strength of Phospholine Iodide.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide for ophthalmic solution)

Effect of Phospholine Iodide and pilocarpine on intraocular pressure control.

*Adapted from Barsam, P. C., Boston U. School of Med.: Time Curves of the Effect of Miotics on Intraocular Pressure and Outflow Facility, Scientific Exhibit, Annual Convention, American Academy of Ophthalmology and Otolaryngology, Las Vegas, Oct. 5-9, 1970.

See next page for Brief Summary of prescribing information.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide)

for 24 hour control in chronic simple (open-angle) glaucoma and glaucoma secondary to aphakia

just 1 or 2 instillations a day
- for long lasting effect on ocular tension—
helps protect against a "silent emergency" at night
- may be substituted for the bedtime dose of a short acting miotic
that controls intraocular pressure by day, but
fails to provide adequate control during the night and early morning
- choice of four strengths for individualized therapy—
may be used alone or as a complementary agent

**BRIEF SUMMARY (for full prescribing information, consult package circular)**
**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE (echothiophate iodide) concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, browache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local)* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE (echothiophate iodide) therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic)* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

# A little innovation is a big help

**Nothing is quite as satisfying as finding a new way to help the patient.**

**You will help a beginning presbyope** adjust to his bifocal correction by simply adding Press-On™ lenses to his present single vision spectacles. The interim Press-On lenses establish usefulness and acceptance. Also, they will help determine the proper seg height, shape and size before the permanent Rx is produced.

**Reading aids for low vision patients** have been a real problem. Adds above +3.00 have been impractical for everybody concerned. Press-On lenses give you bifocal segments of any size and shape incorporating proper prism to insure comfortable binocular vision. They can be applied in minutes.

**Post-operative cataract patients** are apprehensive. Wouldn't it be a happy innovation to hand these patients their own comfortable glasses with an interim aspheric Press-On lens correction that provides a panoramic field of view. They will see better and look better, immediately.

These are a few examples. Clip the coupon, and we'll send you more ideas plus a Press-On lens for your own use.

All OSG Fresnel lenses provide optimum asphericity regardless of power.

# Introducing
# SWIRL CLEAN™
## electric contact lens cleaner by Contique™

## the professional way to clean contact lenses

Until now, the most common method cleaning contact lenses has been to rub the between the fingers. As you know, this syste has three serious drawbacks: 1) it doesn't clea properly; 2) it *can* scratch or warp lenses; 3) may not be sanitary.

### A new, more efficient technique

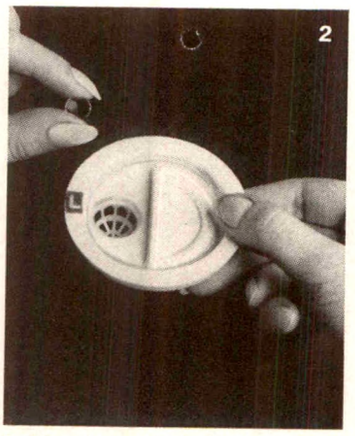
The new Swirl Clean electric contact le cleaner by Contique approaches the problem a totally different manner: It combines th cleaning power of a high-speed agitator wi the detergent action of Contique Cleaning Sol tion. The result is thorough but gentle clea ing—with a minimum of handling and le chance of lens loss.

Swirl Clean doesn't stop there. It provid a convenient place to soak and store lenses b tween wearings.

### Perfect for office use

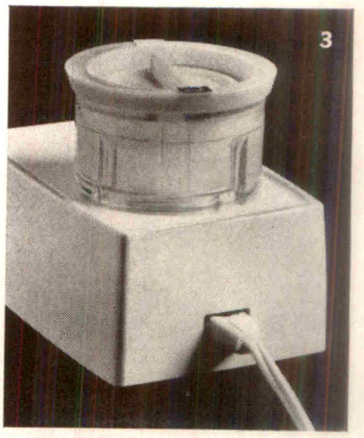
How many times have you wished for ju such an efficient way to clean your patien contacts—when you are delivering a new p or after making an adjustment?

Swirl Clean fills this long-felt need p fectly. It's compact. Easy to use. And it *loo* highly professional. Your patients can s you've gone to the expense of securing the m advanced cleaning device available to ma sure their lenses are clean and comfortable.



And it takes only a few seconds to cle contacts with the Swirl Clean. Once you get in the habit, you'll wonder how you managed wi out it.

### Your patients will want one, too



When they see how effortlessly you cle their contacts with the Swirl Clean, your n contact lens wearers will want one of their o to use at home. That's why it makes good bu ness sense to stock a few units to sell or reco mend to your patients. They'll never be m psychologically receptive than at the mom

*Fill cleaning chamber ¾ full with old water. Add 6-8 drops of Contique Cleaning Solution and place on base.*

**2** *Place lenses in bottom of clearly marked LEFT and RIGHT baskets of lens holder. Close lid. Place lens holder on cleaning chamber.*

**3** *Flip "ON" switch and run Swirl Clean 30-60 seconds. You can see the lenses being swirled clean before your eyes.*

hey get their new contacts. It's also a good way of starting them off on a proper lens-care regimen and helping them become satisfied wearers.

### Read what Swirl Clean users say

• An O.D. in Knoxville, Tenn. writes: "The compactness of this unit makes its use a pleasure in my office." An M.D. in Bakersfield, Calif. calls Swirl Clean "a very valuable asset to our office." An optician in Long Beach, Calif.: "Excellent method of cleaning lenses after lab adjustment."

Enthusiastic comments have also come in from contact lens wearers all over the country. "My vision is so much better with clean contacts." (Boston, Pa.) "I enjoy its convenience and notice my lenses are more comfortable." (East Point, Ga.) "Cleans lenses 100% better than by hand." (Hyde Park, Mass.) "I wear lenses 16 hours a day and find their comfort greatly increased." (Indianapolis, Ind.)

These comments are on file at Alcon Laboratories and may be examined by anyone interested.

### Complete lens care by Contique

Used with the new Swirl Clean, *Contique Cleaning Solution* dissolves eye-irritating deposits such as mucus, oil and film. Yet it's so gentle you can recommend it with complete confidence. *Contique Soaking Solution* "conditions" lenses by keeping them chemically moist when stored in the special Swirl Clean soaking dish, increasing wettability and wearing comfort. *Contique Wetting Solution* creates a liquid cushion between lens and eyes, makes placement smooth and easy, and can also be used to re-wet lenses during the day.

This family of lens care products from Contique can help your patients become successful, satisfied contact lens wearers. Almost $6 worth of Contique solutions are packed with every Swirl Clean at no additional cost. For more information about the new Swirl Clean and other Contique products, call your optical wholesaler today.

# Fly now. Pay later.

And he will. Wind, cold and glare on the slopes make for red, watery eyes back at the lodge. If he hasn't got goggles, he should have Vasocon-A. Long-acting vasoconstrictor, decongestant, antihistamine combination. It relieves the burning, itching and watering of windblown eyes. Reduces conjunctival hyperemia in all minor eye irritations. Helps with contact lens insertion and removal, as well. Vasocon-A. It's the only way to fly.

Smith, Miller & Patch, Inc., New York

CAUTION: Federal law prohibits dispensing without prescription. See package insert before prescribing.

COMPOSITION: Naphazoline HCl 0.05%; antazoline, 0.5%; boric acid, 1.2%; sodium carbonate anhydrous; sodium chloride; phenylmercuric acetate (preservative) 0.002%.

SIDE EFFECTS: Except for transitory stinging, side effects have rarely been encountered.

CONTRAINDICATIONS: Should not be used by patients with narrow angle glaucoma. If irritation persists or increases, patient should be advised to discontinue use and return to physician.

SUPPLIED: 15 cc dropper-tip vials.

## Vasocon-A

Smith, Miller & Patch, Inc., New York

# COVELLI CRYOEXTRACTOR

FOR CATARACTS

*Now available...*

ACTUAL SIZE

## NO MORE ACCIDENTAL ADHESIONS!

ONCE YOU GRASP THE LENS, AT NO TIME DOES THE IRIS OR ANY OTHER TISSUE ADHERE TO THE PROBE, EVEN WHEN THERE IS DIRECT CONTACT!. THIS EXCEPTIONAL ADVANTAGE IS DUE TO ITS SPECIALLY DESIGNED TIP.

OTHER IMPORTANT ADVANTAGES

- Thin tip (2.75 mm.) with special shape for better visibility.
- Light weight (11 g.) Just like your ball pen.
- Heat - resistant, so it can be autoclaved repeatedly.
- Durable, it can be used a great number of times.
- Rechargeable, uses gas *"FREON" 12; commercially available.
- Low price.

soflens™
CONTACT LENS
(polymacon)
See full prescribing information which follows.

Conventional methods of fitting contact lenses do not apply to SOFLENS Contact Lenses (polymacon). For a detailed description of the fitting technique, refer to the SOFLENS Fitting Guide, copies of which are available from: SOFLENS Division, Bausch & Lomb Incorporated, Rochester, New York 14602.

**DESCRIPTION:** The SOFLENS Contact Lens (polymacon) is a hemispherical shell of approximately 13mm chord diameter and 0.1 to 1.0mm thickness. It consists of 61.4% poly (2-hydroxyethyl methacrylate) and 38.6% water by weight when immersed in normal saline. The SOFLENS Care Kit is a package required for lens asepticizing, cleaning, and storage consisting of the following:

| | |
|---|---|
| SOFLENS Carrying Case | Cat. #140301 |
| SOFLENS Aseptor-Patient Unit | Cat. #140302 |
| SOFLENS Squeeze Bottle | Cat. #140304 |
| SOFLENS Salt Tablets | Cat. #140305 |
| SOFLENS Patient Instruction Book | Cat. #140300-100 |

**ACTIONS:** The SOFLENS Contact Lens (polymacon) absorbs water to 38.6% of its dry weight when equilibrated in normal saline solution. In its hydrated state a SOFLENS Contact Lens (polymacon) becomes soft and pliable. When placed on the human cornea the hydrated SOFLENS Contact Lens (polymacon) acts as a refracting medium to compensate spherical ametropias. The material has a refractive index of 1.43 and the lens has a visible light transmittance greater than 97%.

**INDICATIONS:** SOFLENS Contact Lenses (polymacon) are indicated for the correction of visual acuity in persons with non-diseased eyes who have spherical ametropias; refractive astigmatism of 1.50 diopters or less and/or corneal astigmatism of 2.00 diopters or less.

**CONTRAINDICATIONS:** SOFLENS Contact Lenses (polymacon) are contraindicated by the presence of any of the following conditions. (1) Acute and subacute inflammations of the anterior segment of the eye. (2) Any eye disease which affects the cornea or conjunctiva. (3) Insufficiency of lacrimal secretion. (4) Corneal hypoesthesia. (5) Any systemic disease which may affect the eye or be exaggerated by wearing contact lenses. (6) Early stages of pregnancy.

**WARNINGS: Medicants and Eye Drops**—SOFLENS Contact Lens (polymacon) must be stored ONLY in normal saline solution. No ophthalmic solutions or medicants, including conventional contact lens solutions, can be used by SOFLENS Contact Lens (polymacon) wearers prior to or while the lens is in place on the eye. Also, no solutions, including conventional contact lens solutions, other than normal saline may be used on SOFLENS when the lens is off the eye.

**Abrasions and Infections**—If the lenses become less comfortable to the wearer than when they were first placed on the wearer's corneas, this may indicate the presence of a foreign body. The lens should be removed immediately and the patient examined. If any eye abrasion, ulceration, irritation or infection is present, a physician should be consulted immediately.

**Wearing Restrictions**—SOFLENS Contact Lenses (polymacon) should be removed before sleeping or swimming and in the presence of noxious and irritating vapors.

**Visual Blurring**—When visual blurring occurs the lens must be removed until the condition subsides.

**Lens Sanitation**—Patients who would not or could not adhere to recommended daily sanitary care of SOFLENS Contact Lenses (polymacon) should not be provided with them.

**PRECAUTIONS: Storage**—SOFLENS Contact Lenses (polymacon) must be stored ONLY in normal saline solution. If left exposed to air, the lenses will dehydrate, become brittle, and break readily. If a lens dehydrates, it should be soaked in normal saline solution until it returns to a soft, supple state.

**Cleaning and Asepticizing**—SOFLENS Contact Lenses (polymacon) must be BOTH cleaned and asepticized daily. One procedure does not replace the other. CLEANING is necessary to remove mucus and film from the lens surface. ASEPTICIZING with the SOFLENS Aseptor-Patient Unit has been shown to prevent the growth of certain organisms, namely Staphylococcus aureus, Pseudomonas aeruginosa, Bacillus subtilis, Candida albicans, and Herpes simplex, on the lens and in the SOFLENS Carrying Case. Fresh normal saline must be prepared daily for cleaning and storing the lenses. The carrying case must be emptied and refilled with fresh normal saline solution just before asepticizing the lenses. If a SOFLENS Aseptor-Patient Unit is not available for asepticizing the lenses, the lenses must be boiled in their carrying case in a pan of water for 15 minutes.

**Hygiene**—Hands must be washed, rinsed thoroughly, and dried with a lint-free towel before handling the lenses. Cosmetics, lotions, soaps, and creams must not come in contact with the lenses since eye irritation may result. If hair spray is used while the lenses are being worn, the eyes must be kept closed until the hair spray has settled.

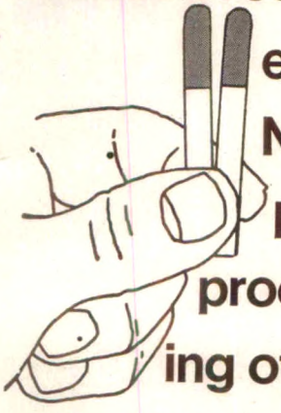
**Fluorescein**—Never use fluorescein while the patient is wearing the lenses because the lenses will become discolored. Whenever fluorescein is used, flush the eyes with normal saline solution and wait at least one hour before replacing the lenses. Too early replacement may allow the lenses to absorb residual fluorescein irreversibly.

**ADVERSE REACTIONS:** Serious corneal damage may result from wearing a lens which has been soaked in a conventional contact lens solution containing preservatives. Eye irritation may occur within a short time after putting on a hypertonic lens. Removal of the lens will relieve the irritation. Very rarely a lens may adhere to an eye as a result of the patient sleeping with the lens on or wearing a hypotonic lens. If a lens adheres for any reason, apply normal saline and wait until the lens moves freely before removing it. Clinical studies indicate visual blurring is experienced by less than 5% of SOFLENS Contact Lens (polymacon) wearers. Rainbows or halos around objects or blurring of the vision may occur if the lenses are worn continuously for too long a time. Removal of the lenses and a rest period of at least one hour generally relieves these symptoms. Excessive tearing, unusual eye secretions, and photophobia are not normal; if these symptoms occur, the patient should be examined to determine their cause.

**DOSAGE AND ADMINISTRATION:** There may be a tendency for the patient to overwear the lenses initially. Therefore, the importance of adhering to the following initial daily wearing schedule should be stressed to the patient:

| Day | Wear Time (hours) | Rest Period (hours) | Wear Time (hours) | Rest Period (hours) | Wear Time (hours) |
|---|---|---|---|---|---|
| 1 | 3 | 1 | 3 | 1 | 3 |
| 2 | 3 | 1 | 3 | 1 | 3 |
| 3 | 4 | 1 | 4 | 1 | 4 |
| 4 | 4 | 1 | 4 | 1 | 4 |
| 5 | 6 | 1 | 6 | 1 | 4 |
| 6 | 6 | 1 | 6 | 1 | 4 |
| 7 | 8 | 1 | 8 | | |
| 8 | 8 | 1 | 8 | | |
| 9 | 8 | 1 | 8 | | |
| 10 | 10 | 1 | balance of the waking hours* | | |
| 11 | 12 | 1 | balance of the waking hours* | | |
| 12 | 14 | 1 | balance of the waking hours* | | |

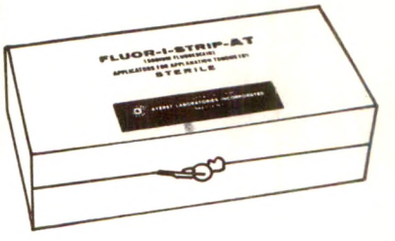
*Lenses should never be worn 24 hours a day.



Care must be taken on the initial visit to assure that the patient is supplied with a SOFLENS Care Kit and fully understands all care and handling instructions for the lenses. As with any contact lens, regular recall visits are necessary to assure patient health and compliance with instructions.

**HOW SUPPLIED:** Each lens is supplied sterile in a glass vial containing sterile normal saline solution. The glass vial is marked with the dioptric power (black for plus power lenses; red for minus) and the manufacturing lot number of the lens. To assure proper lens care and handling, each SOFLENS patient must be supplied with a complete SOFLENS Care Kit.

**BAUSCH & LOMB**
SOFLENS DIVISION



**When fitting contact lenses: to guard against the risk of infection inherent in the use of sodium fluorescein solutions, stain eyes with sterile Fluor-I-Strip-A.T. No excess fluorescein to stain the patient's face or clothing...water-proof grip to prevent staining of your fingers. Simply retract upper lid, apply dry orange tip of flexible applicator to the bulbar conjunctiva at the temporal side. For all these benefits: Specify Ayerst**

**FLUOR-I-STRIP®-A.T. (sodium fluorescein)**
**STERILE OPHTHALMIC APPLICATORS.**

*Each applicator contains* not less than 1.0 mg. sodium fluorescein—provided by precise impregnation with a solution of sodium fluorescein and 0.5% chlorobutanol (chloral derivative), polysorbate 80, boric acid, potassium chloride, and sodium carbonate. *Supplied:* No. 1048—Boxes of 100 envelopes, each envelope containing 2 firm sterile applicators—one for each eye.

OPHTHALMOS DIVISION

The Ophthalmos Division
AYERST LABORATORIES
New York, N.Y. 10017

7047

**Composition:**

**Inflamase**

*Prednisolone Sodium Phosphate .....0.125%
(Equivalent to Prednisolone 0.1%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

**Inflamase Forte**

*Prednisolone Sodium Phosphate 1.0%
(Equivalent to Prednisolone 0.8%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

Prednisolone Sodium Phosphate is a water soluble inorganic ester of prednisolone. It is approximately 2,000 times as soluble in water at 25°C. as is hydrocortisone.

*Licensed under patent #3,134,718.

**Indications:** Inflamase and Inflamase Forte ophthalmic solutions may be used effectively in the following conditions of the anterior segment of the eye: superficial keratitis, including punctate epithelial lesions (Thygeson type), phlyctenular keratoconjunctivitis, and Sjogren's keratoconjunctivitis (with systemic steroids); deep keratitis, including interstitial or parenchymatous keratitis, acne rosacea, sclerosing keratitis; herpes zoster opthalmicus (do not use in herpes simplex); non-purulent conjunctivitis, including vernal, allergic, catarrhal; iridocyclitis; acute iritis; recurrent marginal ulceration, whether endogenous or due to atopic or contact allergies, or microbial allergy; corneal injuries, such as aseptic thermal, radiation, or chemical burns and corneal injuries following surgery or the penetration of foreign bodies; lid allergy; and non-purulent blepheritis, including catarrhal and allergic.

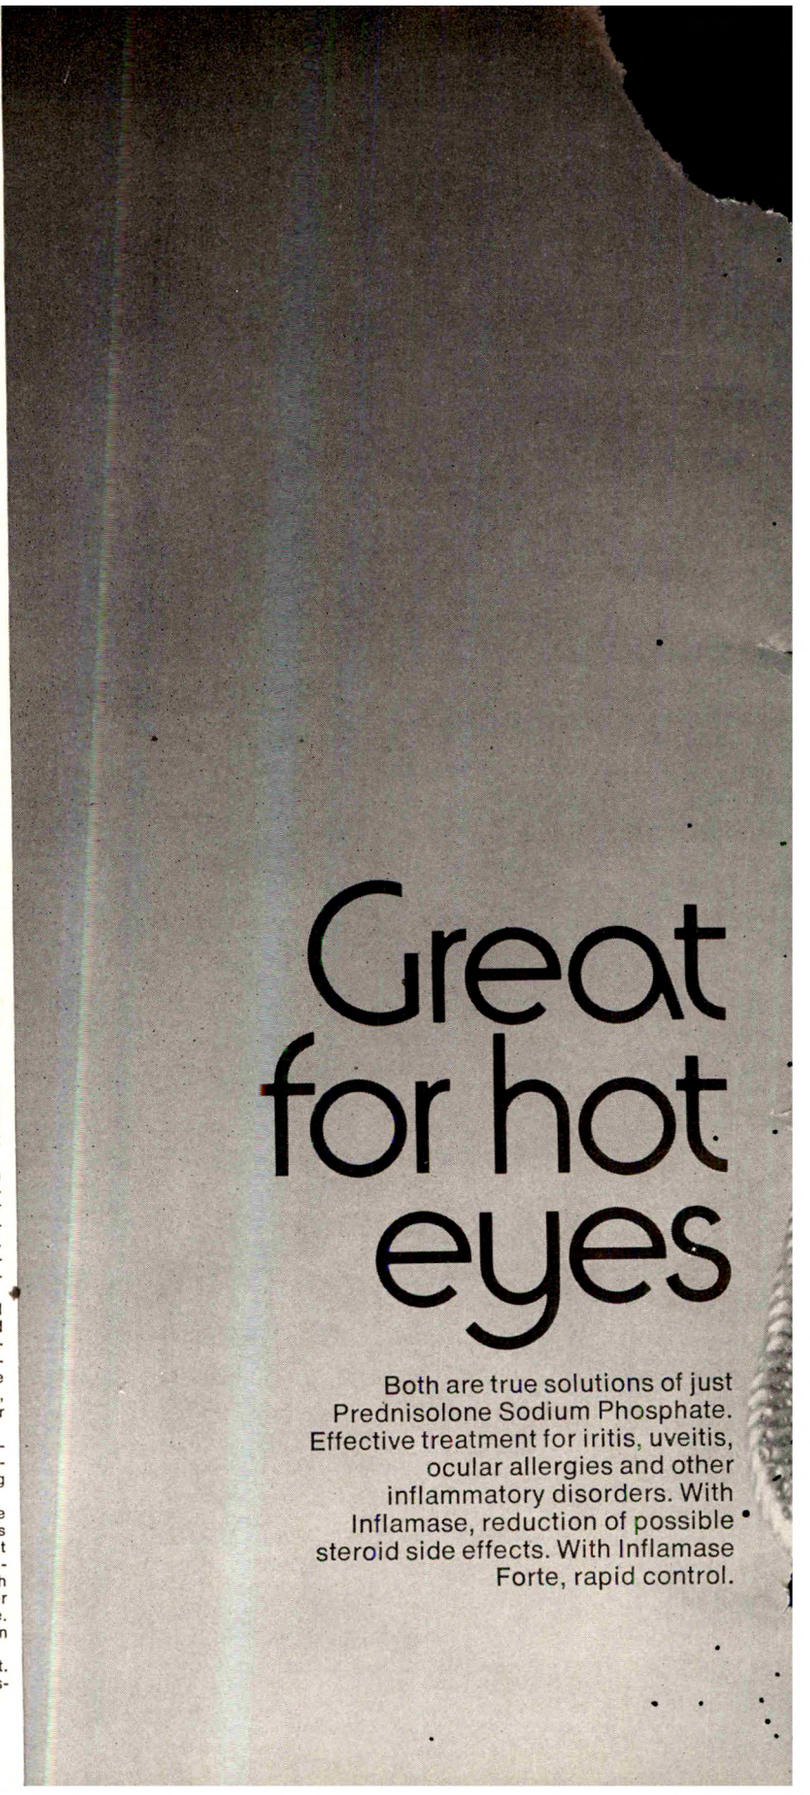
Inflamase and Inflamase Forte ophthalmic solutions have their principal effect on the anterior segment of the eye (cornea and the anterior uvea), with acute disorders responding more favorably than chronic disorders. Inflamase Forte 1% solution is recommended for moderate to severe inflammations particularly when rapid control is desired. In stubborn cases of anterior segment eye disease, systemic adrenocortical hormone therapy may be required. When the deeper ocular structures are involved, systemic therapy is necessary.

**Dosage:** Initially, 1 or 2 drops placed in conjunctival sac every hour during day and every 2 hours during night until improvement occurs. Thereafter, 1 or 2 drops 2 to 4 times daily.

**Contraindications:** Contraindicated in acute herpes simplex, ocular tuberculosis, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva; fungal diseases of the eye. Purulent conjunctivitis, purulent blepharitis, and infectious conditions are contraindications to the use of steroids.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.

**Warning:** If irritation persists or develops, patient should be advised to discontinue use and consult prescribing physician.



**How Supplied:** 5 cc plastic squeeze bottle with dropper tip. These products are sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area, or other areas with the dropper tip of the bottle. Keep bottle tightly closed when not in use.

Store in cool place. Protect from light.

**Caution:** Federal law prohibits dispensing without prescription.

# CONTACT LENSES AND THE APHAKIC PATIENT

## Part 4: Fitting Considerations

Aphakic lenses, like all corneal contact lenses, can be satisfactorily fitted in a wide range of sizes, provided that the other variables are adjusted accordingly. The smaller the diameter, the "looser" the lens, thus, for sufficient adhesion, it must be made steeper, thinner, and/or with a larger optical zone. Conversely, a large lens tends to be "tight"; thus, to avoid interference with tear interchange, we can compensate by making it flatter, thicker, and/or with a smaller optical zone. Occasionally, a large diameter lens may even require auxiliary venting, using apertures or channels.

The practitioner accustomed to fitting conventional diameter lenses (9.0 mm to 9.8 mm) can compensate for the extra weight of aphakic lenses in one of two ways:

(1) Order base curves one-half diopter steeper than usual, all other specifications being the same (except thickness).

(2) Order diameters .4 mm to .6 mm larger than usual, all other specifications being the same (except thickness).

Either way, the MINUS-CARRIER LENTICULAR LENS should be used when dealing with a keyhole pupil and some upper lid cover, or with a low lower lid. The TP (TANGENTIAL PERIPHERY) LENS is preferred when the patient has a small, round pupil, especially in conjunction with a tight upper lid.

Turning now to small lens fitting: Good results with aphakics depend on reducing lens weight to a minimum. This is best achieved with the MINUS-CARRIER LENTICULAR LENS made with a small (preferably 7.0 mm) anterior optical zone. The base curve should be 0.25 to 0.50 D. steeper than usual for a small thin lens of the same diameter (see my monograph "Small, Thin Contact Lenses," page 4, table II). If the LENTICULAR LENS does not center properly due to lid effects, then a TP (TANGENTIAL PERIPHERY) LENS should be tried, made to the same specifications (except that the thickness will be about .10 mm greater due to the tangential design).

In cases of "against the rule" corneal astigmatism of more than 2.00 D., if proper centering is not attainable with spherical lenses, then inside toric lenses should be considered. In cases where the effective pupil size is too large for coverage by a LENTICULAR LENS, we can sometimes use a small SINGLE-CUT LENS made without peripheral curves (lens diameter = optical zone) so that the entire lens is optimally functional. It should always be borne in mind that small lenses must have more perfect centering than other types; otherwise, they cannot be used successfully.

E. WILLIAM TILLYER

# Photochromic glass

In recent years, photochromic glass lenses have become extremely popular. A review of this material's characteristics and ways of handling it seem appropriate at this time.

Briefly, photochromic glasses are those glasses whose transmissions are changed by the increase or decrease of broad or narrow bands of light emission. In our industry, the most widely recognized glass is Photogray® glass made by Corning Glass Works.

In Photogray glass, silver halides are buried within the glass. These halides darken when exposed to ultraviolet light. When the ultraviolet source is removed, the halides gradually fade and the glass returns to a lighter shade.

Ultraviolet light is the only light transmission that causes the on-off effect. Photogray glass does not absorb infrared heat rays. In fact, infrared transmission (heat) somewhat inhibits the effect. When exposed to direct sunlight at 77°F., transmittance drops to 45%. When exposed to sunlight at 34°F., transmittance drops to 34%. This is the reason why Photogray glass acts faster, and more completely, on cold sunny days than it does on hot sunny days.

Before being exposed to ultraviolet, Photogray lenses have a slightly greenish hue. After exposure—and removal from the exposure—Photogray lenses return to a pinkish color (similar to our Cruxite® AX lenses). Transmission is about 85%.

That is why a new prescription lens does not match a lens which has undergone several exposures. And why we recommend pre-exposure to sunlight, or other ultraviolet source, before giving a replacement lens to the patient. Exposing the lens several times usually produces an excellent match.

Photogray lenses do not darken appreciably when worn while driving. The automobile windshield and windows cut out most of the ultraviolet rays in the area where Photogray is activated.

Photogray lenses can be heat treated on standard machines, provided the proper time/temperature tables are used. But they will not activate completely unless you closely follow the tables. Reducing the heat and time below the recommended limits may curtail the activity of the glass.

We have had some success with colored metallic oxide vacuum coatings (Ultracoat) on the rear surface. This slightly reduces the range of activation but provides a darker lens to start with.

Photogray lenses cannot be fused and fused bifocals are not available. However, this shouldn't cause problems because the one-piece Executive® bifocal lens—with all its innate advantages—is available in Photogray.

# are your contact lens patients afraid of you, doctor?

How about those who lose a lens and never report it to you? Or those who go back to eyeglasses without consulting you? Maybe they simply quit wearing contacts; or maybe they'll go to another specialist for a replacement after a loss.

Either way you both lose. They lose time, money and the benefits that contacts could have given them. You lose a contact lens patient—maybe even the entire patient. The inconvenience and expense of replacing lost lenses are two things your patients don't have to put up with.

RLI can prevent these unknowns from happening to either one of you. We'll be happy to supply you with complete details. Your patients need never be afraid of returning to you for a replacement lens again. Let us prove it! Contact RLI today.

# SUPRAMID EXTRA®

**SUTURE.** Polyfilament but neither braided nor twisted. New cable-type construction with several strands enclosed in a perfectly smooth cover of the same material, gives great pliability and superior strength. Strong as steel wire, handles as silk. No stitch irritation, no growth of tissue into suture. Sizes 10-0 to 8.

**SPECIAL NEEDLES:** Our CT needle for cataracts (wire size 0.30mm, length 9mm), CA needle for corneal work (wire size 0.30mm, length 6mm), and EX needle for special keratoplasties (wire size 0.2mm, length 5mm), a flattened reverse cutting needle to prevent "leaking wounds," equal to the smallest hand made eyed needles No. 82F, **and finally the smallest spatula needle on the market, length 5 millimeters, wire size 0.2mm, double armed with 10-0, 9-0 and 8-0 black Supramid Extra. Code Nos. 2SC-100, 2SC-90 and 2SC-80.**

**A NEW PRODUCT:** Implants—Sleeves (Tubes) for preventing adhesions in Eye Muscle Surgery. Method development by Edward A. Dunlap, M.D. Reference: Dunlap, Edward A.: Plastic Implants in Muscle Surgery, Archives of Ophthalmology, 80: 249-257, August 1968.

**TUBING.** *Fully inert because it is made of the same material as the suture;
* Thinnest walls of any surgical tubing, fully transparent and can be *repeatedly* autoclaved;
* Most economical. It is in your interest to compare prices and quality.

**FOIL.** Excellent results with our suture created the demand for Foil for plastic and reconstructive surgery in such cases as orbital fractures, lid reconstruction, etc. Foil is chemically identical with the sutures, thus just as inert when buried in the tissue.

Available in thickness from 0.05mm to 2.00mm, in sheets 15 x 20cm.

Can be steam-autoclaved, cut to size, and carved to shapes and forms.

# It's been helping to save sight for a long time

And DIAMOX does not interfere with other forms of glaucoma therapy which influence the outflow mechanism. In fact, a complementary effect may be obtained when DIAMOX is used in conjunction with miotics.

Treatment with DIAMOX may retard progress of glaucoma by reducing secretion of aqueous humor and thus intraocular pressure. With DIAMOX SEQUELS, acetazolamide is slowly released, and concentrations peak at 8 to 12 hours. A single dose may provide a therapeutic effect for as long as 18 to 24 hours. It is thus possible to maintain the inhibitory effect on aqueous humor formation with a twice-daily regimen . . . an important consideration for the patient's rest and for minimization of side effects.

**DIAMOX®**
ACETAZOLAMIDE
**SEQUELS®** 500 mg
Sustained Release Capsules

**Contraindications**—Situations in which sodium and/or potassium serum levels are depressed, in kidney and liver disease or dysfunction, suprarenal gland failure and hyperchloremic acidosis. Long-term administration is contraindicated in chronic noncongestive angle closure glaucoma.

**Warning**—Although teratogenic and embryocidal effects demonstrated in mice at more than ten times the equivalent therapeutic doses have not been evidenced in humans, DIAMOX Acetazolamide should not be used in pregnancy, especially during the first trimester, unless the expected benefits outweigh these potential adverse effects.

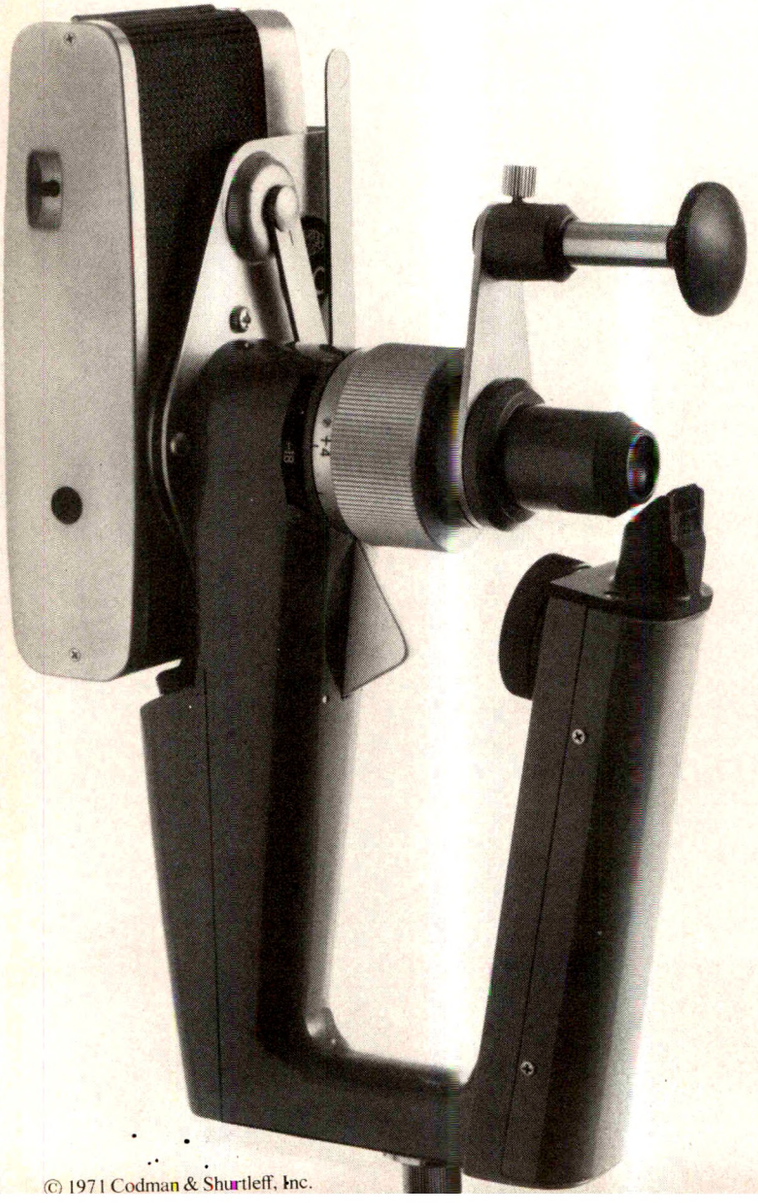
**Precautions**—Increasing the dose may increase drowsiness and paresthesia and decrease diuresis. Reactions common to sulfonamides may occur: fever, rash, crystalluria, renal calculus, bone marrow depression, thrombocytopenic purpura, hemolytic anemia, leukopenia, pancytopenia, agranulocytosis. If such occur, discontinue drug and institute appropriate therapy.

**Side Effects**—During short-term therapy: paresthesias, loss of appetite, polyuria, drowsiness, confusion. In long-term therapy an acidotic state may supervene. Transient myopia has been reported. Other occasional reactions: urticaria, melena, hematuria, glycosuria, hepatic insufficiency, flaccid paralysis, convulsions.

354-1

Lederle LEDERLE LABORATORIES, A Division of American Cyanamid Company, Pearl River, New York 10965

Modern materials and design techniques have made this camera more versatile and easier to use than older types, and lowered the cost as well.



The Olympus Fundus Camera from Mentor is light, compact, balanced – ideal for office diagnosis and records. No additional apparatus is required for very sharp, evenly illuminated photographs – regardless of patient or camera movement.

Trigger, lens selection, and fine focusing are controlled by one hand while you view the area of interest through a bright, clear viewing system. Diopter settings range from +16 to −22 (making external photographs possible) including ±4 of fine focus. Newly developed objective optics completely eliminate spurious light reflections and produce excellent color records – 40 on a standard 20-exposure roll.

There is nothing like the Olympus Fundus Camera from Mentor and there is nothing like its price: $985 complete. Write for full information. Mentor Division, Codman & Shurtleff, Inc., Randolph, Mass. 02368.

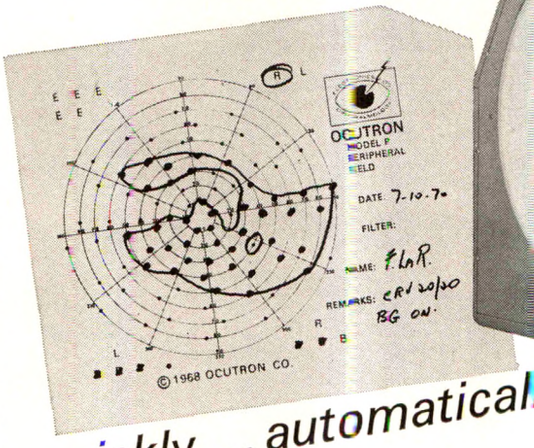
# MURO
# GONIO-GEL

A STERILE GEL OF METHYLCELLULOSE 4000 cps 2.5%
Preservatives: Methylparaben and Propylparaben

## VALUABLE FOR BONDING OF GONIOSCOPIC PRISMS TO THE CORNEA

- Simplifies gonioscopy in upright and recumbent positions
- Reduces fluid spillage
- Helps maintain a tight lens fit
- Index of refraction 1.336



Apply small amount of Gel to inner surface of Gonio lens.
Available in ⅛ ounce ophthalmic tubes.

# *Now* OCUTRON®

## *offers you visual fields*

...whenever you want
...as often as you want
without your being there

U.S. Patent Nos. 3,288,546
and 3,421,498

## *quickly...automatically!*

The Ocutron® Visual Field Tester, developed by a leading ophthalmologist, is a highly precise electronic instrument that automatically examines the visual field and records it permanently on the standard chart that you are accustomed to using and interpreting.

Without the presence of doctor or nurse, the patient tests himself by push-button response to stimuli of standard light targets as they appear within the white hemisphere. This response is electrically registered on the chart.

Difficult and time-consuming fields like the above glaucoma field are as easily and quickly tested as a simple normal field.

Background may be lighted or not, as desired, for light or dark adapted fields. Built-in check on patient fixation and patient reliability.

Particularly suitable for high volume performance. Simple enough for screening. Accurate enough for definitive, repeatable field study.

For further information write for new literature
or contact your ophthalmic distributor.

# NEVER BEFORE . . . have all these features been included in one Ophthalmoscope.

***Check them:***

- ☐ Better view of macula with less reflection.
- ☐ Stereoscopic observation around opacities in the transparent media.
- ☐ Maximum stereopsis at all times commensurate with the size of the pupil.
- ☐ Now, after many years of research, one instrument[1] affords the best features for routine indirect ophthalmoscopy with the possibility of binocular viewing through pupils as small as 1.5 mm.
- ☐ Better illumination for viewing the fundus periphery.
- ☐ Adjustable diaphragms in the eyepieces insure easy and exact alignment of the ophthalmoscope both vertically and horizontally to prevent diplopia.
- ☐ A special optical system minimizes light loss and conducts most of the available light into the pupil.
- ☐ Built-in infrared filter prevents unnecessary heating of fundus tissues and makes examination far more comfortable for the patient.
- ☐ Eyepieces incorporating any lens corrections to suit the observer's prescription may easily be inserted and removed.
- ☐ Unusually large mirror attachment enables a second observer to view stereoscopically from either side of the primary observer.
- ☐ Headband is designed for comfort. Weight of the instrument is distributed over a large portion of any head to minimize the discomfort of wearing an instrument on the head for a prolonged period.
- ☐ All optical elements are completely enclosed and dust free.
- ☐ Lamp alignment knobs to focus filament are conveniently located outside the instruments.
- ☐ Intensity of illumination is continuously adjustable with a rheostat on the headband.
- ☐ Lamp housing is specifically designed to remain cool. Even after prolonged use it is not hot to the touch; there is a minimum of heat transmitted to the doctor's forehead.
- ☐ Filter is available for fluorescein study.

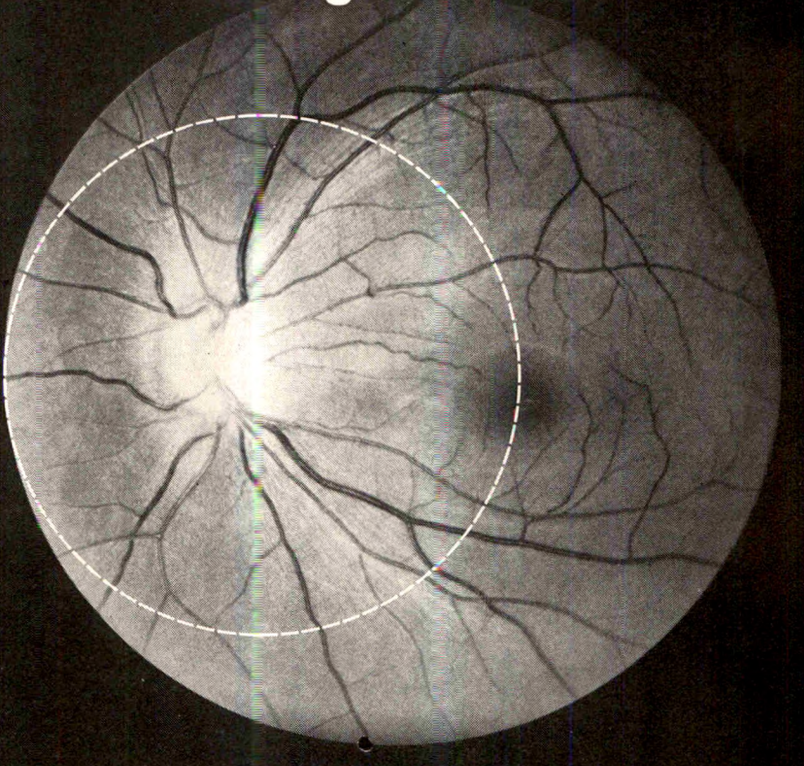
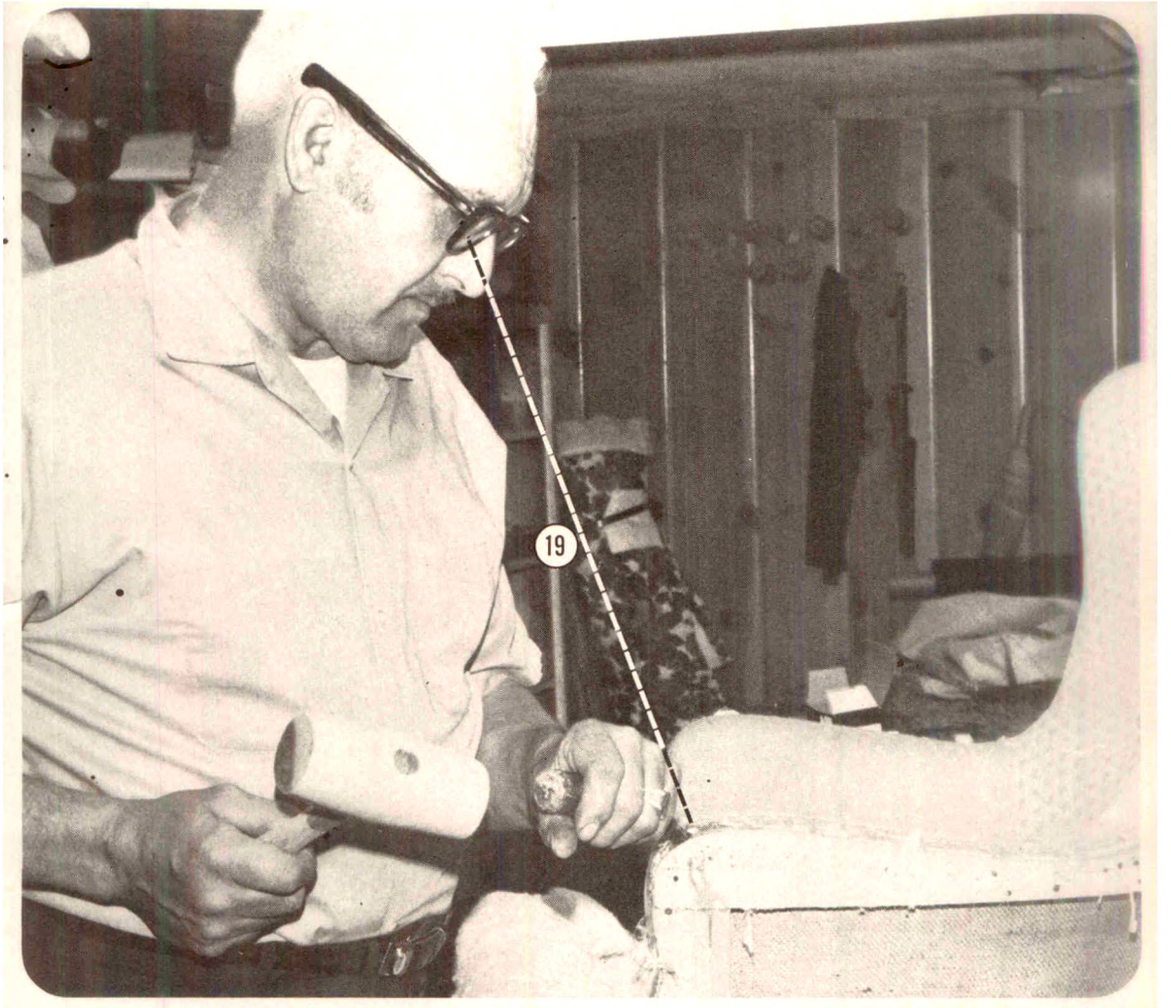
Up to twice as much coverage of the retina as any other fundus camera offers—that's just one advantage of the unique Nikon Retinapan-45 Table Fundus Camera.



Simple to operate and producing photographic images of startling clarity, this new camera is ideal for hospital investigation. Opthalmologists can also make excellent use of it in their own offices.



An integral electronic flash system provides high-intensity light with uniform edge-to-edge brightness. Fluorescent photography is made more effective than ever before. And you can switch over instantly from manual or motorized 35mm photography to 3¼ x 4¼ Polaroid®.

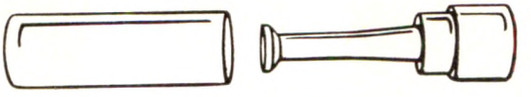
*Occupational Vision Studies*
*(From Study #27, Volume II, Guide to Occupational and Other Visual Needs)*

# Upholsterer

Much of the upholsterer's work utilizes his near and intermediate vision, often in awkward positions. Because of the nature of his work and the conditions under which he performs his tasks, the upholsterer often will require larger-than-normal segs if he is a presbyope.

Details of the upholsterer's vision needs are fully outlined in the study referred to at left and many of his tasks are illustrated with photos. There are forty-seven other occupations as painstakingly covered in the loose-leaf volume. It belongs on every refractionist's desk as a working guide to vision needs of many vocations.



To help the refractionist specify the proper multifocal form for *any* vocation, Vision-Ease manufactures over thirty different styles and sizes of multifocal segments, many in absorptive tints. Your full-service Vision-Ease distributor can advise you as to availabilities. Check him the next time you have a multifocal problem.

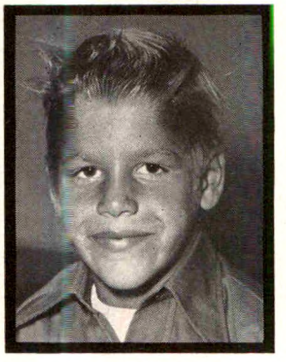
**What you set is what you get.**

# The shape of the

The shape of the future often presents itself in an idea of startling simplicity. Hoskin Forceps combine clinical and engineering innovation to achieve a unique method of minute holding. The simple rounded contours of the tip grip firmly and yet with minimum trauma. We really mean minimum trauma. The arms of the forceps are balanced and spaced with mathematical precision so that the tips never cross, never warp and are never forced apart, no matter what pressure is applied. And this shape of the future is yours, today!

# future.....



There is a choice of four tip sizes, miniaturised micro, micro, fine and fixation, each of which are ideally suited to the tasks they perform in conventional or microsurgery. The range is enhanced by a special matt anti-reflex finish which is ideal when used under intense directional illumination.
A range of shapes with skeleton and solid grips is provided to meet every surgeon's preference.

**A new standard of excellence:**

# the world renowned ophthalmological instruments of aus JENA.

aus JENA the instruments that are considered the standard by which others are measured. Now, under an exclusive agreement between International Micro-Optics and Jenoptik Jena G.m.b.H., GDR-69 JENA, Carl Zeiss Strasse 1, aus JENA instruments are available throughout the United States. The slit lamp and light coagulator shown here are only representative of the complete line of instruments. For further information, write or call today.

**Model 69 Slit Lamp**

A widely accepted design has been evolved to produce an instrument of exceptional efficiency and operating ease. The microscope and slit lamp may be swung around a common vertical axis. Five different magnifications are changed quickly and conveniently. Hruby-lens and applanation tonometer may be fitted. New features make the Model 69 Routine Slit Lamp a more efficient and comfortable instrument for physician and patient alike. Brightness has been increased. Slit width is easily varied, the slit image may be rotated, and the vertical slit may be shortened to a point. The entire instrument is more compact and cooler operating. All instruments have been simplified.

**Model 5000 Light Coagulator**

Here is a highly refined instrument for light coagulation surgery offering optics similar to those of large binocular and reflex-free ophthalmoscopes. The Model 5000 Light Coagulator has a 30° diameter reflex-free field of view. It facilitates the stereoscopic spotting and observation of defective retinal areas, and the coagulation of lesions between 1° to 10° in diameter by means of an intense xenon flash. An attachment permits coagulation in the anterior section of the eye. For retinal photography, the flash provides edge-to-edge illumination without coagulation.

# SUGGESTIONS TO AUTHORS

## For the preparation of manuscripts for American Journal of Ophthalmology

THE AMERICAN JOURNAL OF OPHTHALMOLOGY publishes original and timely contributions dealing with clinical and basic ophthalmology. Each article submitted is evaluated by two or more referees and accepted unchanged (rarely), returned for revision and subsequent editorial consideration, or rejected. Acceptance is conditioned by such factors as the originality, significance and soundness of the contribution, the suitability of the subject matter for THE JOURNAL, the care with which the manuscript has been prepared and the amount of editorial effort required to prepare the manuscript for publication.

Papers are accepted on the condition that they have not been published or accepted for publication in any other journal, whether printed in English or any other language. A paper read before a society and published in the society's transactions will be considered for THE JOURNAL if the society publication does not reach as wide an audience as the contribution merits. The author must indicate the time and place of the meeting and the name of the society publication. It is not possible to coordinate the date of publication of such papers in THE JOURNAL with that in the society publication.

Authors will be advised promptly of receipt of their papers. Thereafter they will be advised within 30 days of acceptance, rejection, or need for revision. Manuscripts which are accepted but require excessive editorial correction or retyping will be returned. Except for papers originating within 500 miles of Chicago, all manuscripts and related correspondence should be transmitted by airmail.

**GALLEY PROOFS** The senior author is provided with one set of galley proofs. The manuscript is not returned and the author must retain a copy for use in correcting the galleys. Alterations should be limited. Corrections should be marked on galleys with standard proof-reading symbols and should be placed both in the margin and in the body of

the text. Proof-reading methods are described in most editorial style books and in many dictionaries. In manuscripts prepared by more than one author, the author responsible for writing the original manuscript should be responsible for the proof-reading. Galley corrections can be minimized by careful preparation of the manuscript in the form in which the author wishes to see it in print. The cost of extensive corrections must be paid by the author.

Galley proofs must be returned by airmail to the manuscript editor, 160 East Grand Avenue, Chicago, Illinois, 60611, within 48 hours of receipt. Failure to return galleys promptly may delay publication for many months.

REPRINTS The senior author of each paper is given 50 free reprints. Additional reprints are provided at cost and must be ordered from the George Banta Company, Inc., Menasha, Wisconsin 54952, when galley proofs are received.

ORGANIZATION OF PAPERS Manuscripts should be submitted in English. Upon request an author using another language will be placed in communication with translators who will translate and prepare a manuscript for editorial consideration. Such service is expensive and by no means assures acceptance of the manuscript. Each paper should be carefully organized and prepared. The statement of the problem should be presented first and supporting details or arguments second. The techniques used should be described well enough to permit the reader to duplicate the study.

Extensive reviews of the literature are rarely desirable. The author should verify personally each reference cited. Primary sources are preferred; references derived from encyclopedic reviews or textbooks are seldom acceptable. (see References, Am. J. Ophth. **63**:1810, 1967) References should be cited in the text as follows:

This was described by Allen and Jones[1] and by Smith.[2] The names of all authors should be cited.

Discussion should relate directly to the topic of the paper. The summary should present an abstract of the entire study in no more than 150 words. Use a good general style manual such as the *Style Manual for Biological Journals*,[1] *Medical Writing*[2] or *A Manual of Style*.[3]

MANUSCRIPT The manuscript should be prepared in the style used by THE JOURNAL. A heavy grade of white bond paper measuring 8½ inches by 11 inches should be used. Margins should be at least 1½ inches on all sides. Paragraphs should be further indented at least a half-inch. The original copy must be submitted. Carbon copies and machine-duplicated copies can not be considered.

**The entire manuscript should be double or triple spaced.** Single spacing should not be used anywhere in the manuscript. The entire

*Suggestions to Authors* — CONT.

manuscript, including the title page, text, references, tables, legends, acknowledgments and footnotes, should be double spaced.

Do not underline titles or sentences or use all capitals anywhere in the manuscript. Indicate words in the margin of the manuscript if italics are desired.

The manuscript should be arranged in the following order:

1. Title page
2. Text
3. Acknowledgments
4. References
5. Tables
6. Legends for figures
7. Footnotes

Each major section should begin on a separate sheet.

TITLE PAGE The title page should be numbered Page 1 and contain the title, the authors' names and the address of the author to whom correspondence should be directed. Each subsequent page should include the page number, the senior author's name and an abbreviated (running) title in the upper right-hand corner.

REFERENCES The author is responsible for complete and accurate references.

The following style is used by THE JOURNAL:

1. Terry, T. L.: Extreme prematurity and fibroblastic overgrowth of persistent vascular sheath behind each crystalline lens. Am. J. Ophth. 25:203, 1942.
2. Reese, A. B.: Tumors of the Eye. New York, Hoeber, 1964, ed. 2, p. 91.

Verification of references is the author's responsibility. Manuscripts with incomplete or inaccurate references, or references which do not correspond with THE JOURNAL style will be returned. References must be cited in the text (see preceding page and numbered in the order in which they are cited. Acceptable abbreviations for publications are listed in the *Style Manual for Biological Journals*. If there is any question which abbreviation to use, the name of the publication should be written out.

TABLES Each table should be numbered with an arabic numeral and cited in the text. The table should be double spaced. Symbols not available on a standard typewriter may be used only if essential to the presentation of data and must be prepared in a graph or diagram containing no typing.

Give each column of each table a heading, and plan small columns. A one-column table may be approximately 45 characters wide; a two-column table may be approximately 90 characters wide. Legends must be submitted describing each table. The legend should not be incorporated in the table.

ILLUSTRATIONS Graphs, diagrams and photographs should be submitted unmounted. Descriptive legends should be typed on a separate manuscript page. The form used by THE JOURNAL for legends should be followed:

Fig. 1 (Janes, Smith and Bank). Histologic section of the eye. (Hematoxylin-eosin, ×70.)

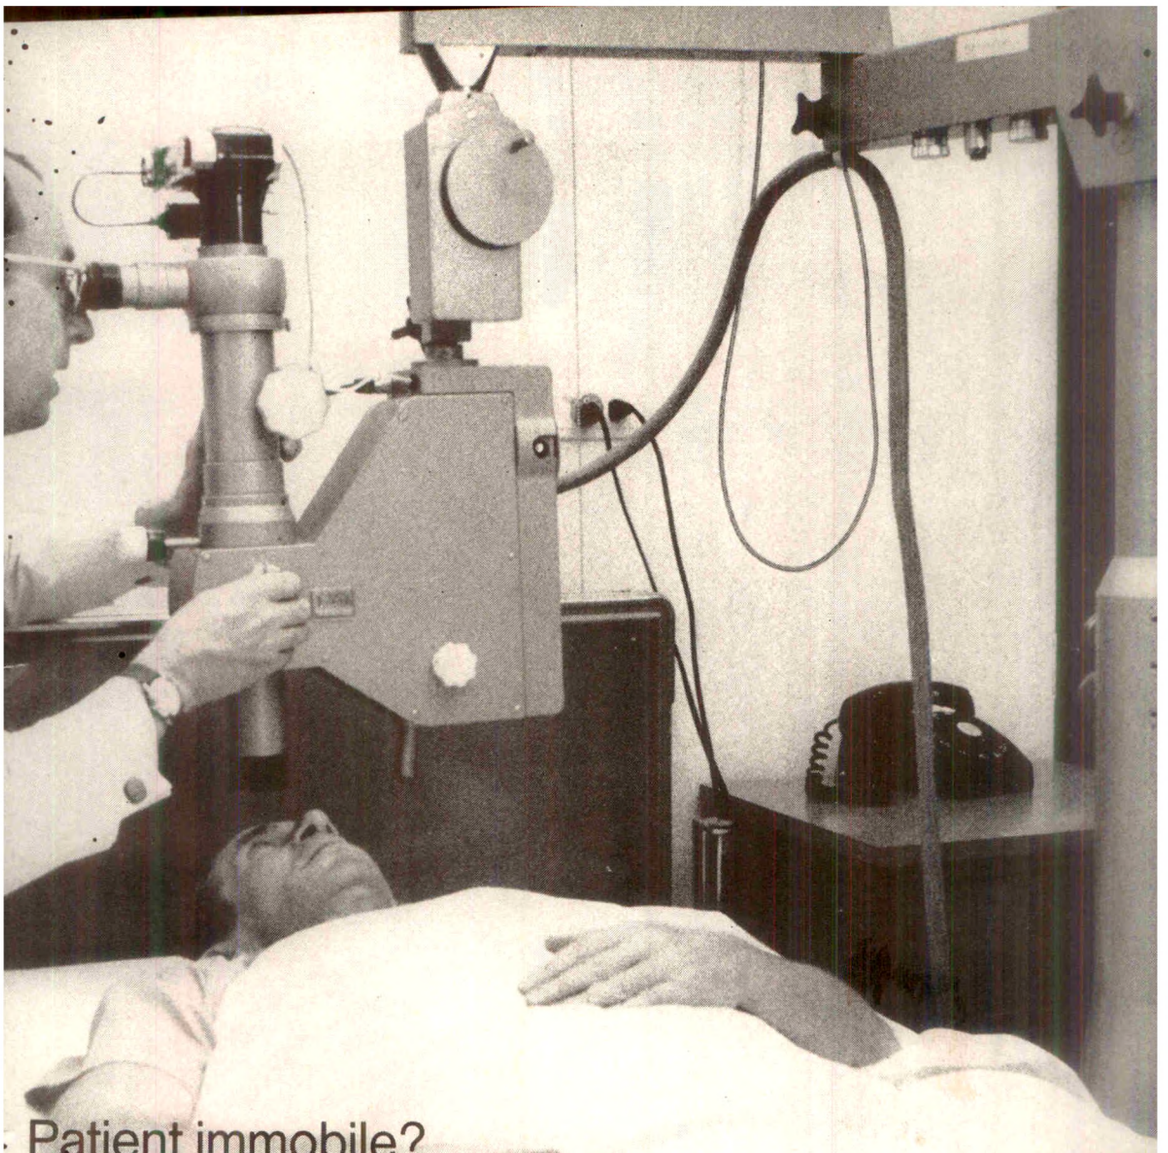
Illustrations should be unmounted and untrimmed. Cropping should be done with a grease pencil on the front surface of the illustration. Each illustration should have its number, an indication of its top and the name of the author written in soft pencil on its back surface. Line drawings and photographs should not be combined in one illustration. The legend should never be incorporated in the illustration itself. Authors are responsible for obtaining permission to use illustrations from other publications.

Graphs and line drawings should be prepared on heavy white paper with India ink. Heavier lines should be used for curves than for axes. Labels should be professionally prepared, of uniform size and parallel to axes.

In a series of illustrations, all figures should be oriented in the same direction. Illustrations should be the same size as or larger than intended reproductions. Figures in THE JOURNAL are 16 picas (2⅔ inches, 1 column), 21 picas (3½ inches) or 33 picas (5½ inches, 2 columns) wide.

Photographs should have a glossy finish and a sharp contrast between black and white areas. Labels, arrows and the like must be professionally prepared. Lettering should be uniform and large enough to be reduced and still be easily read.

Reproductions are enhanced if original art is scaled to the page size of THE JOURNAL (5½ inches by 7¾ inches). Preferably, the artist should make the original drawing twice the size of the final reproduction. Thus, if the size of the original drawing is twice that of a page of THE JOURNAL, it will be 11 inches by 15½ inches and have an area of 160.5 square inches. When reduced to the size of a page of THE JOURNAL, it will have an area of 41.5 square inches, or a 75% reduction in area. Lettering must be planned with this reduction in mind.



Colored figures are used infrequently and are necessary only when required to demonstrate the thesis of the author. It is expected that authors will underwrite the cost of color illustrations in part. Ordinarily, this runs between $500 and $1,200 per page. Both color transparencies and prints must be submitted with the paper, together, if necessary, with a sheet indicating the proposed distribution of the figures.

# Patient immobile?

## Now there's a Zeiss Fundus Camera you can bring to his bedside.

If you have had experience with ocular fundus photography, in all likelihood you have had experience with Zeiss. Zeiss Fundus Cameras are world-famous for optical quality, versatility and ease of operation.

Now, with the Zeiss Motorized Bedside Fundus Camera, *all* the techniques of fundus photography can be brought to the immobile patient. For instance, to stroke or accident victims, where the irregularities in the venous or arterial systems that only fundus examination can reveal are of maximum importance.

Motorized operation and free horizontal rotation make adjustment and focusing easy. And the sturdy stand eliminates operator fatigue as a factor in serial photography—a necessity for fluorescein fundus work. The exclusive Allen Stereo Separator lets you make ocular fundus stereograms automatically with no equipment adjustment.

An important feature of all Zeiss fundus cameras is the *reflection-free* optical system. It is designed so that no reflections from the patient's eye can reach the observer or the camera. And, of course, all images are sharp from edge to edge.

If you would like to learn more about this unique instrument, or about fundus photography in general, write: Carl Zeiss, Inc., 444 Fifth Avenue, New York, N.Y. 10018.

Americana Hotel — Miami Beach, Florida

By popular request, TWO courses will be offered in 1972—

## COURSE I. BASIC INTRODUCTION TO NEURO-OPHTHALMOLOGY—January 4-5, 1972

Because of demand for basic teaching in Neuro-ophthalmology, this two day course will be aimed at the level of the resident with no previous exposure to this field. How to do a neuro-ophthalmological examination; common optic nerve and chiasmal problems; nystagmus and motility disorders; hemispheral disease; eye signs of posterior fossa lesions; and diseases of the orbit will be reviewed. Two hours of basic neuroradiology will cover the normal arteriogram and the normal pneumoencephalogram for the ophthalmologist. A special feature will be actual cases present for examination and discussion showing classic neuro-ophthalmological entities.

## COURSE II. GENETICS IN NEURO-OPHTHALMOLOGY—January 6-7, 1972

This will be an advanced clinical seminar on Genetics in Neuro-ophthalmology, aimed at the highest possible clinical level. This is designed specifically for the board eligible or certified ophthalmologist, neurologist, neurosurgeon, or pediatrician who wants the latest pearls on neuro-ophthalmological problems of genetic interest and advice on practical genetic counseling in these cases. Two hours of genetics gems by Dr. Victor McKusick will bridge the gap between basic science and the clinician. Hypopituitarism in children, retinal pigment epithelial disorders, genetics of optic nerve disease, pediatric neuro-ophthalmology gems, and genetic syndromes of eye interest will be covered. Interesting patients illustrating these syndromes will be presented for examination and discussion.

The fee for each course is $100 for practitioners and $40 for residents. If desired, the practitioner can take both courses for $200 and the residents for $80. Seating will be in order of receipt of checks. Checks should accompany registration request. The Americana Hotel gives a special rate for this course which is about one half their usual winter rate. Please do not ask for refunds after December 1.

## FACULTY FOR THE COURSES WILL INCLUDE

Dr. William W. Cleveland
Dr. Robert B. Daroff
Dr. Noble J. David
Dr. John Flynn
Dr. Fredie P. Garganc
Dr. J. Donald M. Gass
Dr. William F. Hoyt
Dr. John A. McCrary III
Dr. Victor McKusick
Dr. Edward W. D. Norton
Dr. David H. Reynolds
Dr. Norman J. Schatz
Dr. J. Lawton Smith
Dr. Frank B. Walsh

## ANNUAL MEETING

**DIPLOMAT**
**HOTEL**
**HOLLYWOOD, FLORIDA**
**February 27-March 3, 1972**

### MONDAY 9:00 A.M.
February 28

**KEYNOTE ADDRESS**
Michael DeBakey, M.D.

Introductory Comments
Morris Fishbein, M.D.

Testimonial to
Guest of Honor
ELMER HOLMES BOBST

Jules Francois, M.D.
Chairman
Yi-Yung Hsia, M.D.
Lawrence Harris, M.D.
Sidney Fox, M.D.
Crowell Beard, M.D.
Byron Smith, M.D.
Pierre Guibor, M.D.

### TUESDAY 9:00 A.M.
February 29

**CATARACT SYMPOSIUM**
Harold Scheie, M.D.
Chairman
Robert Schimek, M.D.
Norman Jaffe, M.D.
Miles Galin, M.D.
Ralph Kirsch, M.D.
John Bellows, M.D.

### 2:00 P.M. to 5:00 P.M.

**GLAUCOMA AND SQUINT**
Saul Sugar, M.D.
Chairman
Miles Galin, M.D.
Milton Best, M.D.
Lawrence Harris, M.D.
Fritz Hollwich, M.D.
Claes Dohlman, M.D.
Edward Dunlap, M.D.

### WEDNESDAY 9:00 A.M.
March 1

**RETINA**
Charles Schepens, M.D.
Chairman
Graham Dobbie, M.D.
Michael Shea, M.D.
Harvey Lincoff, M.D.
Kenneth Hovland, M.D.
C. Hillsdorf, M.D.
Ruth Long, M.D.
H. Freeman, M.D.

**A.M.A. APPROVED**
**CONTINUING EDUCATION COURSES**

**PRACTICAL COURSES**
WEDNESDAY
and
THURSDAY

2:00 P.M. to 5:00 P.M.

*Active:* dexamethasone 0.1%, neomycin sulfate equivalent to 3.5 mg/cc neomycin, polymyxin B sulfate 6000 units/cc.

available as sterile ophthalmic drops and sterile ointment...

Alcon *dedicated to advances in ophthalmic therapy*

DESCRIPTION: *DROPS*—Sterile suspension containing: *Active:* Dexamethasone 0.1%, Neomycin (present as sulfate) 3.5mg/cc, Polymyxin B Sulfate 6000 units/cc; Vehicle: Hydroxypropyl Methylcellulose 0.5%; *Inactive:* Sodium Chloride, Polysorbate 20, Hydrochloric Acid and/or Sodium Hydroxide (to adjust pH), Purified Water; Preservative: Benzalkonium Chloride 0.004%. *OINTMENT*—*Active:* Dexamethasone 0.1% Neomycin Sulfate equivalent to 3.5mg/gm Neomycin; Polymyxin B Sulfate 6000 units/gm; *Inactive:* White Petrolatum, Anhydrous Liquid Lanolin; Preservatives: Methylparaben 0.05%, Propylparaben 0.01%. CONTRAINDICATIONS: This drug is contraindicated in tuberculous, fungal, and most viral lesions of the eye (herpes simplex/dendritic keratitis); vaccinia, varicella; acute purulent conjunctivitis and acute purulent blepharitis, and in those persons who have shown hypersensitivity to any of its components. PRECAUTIONS: Extended use may cause increased intraocular pressure which should be checked frequently and may result in overgrowth of nonsusceptible organisms. Perforation can occur in diseases causing thinning of the cornea. Discontinue use if sensitivity occurs. Not recommended for long-term use in pregnant patients.

# VERHOEFF'S "TERATO-NEUROMA"

## A CRITICAL REAPPRAISAL IN LIGHT OF NEW OBSERVATIONS AND CURRENT CONCEPTS OF EMBRYONIC TUMORS

THE FOURTH FREDERICK H. VERHOEFF LECTURE

LORENZ E. ZIMMERMAN, M.D.

*Washington, D.C.*

It was, of course, a most unanticipated honor for me to be invited to deliver this Fourth Verhoeff Memorial Lecture. Dr. Verhoeff occupied such a remarkable position, not only in the history of American ophthalmology, but especially in the development of ophthalmic pathology in the United States, that I—as a pathologist—am most happy to be able to pay this tribute to him. When he began his work in ophthalmic pathology at the turn of the century, great contributions had been made by the European masters, but on this side of the Atlantic there was only a great void. Once Verhoeff rolled up his sleeves and began his work at the Massachusetts Charitable Eye and Ear Infirmary in Boston, that void soon began to disappear. Before long the Europeans knew they were in for some stiff competition. No one, of course, could have anticipated then that this remarkably energetic man would continue his productive career for another 60-plus years!

I am so very pleased that Dr. Verhoeff did remain active as long as he did, for otherwise I would not have been able to see him in action. When I attended my first meeting of the Ophthalmic Pathology Club in 1954, Dr. Verhoeff was already 80 years old, but who would have thought so once the meeting was under way! No matter what was being presented, Dr. Verhoeff would see things in the contributor's slides that had been overlooked, or he would recall a similar case that everyone else had forgotten, or he would ask a question that no one else had considered.

Dr. Verhoeff had a very bad reputation for being a sort of "people-eater," but, fortunately, he was very kind to me. I guess I was lucky that I didn't enter the field of ocular pathology a decade or two earlier, for I've been told that Dr. Verhoeff did mellow a bit after he became an octogenarian.

Everyone has his favorite stories about Dr. Verhoeff, and Dr. Cogan even coined a new term to officially recognize them when he delivered the Third Verhoeff Lecture,[1] so let me add my contribution to this "Verhoeffiana."

I am sure that many of you will recall that the Ophthalmic Pathology Club used to meet in Washington just before the Wilmer meeting in Baltimore and that Dr. Verhoeff was always a prominent figure in the front row

Presented at the 107th annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, May 25, 1971.

Reprint requests to Lorenz E. Zimmerman, M.D., Chief, Ophthalmic Pathology Branch, Armed Forces Institute of Pathology, Washington, D.C. 20305.

at the Wilmer meeting, where he was usually called on to initiate the discussion of almost every paper. The episode I will recount took place at the 1956 Wilmer meeting, when Professor Alan Woods was still Chairman of the Department of Ophthalmology at Johns Hopkins. This was just a few years after Hellie Wilder had published her epochal paper[2] establishing toxoplasmosis as an important cause of chorioretinitis in adults and just two years after T. gondii was first recovered from the eye of an adult patient at the Walter Reed Army Hospital.[3] Professor Woods had selected for his traditional opening lecture of the annual Wilmer meeting a review of the toxoplasmosis story in relation to his clinical and laboratory investigations of uveitis patients studied at the Wilmer Institute.[4] Dr. Verhoeff opened the discussion by immediately shocking the audience with his statement that Professor Woods and everyone else interested in ocular toxoplasmosis had overlooked the fact that he himself had more than 25 years earlier presented an excellent, detailed description of the clinical and pathologic features of Toxoplasma chorioretinitis. I still vividly recall how stunned I was by such an impossible claim. I feared that Dr. Verhoeff's age was getting the best of him, but then—just as a ripple of skeptical snickering was beginning to go through his audience—Verhoeff explained, "the only trouble is that I called it tuberculosis."[5]

That experience taught me several things about Dr. Verhoeff. At the age of 82 he was still very "sharp" and had a great sense of humor. He was honest. In his original description of the case that he diagnosed as one of localized tuberculous chorioretinitis,[5] he had admitted that he could not demonstrate any acid-fast bacilli. Instead of leaving this mistake buried, he was bringing it out in the open. He recalled his case vividly enough to be able to make the correct diagnosis in retrospect, and I believe his revised diagnosis of toxoplasmosis was the correct one because his published photographs certainly are most consistent with such an interpretation.

Two-thirds of a century ago, at the 40th annual meeting of the American Ophthalmological Society in Atlantic City, Verhoeff—then a guest of the Society—described in minute detail a rare tumor that arose from the pars ciliaris retinae.[6] Although he considered it a "terato-neuroma," his description is now generally accepted as the classic reference for the intraocular medullo-epithelioma (or "diktyoma," as many still prefer to call this tumor). While justly proud of his original contribution and of the wide recognition it subsequently received, not only in ophthalmologic circles but also by such an eminent oncologist as Willis,[7] and by such authoritative neuropathologists as Russell and Rubinstein,[8] he was nevertheless miffed by the fact that his name for the tumor never became very popular. In discussing a paper entitled "Intraocular diktyoma and glioneuroma," by Fralick and Wilder[9] at the 1949 meeting of this Society, Verhoeff typically and inimitably made the following remarks:

> In their very interesting paper the essayists indicate that I was the first to point out the real nature of the type of tumor with which they are dealing. I did this in a paper read by invitation before this Society 45 years ago, and I therefore cannot deny the allegation. Scarcely a member is now alive who remembers that famous day and year. I recall that I exceeded the time limit and the Society voted me an indefinite extension of time. I hope this carries over to include my present discussion.
>
> The case I reported was all mine, clinically and pathologically. Conditions were different in those days. I removed the eye, embedded it, repaired the microtome, sharpened the microtome knife, cut all the sections, prepared all the staining fluids, stained the sections by various methods, modified Mallory's method for neuroglia, made the drawings, supervised the making of the photomicrographs, made the lantern slides, and typed the manuscript on a Blickensdörfer typewriter. I did not sweep out the laboratory—a cross-eyed orderly did this.
>
> Fuchs never had one of these cases, but studied sections of such tumors reported before 1908 by other observers. I sent him a full set of sections of my tumor, including some stained differentially. In his paper he accepted all my views as to the nature of these tumors—in fact, he made them his own. But he rejected the name I suggested—terato-neuroma, meaning a monsterlike growth consisting primarily of nervous tissue—and brought forward the name "diktyoma." This term, five years previously, had been devised by Emanuel for the tumor now

called retinoblastoma. In my opinion it is not a good name for either tumor. That its meaning lacks precision is shown by the fact that it has been used for two such different tumors. My tumor contained embryonic retina, abnormal neuroglia, and embryonic vitreous. It showed what appeared to be abortive attempts to form whole embryonic eyes. The tumor of the essayists contains embryonic retina, neuroglia, fibrous tissue, and cartilage. Formation of embryonic vitreous if it occurs is not conspicuous. The tumor is said to contain ganglion cells, but it is not stated how these were identified. There is no evident reason why such a tumor should not contain ganglion cells, but atypical glial cells can closely resemble ganglion cells. I should like to ask whether or not Nissl bodies were demonstrated. Obviously the term "diktyoma" is inadequate for these tumors. The essayists realized that this was so in their case, for they found it necessary to add the term "glioneuroma." If they had used my term, terato-neuroma, this addition would have been needless.

Verhoeff then concluded his discussion of the Fralick-Wilder paper by showing some of his original slides and in doing so stated, "It might be well to show these every 45 years." How I wish that he were here today so that he could give a spicy rebuttal to some of the criticisms I shall be making of his pet name, for while I agree with him that terato-neuroma would have been an entirely appropriate designation for the tumor described and illustrated by Fralick and Wilder, I don't agree that it was a suitable name for his original medullo-epithelioma.

For this Verhoeff Lecture, then, I have chosen to review Verhoeff's original description of his tumor and his concept of the nature of that tumor, which led him to propose the name "terato-neuroma." I shall do this in the light of my own experience, based on a recent re-examination of over 100 tumors of the ciliary epithelium on file in the Registry of Ophthalmic Pathology.[10] These rare tumors exhibit many histologic variations from case to case, and it is therefore easy for the pathologist who hasn't had the benefit of a large experience to become so impressed by certain features of a given case that he misses the "big picture." Fortunately, however, Verhoeff, in his original description, did describe and emphasize the most significant features that distinguish this tumor from others with which it might be confused. It is a tribute to his powers of observation and his facility for detailed description that his paper has become a classic. Independently, when I first became interested in these tumors several years ago, I made a number of the same observations and arrived at some of the same interpretations[11] as Verhoeff had done many years earlier, and for a long while I believed them to be "original," as I had not then read Verhoeff's ancient paper. What a surprise when subsequently I found out that Verhoeff had "scooped" me by more than half a century!

Verhoeff's patient was a two-and-one-half-year-old child whose affected eye had become blind, cataractous, and enlarged from secondary glaucoma by the time the parents brought her in for enucleation. Retinoblastoma ("glioma retinae") was the preoperative diagnosis. Upon opening the eye, Verhoeff found a tumor that arose from the ciliary body in the upper nasal quadrant, filled the posterior chamber in that area, and displaced the cataractous lens, pushing it aside. It had many excrescences over its surface, and there were, in addition, many tiny globular bodies attached to the pupillary margin of the iris. Microscopically,* Verhoeff found the tumor to have had its origin in nonpigmented ciliary epithelium (pars ciliaris retinae) of the pars plicata (Fig. 1). It produced intricate convolutions enclosing lumina of various shapes and sizes. The structures forming these convolutions were chiefly of two types. One, which Verhoeff considered the more primitive form, consisted of a single layer of columnar epithelium with oval vesicular nuclei and staining more deeply than the normal ciliary epithelium. The other consisted of thicker bands composed of multilayered elongated cells. One border of these bands was typically sharply defined and resembled the outer lim-

*I had hoped to be able to show photomicrographs from Verhoeff's original case but was unable to obtain any photogenic slides, so I will substitute photomicrographs from other cases in the Registry.

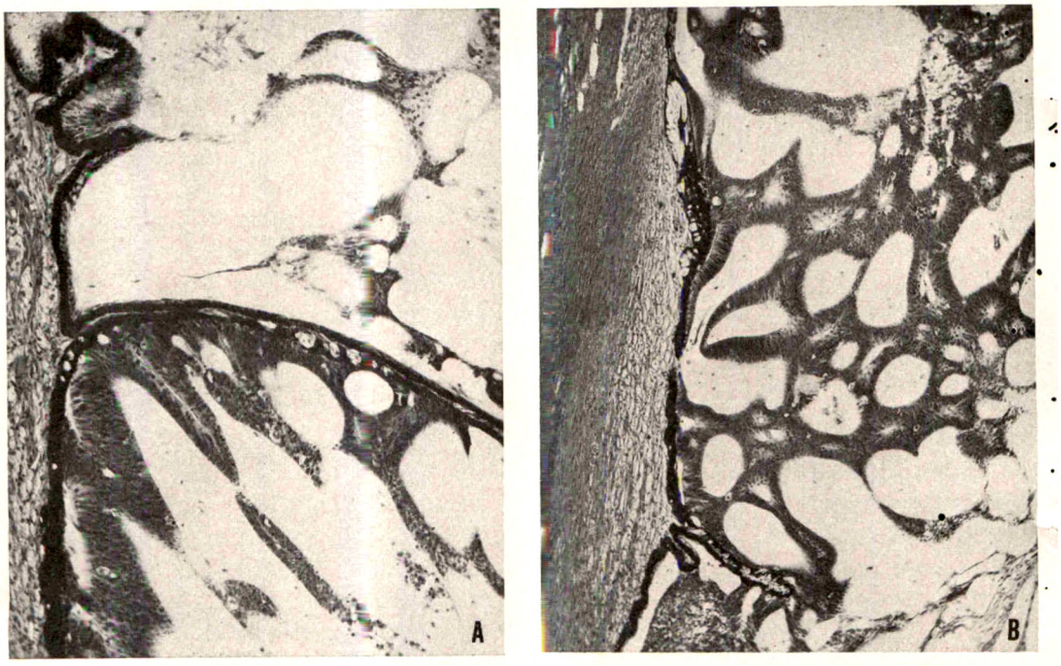

Fig. 1 (Zimmerman). The medullo-epithelioma arises from the nonpigmented ciliary epithelium and produces intricate convolutions enclosing lumina of various shapes and sizes. The neoplasm is composed of structures resembling the medullary epithelium of the embryonic ciliary epithelium and retina (hematoxylin and eosin, left: ×115, right: ×80). (AFIP Negs. 70-9497-9).

iting membrane of the embryonic retina (Fig. 2). Mitotic figures were generally most conspicuous along this surface of the bands. The opposite surface was less well defined but was almost always intimately united with a "fibrillated connective tissue not to be distinguished from viteous humor." Verhoeff stressed that "this vitreous humor has not simply been enclosed by the tumor, since the latter does not come in contact with

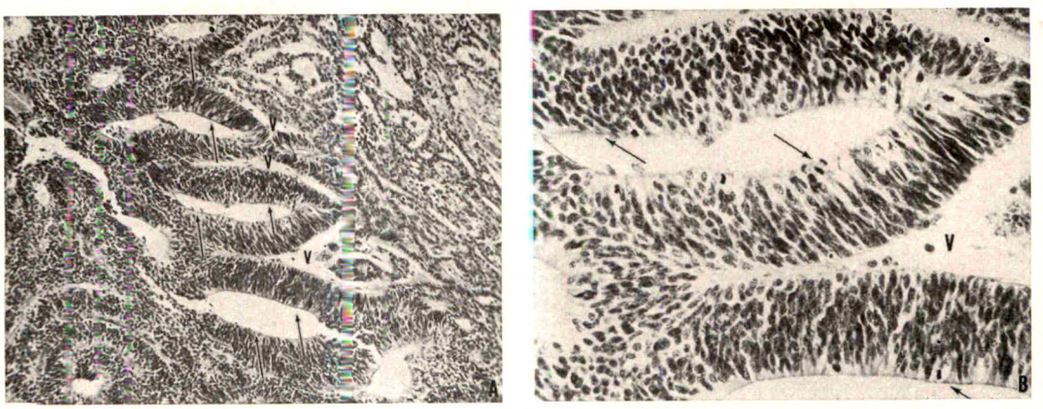

Fig. 2 (Zimmerman). (A) The multicellular bands are polarized, forming a sharply defined structure analogous to the external limiting membrane of the retina along one surface (arrows); the less well-defined opposite surface is in contact with primitive vitreous (V) (hematoxylin and eosin, ×115). (AFIP Neg. 70-8363). (B) The center of the field shown at left has been enlarged, revealing considerable mitotic activity along the outer limiting membrane but hardly any along the vitreal surface (hematoxylin and eosin, ×305). (AFIP Neg. 70-8362).

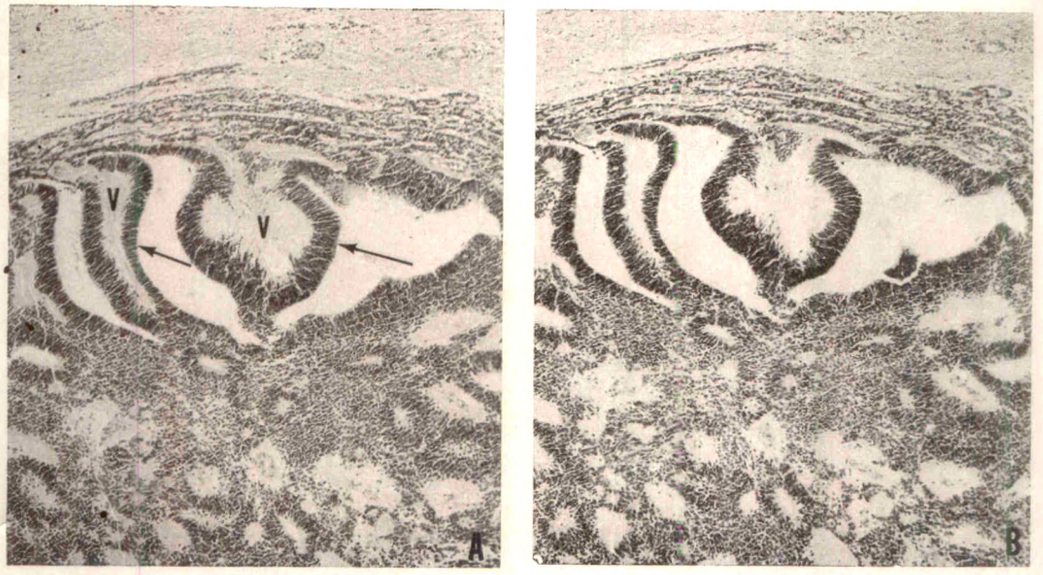

Fig. 3 (Zimmerman). (A) In contrast with the structures shown in Figure 2, in which the luminal surfaces of the bands are formed by the external limiting membrane and the lumina are empty, here the concavities are filled with vitreous (V) and the outer convex surfaces (arrows) are formed by the external limiting membrane. The vitreous is easier to visualize here than in Figure 2 because the section was stained by alcian blue (×60). (AFIP Neg. 70-8365). (B) Adjacent section to that used for A, but before staining with alcian blue the section was treated with hyaluronidase. The vitreous is now unstained by alcian blue (×60). (AFIP Neg. 70-8366).

the normal vitreous humor, but it is newly formed, and the stages in its formation can be easily traced." Verhoeff pointed out that, depending upon how these bands were folded, one could see various patterns. Sometimes one could see lumina that were generally empty or perhaps filled only with cell debris or serum, bounded by the external limiting membrane (Fig. 2). In such instances, the bands circumscribing such structures were surrounded by the delicate connective tissue resembling embryonic vitreous. In other instances, the globoid bodies contained the embryonic vitreous and the outer surface of the bands was outlined by the external limiting membrane (Fig. 3).

In my own studies of this curious structure of these tumors, I had the advantage of some newer stains that were not available in Verhoeff's day—stains that vividly reveal the acid mucopolysaccharide in the vitreous.[12] These stains provided dramatic confirmation of Verhoeff's observations (Figs. 3 and 4). The cellular bands that produce the characteristic diktyomatous pattern of these medullo-epitheliomas, whether they be those that resemble the embryonic ciliary epithelium or those that resemble embryonic retina, are strikingly polarized, forming a fenestrated membrane corresponding to the external limiting membrane along one surface while producing embryonic vitreous along the other.[11]

So much for our basic points of agreement about the structure of these tumors. Wherein do we disagree? Verhoeff shared the classic views of the day concerning formation of the vitreous humor. This was regarded as a product of the mesoderm. He believed that blood vessels and associated mesodermal structures derived from the stroma of the ciliary body were carried into the lesion and were responsible for the formation of the vitreous humor that appeared to be such an integral part of the tumor. Verhoeff envisaged the neoplasm as making "abortive attempts to form eyes," and since he regarded the formation of vitreous as a

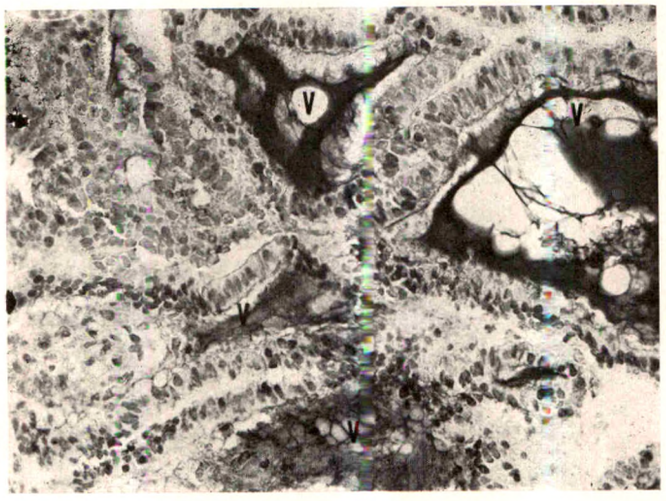

Fig. 4 (Zimmerman). In this preparation the embryonic vitreous (V) is deeply stained by alcian blue. Observe that this vitreous is never present along both surfaces of the medullary epithelium, just as the embryonic vitreous is never formed along both surfaces of the embryonic retina and ciliary epithelium (×305). (AFIP Neg. 63-2182).

function of the mesoderm, he thought the tumor was more closely allied to the teratomata than to any other recognized class of tumors. Moreover, he felt the complexity of its structure, the degree of its differentiation, and the early period of life at which it occurs were all consistent with this suggestion.

Already at the time of his paper, Verhoeff was aware of the fact that some investigators were challenging the traditional concept of the vitreous as a product of the mesoderm. He cited the "recent views of Haemers and others, who believe it to be derived from the neuroglia of the retina," but he rejected this suggestion because his own observations, making use of a variety of special staining methods, led him to the conclusion that the fibrils in the vitreous did not take origin from the retina. Since then, however, embryologists and others have largely come to agreement that the medullary epithelium does play a most important rôle in the formation of the embryonic vitreous.[11,13-15]

That the mucoid material resembling primitive vitreous contained within some of the vesicles cannot be ascribed to mesodermal elements carried into the tumor from the stroma of the ciliary body is established by those cases in which free-floating vesicles in the anterior chamber have been observed over a period of time during which they progressively enlarged.[16,17] In such cases there may be no connection of these vesicles to the iris or ciliary body (Fig. 5). As Treacher Collins pointed out in his discussion of the remarkable case reported by Spicer and Greeves,[16] it demonstrated how pathology can help to explain embryologic processes. He stated, "It used to be generally thought that the vitreous humour was of mesoblastic origin; but of late embryologists had regarded it as derived from the neural epiblast; and this specimen bore out that view very conclusively. Further, it showed not only that the vitreous humour was derived from the secondary optic vesicle, but that it came from only the front part."

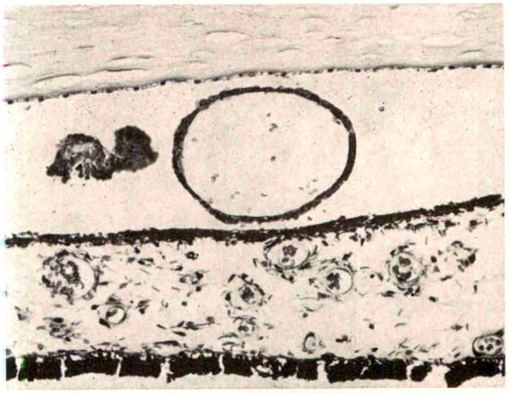

Fig. 5 (Zimmerman). Free-floating "cyst" in anterior chamber. Material indistinguishable from vitreous fills the lumen (alcian blue, ×140). (AFIP Neg. 71-5601).

Thus, a major blow to Verhoeff's concept is the fact that he did not demonstrate convincingly that his tumor had intrinsic elements representative of germ layers other than the neural ectoderm. Interestingly, however, earlier at the same meeting in 1904, Alling[18] had presented the case of a four-year-old child whose enucleated eye had been found to contain a congenital tumor of the ciliary body containing cartilage as well as epithelium. The tumor had been studied microscopically by Arnold Knapp, who considered it an undifferentiated (embryonal) tumor. From the description and from the remarkably good photomicrographs that document the case report, I am convinced that Alling's case was indeed a medullo-epithelioma of the ciliary body containing cartilage. Verhoeff's had been sent sections of that tumor, and he commented on the case after it was presented at the meeting. Strangely, Verhoeff did not recognize it as related to his own tumor, and, in fact, stated that he believed it was an endothelioma! Had he recognized Alling's tumor for what it was—a teratoid medullo-epithelioma—he would have been able to make a much better case for his name, "terato-neuroma."

There is, however, still another objection to that name, "terato-neuroma." As Willis[19] points out, ever since Virchow's time the term "neuroma" has been reserved for tumors that contain mature neurons. Verhoeff made no claim that his tumor contained such elements; to the contrary, it consisted of immature derivatives of the primitive medullary epithelium. It is difficult to understand, therefore, why the term "medullo-epithelioma" did not appeal to Verhoeff.

Verhoeff stated that he knew of no class of tumors other than the teratomata with which his tumor might be more appropriately grouped. There is, however, a group that Willis[20] calls the "embryonic tumors," which he defines as tumors that arise during embryonic, fetal, or early postnatal development from a particular organ, rudiment, or tissue while it is still immature. He also points out that some embryonic tumors also show divergent differentiation (heteroplasia), forming tissues of kinds that do not normally occur in the part. A familiar example would be the presence of rhabdomyoblasts in an embryonic tumor of the kidney (Wilms' tumor). I agree fully with Willis that the medullo-epitheliomas of the ciliary body logically belong in the group of embryonic tumors.

The cases presented to this Society by Alling and by Fralick and Wilder contained islands of hyaline cartilage; since then cartilage has frequently been found in the loose mesenchymal tissue associated with these medullo-epitheliomas (Fig. 6).[21] Differentiation into brain tissue has also been observed in a number of them (Fig. 7).

Before leaving the subject of names and classifications of tumors of the ciliary epithelium, I should point out that because I couldn't find a good classification of these tumors, I was forced to develop one of my own.[10] Fuchs[22] made an astute observation that is still generally correct. He noted that they could conveniently be placed in two main groups: (1) those occurring in children and resembling embryonic retina, which he called diktyomas, and (2) those of adults representing neoplastic transformation of hyperplastic epithelium, usually in eyes that had been inflamed or traumatized. Fuchs's name, "diktyoma," was selected to call attention to the network of medullary epithelial bands that are so conspicuously present in some of these tumors of infancy. I have already cited Verhoeff's objections to the name "diktyoma." Russell and Rubinstein[8] summed up the situation very well: "Apart from brevity, this term has little to recommend it." Strangely, it continues to enjoy considerable popularity. I must confess that unless I watch very carefully I find myself using "diktyoma" instead of "medullo-epithelioma"!

Grinker[23] apparently first introduced the term "medullo-epithelioma," but based it, at least in part, on a misconception. He stated,

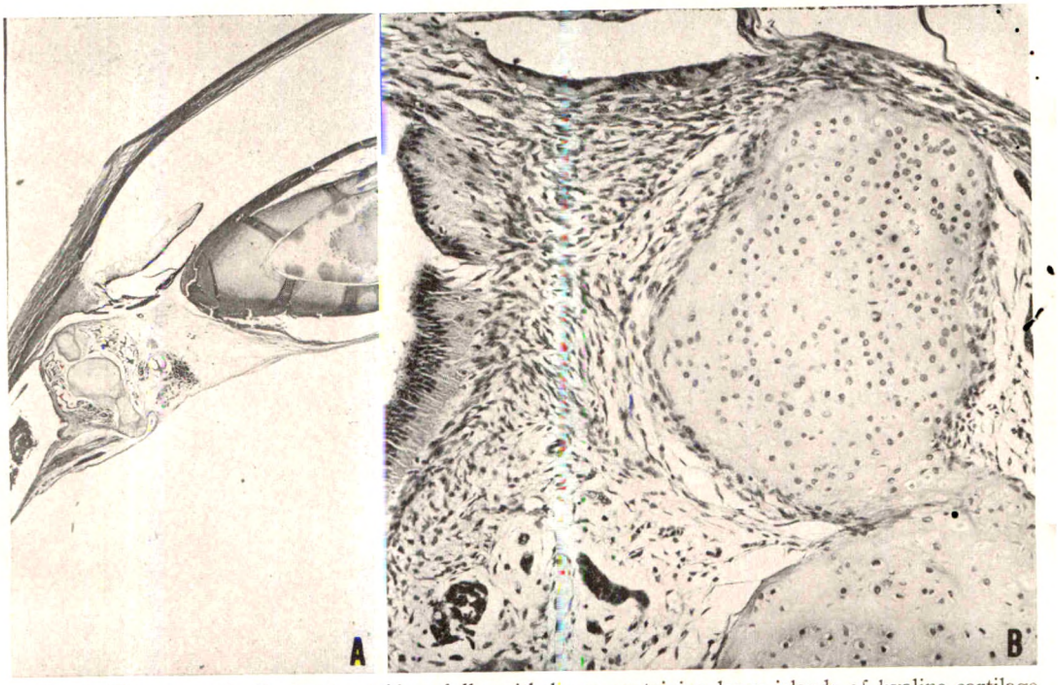

Fig. 6 (Zimmerman). Benign teratoid medullo-epithelioma containing large islands of hyaline cartilage embedded in a loose mesenchymal stroma. (hematoxylin and eosin, left: ×10, right: ×115). (AFIP Negs. 70-8774-5).

"In the retina, medullary epithelium persists in almost undifferentiated form throughout adult life in the epithelium of the pars ciliaris retinae, and it is from this tissue that medullo-epitheliomas of the retina usually arise." Actually, the ciliary epithelium is not poorly differentiated tissue, and the acquired tumors that arise from it do not resemble the medullo-epitheliomas that arise from the embryonic medullary epithelium. Nevertheless, certain authoritative writers such as Andersen,[21] Duke-Elder and Perkins,[24] and Reese,[25] have followed Grinker's suggestion and have lumped together both embryonic and

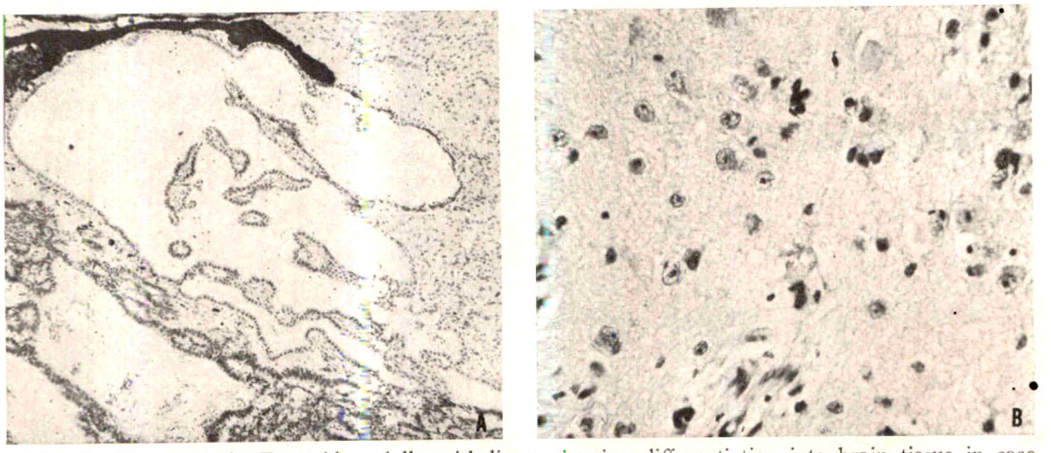

Fig. 7 (Zimmerman). Teratoid medullo-epithelioma showing differentiation into brain tissue in case reported by Fralick and Wilder[9] (hematoxylin and eosin, left: ×80, right: ×305). (AFIP Negs. 70-8774-5).

acquired tumors of the ciliary body under the heading of medullo-epithelioma. In Andersen's classification,[21] the former are called embryonal medullo-epitheliomas, the latter adult medullo-epitheliomas. Both designations are objectionable. To better understand why these are objectionable, let me again make reference to Willis's concept of medullo-epitheliomas. These are considered embryonic tumors, neoplasms that arise from embryonic or fetal tissues. Following this concept, the term "embryonal medullo-epithelioma" becomes redundant (medullo-epitheliomas are by definition embryonic neoplasms) and "adult medullo-epithelioma" becomes contradictory. Duke-Elder and Perkins[24] tried to classify these tumors, but their classification is also objectionable on several grounds. They, too, place "adult epitheliomas" under the heading of medullo-epitheliomas, and all of these are grouped among the malignant neoplasms. They apparently do not recognize a benign form of medullo-epithelioma. While I am criticizing the classification proposed by others, I should also admit that the discussion of these tumors that Hogan and I[26] gave in our book, Ophthalmic Pathology, is very poor and our classification of them is totally inadequate. These deficiencies will be corrected in our next edition!

From a conceptual point of view I believe it is logical (and probably correct) to assume that intraocular medullo-epitheliomas are congenital neoplasms. At least the anlage from which the tumors arise is undoubtedly present at birth even though the clinical manifestations of the tumor that lead to its recognition may not develop until long after birth. In striking contrast, the group that other authors have called "adult medullo-epitheliomas" arise, I believe, from fully differentiated ciliary epithelium that subsequently undergoes neoplastic change, not infrequently after having passed through a stage of non-neoplastic reactive hyperplasia (pseudoadenomatous hyperplasia). Thus, I recently suggested[10] that we divide these epithelial tumors of the ciliary body into two main groups, the congenital and the acquired (Table 1).

Just a word about the glioneuroma: We have only two examples, the one recorded by Kuhlenbeck and Haymaker[27] and a remarkably similar unpublished case presented to the Verhoeff Society by Dr. William Spencer of San Francisco. In both of these cases, a large part of the anterior segment of the eye was replaced by a large mass of very mature, well-differentiated brain tissue containing neurons as well as glia. None of the usual embryonic retina, ciliary epithelium, and primitive vitreous characteristic of medullo-epitheliomas was present. Glioneuromas belong in the class of choristomatous malformations, portions of the iris and ciliary body having failed to develop normally and having produced instead large, well-differentiated masses of tissue resembling brain.[10]

With the exception of these rare glioneuromas, the congenital group comprises the "pure" and the "teratoid" medullo-epitheliomas. The "pure" medullo-epitheliomas by definition contain elements that closely resemble the medullary epithelium, but in addition they may also contain structures resem-

bling those derived from the secondary optic vesicle or optic cup; of these, the most frequently observed are retinal pigment epithelium, ciliary epithelium, vitreous, and neuroglia. In the malignant varieties one also sees masses of tightly packed neuroblastic cells, sometimes showing marked mitotic activity, making these tumors indistinguishable from poorly differentiated retinoblastomas. Structures resembling poorly differentiated Flexner-Wintersteiner rosettes may also be observed (Fig. 8).

To qualify as a teratoid medullo-epithelioma there must be one or more heteroplastic elements present in addition to the medullo-epitheliomatous components. From Verhoeff's description and illustrations of his tumor, we would have to assume that there were no truly heteroplastic elements present. By far the most frequently observed heteroplastic element in medullo-epitheliomas is hyaline cartilage (Fig. 6); next is tissue resembling brain (Fig. 7). Recently we have become aware of the fact that skeletal muscle may also be present, usually resembling the moderately well-differentiated rhabdomyosarcomas.[10,28]

One of the most interesting teratoid medullo-epitheliomas that I have seen (Fig. 9) contained remarkably organoid formations consisting of a central tubular structure lined by medullary epithelium oriented as in the primary optic vesicle with a sharply outlined inner limiting membrane along the luminal surface and much less sharply outlined surface in contact with the surrounding mes-

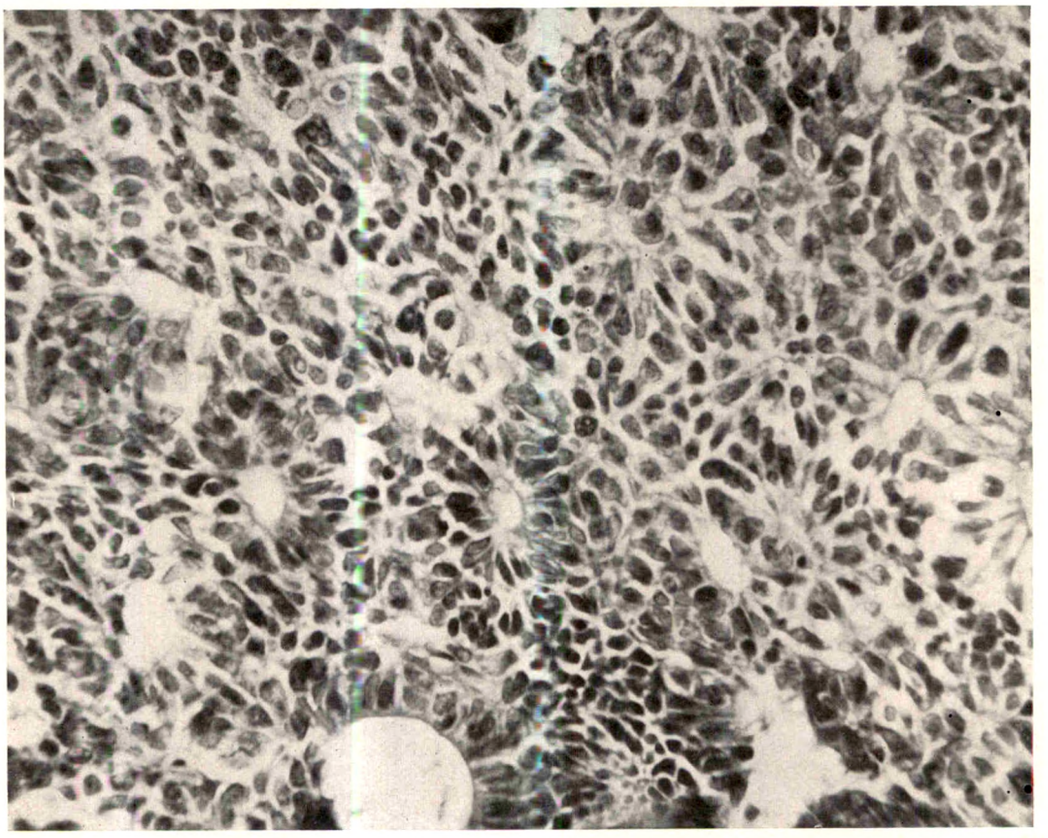

Fig. 8 (Zimmerman). Structures resembling Flexner-Wintersteiner rosettes may be observed in malignant medullo-epitheliomas (hematoxylin and eosin, ×380). (AFIP Neg. 70-8781).

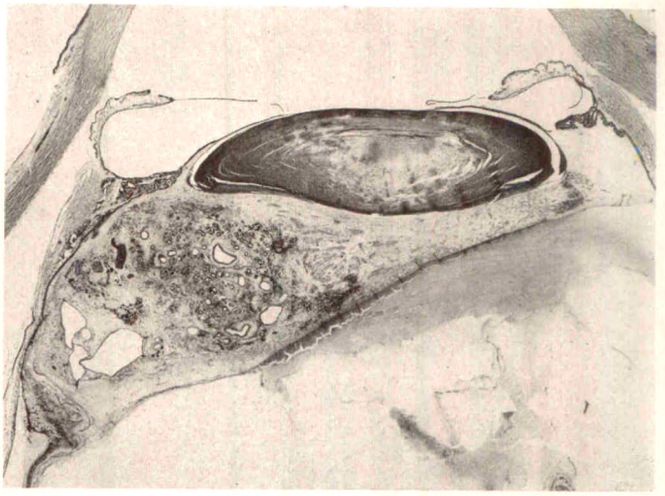

Fig. 9 (Zimmerman). Teratoid medullo-epithelioma. Many tubular and vesicular structures are contained in large retrolental mass of mesenchymal tissue. See Figures 10-12 for details shown at greater magnification (hematoxylin and eosin, ×7). (AFIP Neg. 70-9265).

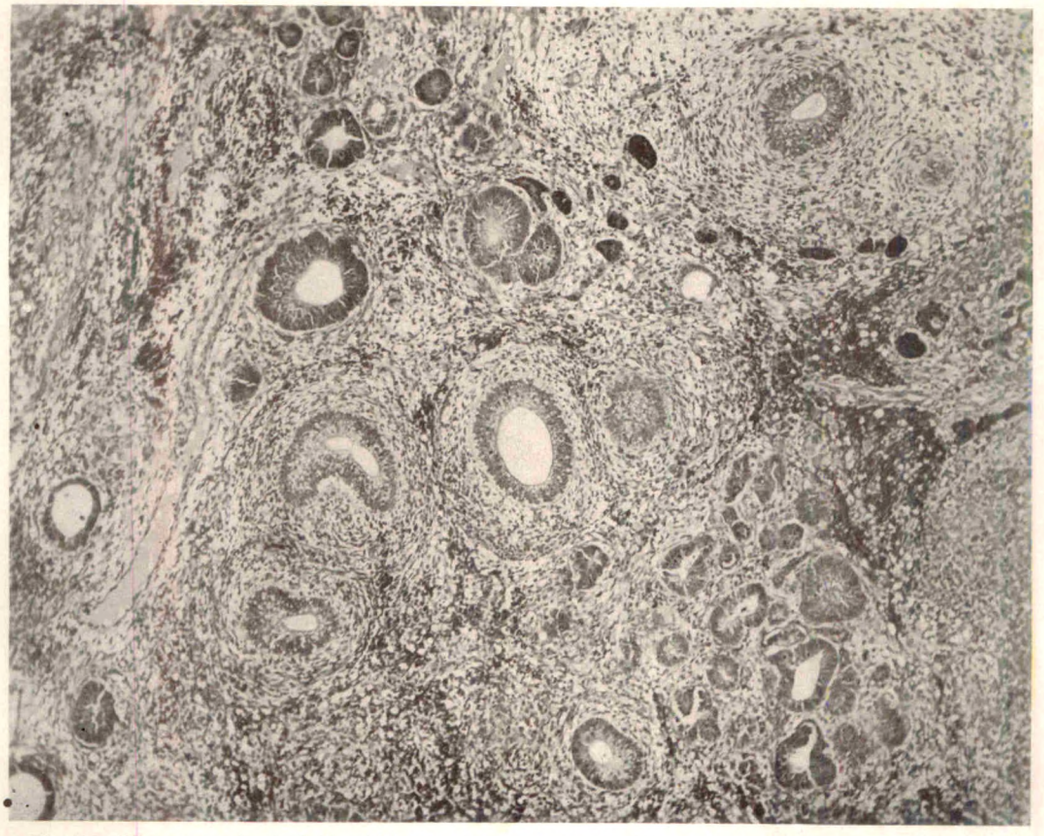

Fig. 10 (Zimmerman). A field within the tumor shown in Figure 9 containing organoid masses of mesenchymal tissue arranged concentrically about tubular structures reminiscent of the primary optic vesicle (hematoxylin and eosin, ×60). (AFIP Neg. 70-8375).

enchyme (Fig. 10). The latter, however, appeared to be clearly oriented concentrically about the medullary epithelium. Within this mesenchyme one could sometimes find bundles of larger, plumper spindle-shaped and straplike cells containing abundant eosinophilic cytoplasm (Fig. 11). These bundles were reminiscent of myotomes, and upon closer scrutiny, well-differentiated skeletal muscle cells containing typical cross-striations could be seen among them (Fig. 12).

In the first case of this sort that came to our attention, it was the presence of large ganglioform cells that stimulated special interest.[28] We were trying to prove to our own satisfaction that the cells were truly ganglion cells, but we were having no success. Finally, electron microscopy was used, even though it was necessary to retrieve tissue from the paraffin block for examination of the cells in question. Instead of providing support for the belief that the ganglioform cells were neurons, electron microscopy proved that they were, in fact, muscle cells with the typical well-differentiated banding of mature rhabdomyoblasts.[29] Even before our electron microscopic study of that tumor was completed we received another that was even stranger in several respects. The entire retina was detached and incorporated in a large mass that involved the ciliary body and iris (Fig. 13). Microscopic examination revealed a remarkably haphazard mixture of neuroepithelial elements, myxoid mesenchymal tissue, and bands of long, plump, spindle-shaped cells (Fig. 14) containing abundant

Fig. 11 (Zimmerman). Another field from the tumor shown in Figure 9 in which bundles of plump spindle-shaped cells (arrows) resembling a myotome are contained in the mesenchymal tissue surrounding the structure lined by medullary epithelium (hematoxylin and eosin, ×60). (AFIP Neg. 70-8374).

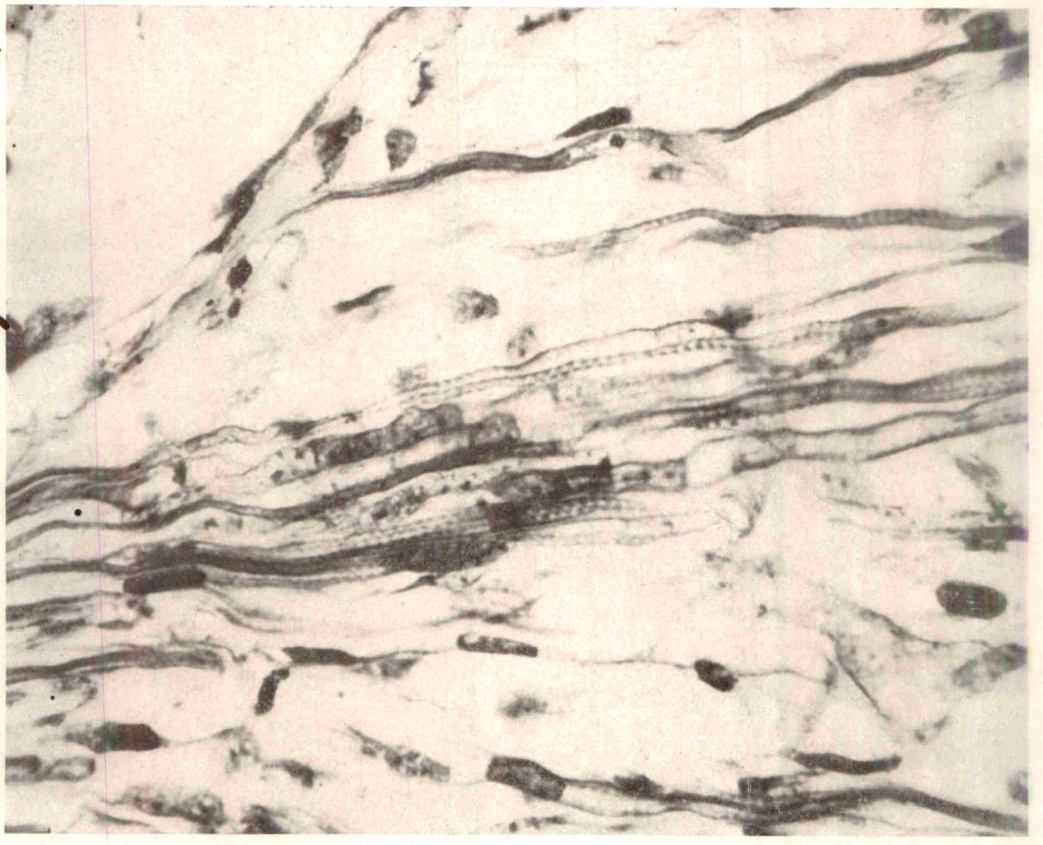

Fig. 12 (Zimmerman). The plump spindle-shaped and straplike cells contained in the mesenchymal tissue of the tumor shown in Figures 9-11 are well-differentiated rhabdomyoblasts exhibiting the typical cross-striations of skeletal muscle cells (phosphotungstic acid-hematoxylin stain, ×525). (AFIP Neg. 70-9149).

eosinophilic cytoplasm in which one could readily see, even without the aid of special stains, the typical cross-striations of skeletal muscle cells (Fig. 15). With appropriate stains one could see a greater number of cells containing such cross-striations (Fig. 16), and even in the loose myxoid mesenchymal tissue one could establish that some of the stellate cells were actually rhabdomyoblasts, thus presenting a picture similar to what one sees in embryonal rhabdomyosarcoma.

In retrospect, the large ganglioform cells (a few of which were also observed in our second case) should have been suspected of being rhabdomyoblasts because we have frequently seen similar cells in rhabdomyosarcomas of the orbit and in other locations. They had the typical concentric cytoplasmic laminations produced by their highly organized myofibrils; they stained intensely with a deep brick-red color with Masson's trichrome stain; and they were rich in glycogen (intensely PAS-positive except after treatment with diastase). Nissl preparations and Bodian stains had failed to provide support for the original notion that these were ganglion cells; yet we did not suspect that these ganglioform cells might be rhabdomyoblasts until we saw them by electron microscopy. From this experience we should learn several lessons. The first is to be more objective. We failed to suspect that the ganglioform cells might be rhabdomyoblasts, not because they didn't have the characteristics of such cells but because their intraocu-

lar location and their association with a neural neoplasm served to effectively eliminate such a possibility from even being considered at our conscious level of differential diagnosis. The second is to "beware of the obvious" and become imaginative. How much are we overlooking every day because our stereotyped thinking doesn't permit us to imagine other possibilities? Finally, the experience again illustrates the potential diagnostic value of electron microscopy. Even when one hasn't had the opportunity to prepare the tissue properly for electron microscopy initially, it is still possible to obtain meaningful (sometimes, as in the present case, crucially diagnostic!) information by retrieving tissue from the paraffin block and then reprocessing it for electron microscopy.

Having had in quick succession these several medullo-epitheliomas with a rhabdomyoblastic component, we naturally began to wonder how often we had overlooked such a component in the past, and we also wondered about the possibility that similar tumors might occur intracranially. With regard to the first consideration, I immediately recalled a case that I used for illustrations in a chapter I prepared for Ackerman's Surgical Pathology.[30] In that case, a huge intraocular medullo-epitheliomatous tumor that contained many large islands of hyaline cartilage, some of which suggested sarcomatous change, also had clusters of very large cells with abundant eosinophilic cytoplasm and large vesicular nuclei containing prominent nucleoli. These cells had always been suspected of being ganglion cells, but their identity had never really been established. Unfortunately, we still don't know whether these cells are rhabdomyoblasts because the original tissue, processed in celloidin, was used for study sets, and I have not been able to retrieve satisfactory tissue for further study by light or electron microscopy. In my recent review of all our ciliary body tumors,[10] I did come across several other cases in which strap cells, racquet cells, or ganglioform cells suggestive of rhabdomyoblasts were present, but in those old cases I was never able to establish conclusively the presence of a rhabdomyoblastic component. Among our more recently accessioned cases, however, we now have a total of four specimens in which we have been able to demonstrate rhabdomyoblasts with typical well-differentiated cross-striations. In three of the four tumors, the cross-striations are demonstrable even in sections stained by hematoxylin and eosin, but in one case they were identified only by electron microscopy.[28]

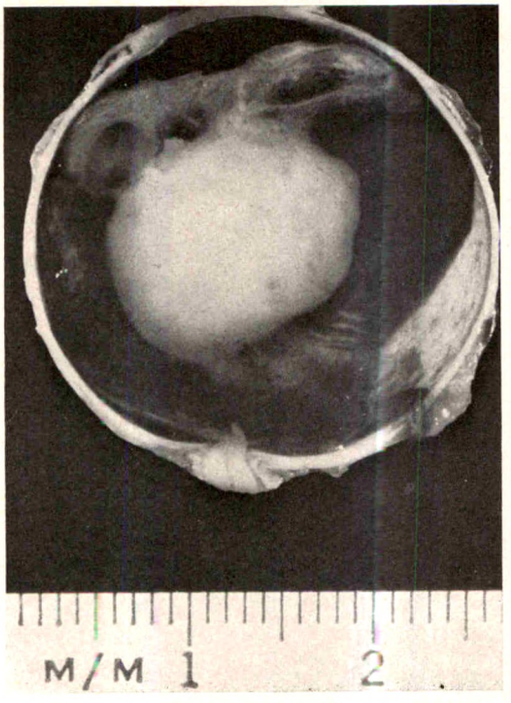

Fig. 13 (Zimmerman). Teratoid medullo-epithelioma. The entire retina and the ciliary body are incorporated into a large mass of neoplastic tissue. See Figures 14-16 for some of the histopathologic features of this unusual tumor. (AFIP Neg. 69-8030-5).

With regard to the occurrence of a rhabdomyoblastic component in other tumors of the central nervous system, a number of cases have been reported.[31-36] Most have been considered cerebellar medulloblastomas and have occurred in children. The term "medullomyoblastoma" has been coined for them. Some authors have considered such tu-

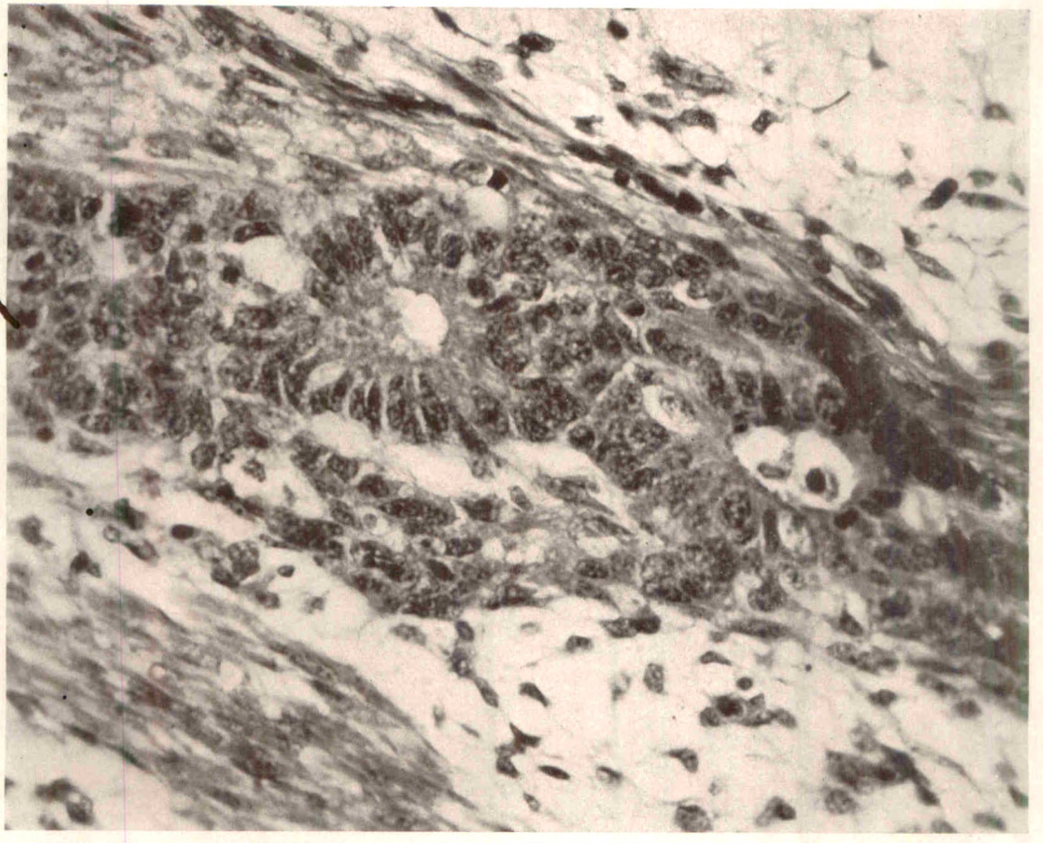

Fig. 14 (Zimmerman). Within the tumor shown in Figure 13 there are numerous neuroepithelial structures intimately associated with loose mesenchymal tissue and bundles of plump spindle-shaped and strap-like cells (hematoxylin and eosin, ×380). (AFIP Neg. 69-9796).

mors as being teratomatous; others have suggested that they are immature leptomeningeal neoplasms (sarcomas) of the posterior fossa. According to Goldman,[35] the primary tumors of the central nervous system containing rhabdomyosarcomatous elements fall into three groups: a teratoid group, in which the sarcomatous elements are associated with medulloblastoma; primary sarcomas that are probably of meningeal origin; and his own "unique" case, in which the sarcoma appeared to be derived from the mesodermal tissue associated with the vascular supply of a primary glioma. Experimentally, medulloblastomas of the cerebellum have been produced in mice, and in some of the resultant neoplasms, cells of a sarcomatous nature have been identified among the neuroblastic elements, though no evidence of rhabdomyoblastic differentiation was described.[37]

The question also arises as to the histogenesis or embryogenesis of the cartilage and skeletal muscle observed in association with these medullo-epitheliomas. Several suggestions may be made, but we have no absolute proof that any one is the correct answer. First, as Verhoeff pointed out, and as I have repeatedly observed in our cases, the tumor usually has some vascular stroma. Often there is a large vascularized mesenchymal retrolental mass that resembles and probably is hyperplastic primary vitreous. The vessels entering this mass in the posterior chamber can often be shown to have had their origin from the stroma of the ciliary body, entering through a colobomatous defect in the continuity of the pigmented and nonpigmented

layers of ciliary epithelium. Thus, one must consider the possibility that heteroplasia took place in the mesodermal tissue contained in the persistent hyperplastic primary vitreous. As we have recently reported,[38] one may see heteroplastic adipose tissue in persistent hyperplastic primary vitreous, but to date we have not seen either skeletal muscle or cartilage in such cases, nor have we seen adipose tissue in our teratoid medullo-epitheliomas. Cartilage, however, is a well-known constituent of the colobomatous defects in the severely microphthalmic eyes of babies born with a 13-15 trisomy,[39] and it may rarely be seen in unilaterally malformed eyes not associated with any systemic anomaly or chromosomal disorder.[40] Thus a most likely possibility is that the cartilage and skeletal muscle observed in association with these medullo-epitheliomas are derived from mesoderm entering through a colobomatous defect in the medullary epithelium.

Another distinct possibility is the origin of these tissues from the neural ectoderm itself. At least one example of the origin of striated muscle fibers from the neural ectoderm is well established. In birds and reptiles, the pupillary muscles have the typical cross-banding of skeletal muscle fibers.[41] Old embryologic studies indicated that these muscles are derived from the medullary epithelium,[42] just as are the smooth iridic muscles of man and most other species. Recently the embryologic development of these "skeletal" muscle cells from the medullary epithelium at the rostral margin of the optic cup in the chick

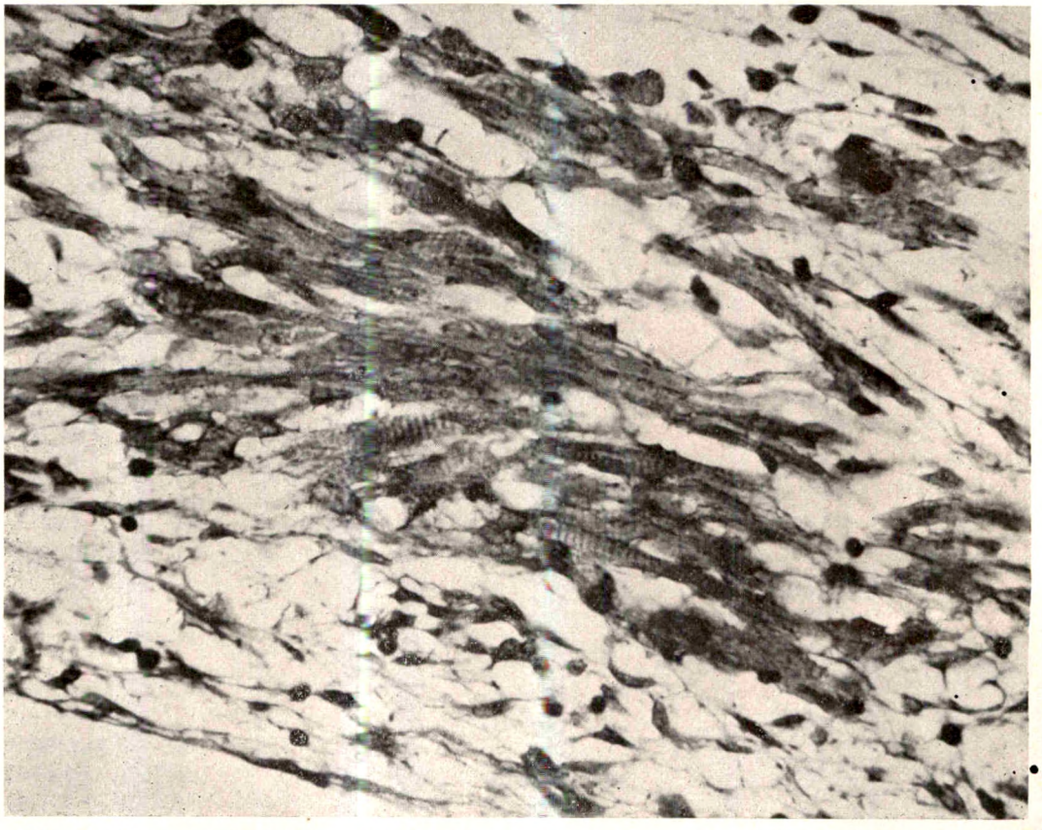

Fig. 15 (Zimmerman). Rhabdomyoblastic differentiation of many cells contained within the loose mesenchymal tissue of the tumor shown in Figures 13 and 14 is evident even without the aid of special stains (hematoxylin and eosin, ×380). (AFIP Neg. 70-7862).

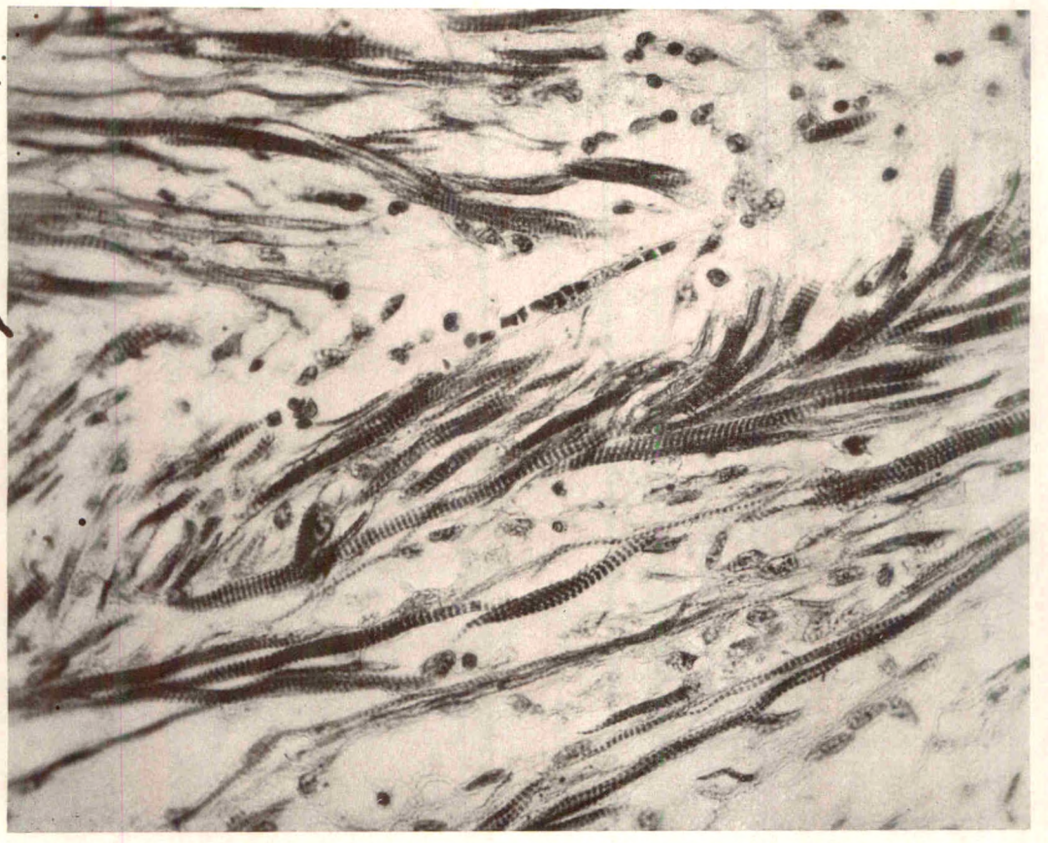

Fig. 16 (Zimmerman). The typical cytoplasmic cross-striations of skeletal muscle are demonstrated much more vividly with the phosphotungstic acid-hematoxylin stain (×305). (AFIP Neg. 69-9805).

has been under investigation by light and electron microscopy in our laboratory, and we can confirm the fact that the neural ectoderm does have the potential for the production of rhabdomyoblasts.[43] In some of our tumors, the extremely intimate relationship of rhabdomyoblasts to neuroepithelial elements suggests the possibility that the two cell types may have arisen from a common precursor.

Still another possibility remains to be considered. According to some embryologists, the mesenchyme should be considered in a functional sense rather than as a genetic entity. It can be derived from various epithelia regardless of their blastodermic layer of origin. In the region of the head, especially, much of the mesenchyme is derived from the neural crest. According to Starck,[44] this neuroectodermal mesenchyme contributes to the formation of cartilage, bone, and odontoblasts and may be termed the "mesectoderm." The cephalic neural crest is also believed to give rise to melanocytes, Schwann cells, neuroblasts, and ganglion cells of the sympathetic nervous system and to leptomeningeal cells. In tissue culture, cells from the neural crest have been observed to differentiate along several pathways, and when grown in the presence of entodermal cells from the pharyngeal area, they produce cartilage.[45] Thus it seems possible that the loose mesenchymal tissue contained in the stroma supporting the medullo-epitheliomatous elements may actually be mesectoderm and that the islands of hyaline cartilage may be derived from such neuro-ectodermal tissue. I have not, however, come across any refer-

ence to the mesectoderm giving rise to skeletal muscle, though, as I have already mentioned, it is well established that in birds and reptiles the neuro-ectoderm can give rise to striated muscle.

Finally, before closing let me say that the knowledge that a sarcomatous orbital tumor may have originated inside the eye can be useful for the surgical pathologist. Recently we were sent in consultation a chondrosarcomatous neoplasm in the orbit of a nine-year-old boy whose eye had been enucleated three years earlier—allegedly for retinoblastoma. When we were able to study the original ocular tumor, our suspicions proved to be correct. The intraocular tumor was not a retinoblastoma but, rather, a teratoid medullo-epithelioma containing a rhabdomyosarcomatous component. We were not able to demonstrate a cartilaginous component in the two blocks of tissue obtained from the eye, but we nevertheless have no doubts that the orbital chondrosarcoma represents a recurrence of the original malignant teratoid medullo-epithelioma. In this connection, the case of intraocular chondrosarcoma in a cat reported by Barron and Saunders[46] is of interest. I have studied that tumor very carefully and believe it, too, belongs in the category of malignant teratoid medullo-epitheliomas, but because the chondrosarcomatous component has so overgrown everything else inside the eye, it is difficult to be certain of this interpretation.

## Summary

Although Verhoeff made an incredibly detailed and accurate histopathologic study of the tumor he described in 1904, the name he chose for it ("terato-neuroma") seems inappropriate because the tumor was neither truly teratoid nor neuronal. In retrospect, and with the large experience we and others have had since Verhoeff's time, it is apparent that his tumor was a sort of prototype of the pure medullo-epithelioma, an embryonic neoplasm containing structures resembling the medullary epithelium of the optic vesicle and its derivatives. Other medullo-epitheliomas that have since been studied contain, in addition, heteroplastic elements—tissues not normally observed in the eye—and may therefore be called teratoid medullo-epitheliomas. Brain, cartilage, and rhabdomyoblasts are the most readily recognized heteroplastic elements observed in these teratoid medullo-epitheliomas.

# EARLY EFFECTS OF SINGLE AND REPEATED DOSES OF L-EPINEPHRINE IN MAN

PETER C. KRONFELD, M.D.
*Tucson, Arizona*

In a recent review of the mechanism of action of the adrenergic drugs in glaucoma, Sears[1] distinguished three effects of topical L-epinephrine upon the maintenance level of intraocular pressure: (1) an early decrease in pressure partly related to a decrease in aqueous production, (2) an early increase in outflow facility overlapping the decrease in aqueous production, and (3) a progressive increase in outflow facility with continued L-epinephrine medication.

In 1962[2] and again in 1964,[3] Kleis, Barkstrom and I reported on early increases in outflow facility in patients with ocular hypertension or primary open-angle glaucoma after single doses of L-epinephrine. These observations were extended and partly confirmed by other investigators. The present paper provides a fuller picture of the early effects of L-epinephrine based on new measurements and intrasubject comparisons with the effects of other ocular hypotensive agents.

## MATERIALS AND METHODS

The patients who participated in this study came from a group with ocular hypertension or primary open-angle glaucoma which has been under observation for several years. The status of their aqueous dynamics has been followed regularly in the outpatient department and this has yielded base line values for pressure and outflow facility ($P_b$, $C_b$) with only slight interference with these patients' normal daily activities. The base line values have been checked at suitable intervals, usually every six months. In general, the diurnal pressure pattern has been that of a high between 7 and 10 A.M. and a low in the evening. During the early morning hours the applanation pressures have been consistently higher than 24 mm Hg. Outflow facility (C), as determined by conventional tonography using Friedenwald's 1955 tables, has not varied significantly between 7 A.M. and 4 P.M.; a few of the patients have shown an increase in C between 7 and 10 P.M.

By repeated paired Schiøtz readings these patients' ocular rigidities were found to lie between 0.0160 and 0.0260. As shown also by other investigators (Lee,[4] Tarkkanen and Karjalainen,[5] Criswick and Drance[6]), during the phases studied, L-epinephrine does not exert a demonstrable effect on ocular rigidity.

L-epinephrine was routinely administered in a single drop of a 2% aqueous solution (containing about 1.02 mg of epinephrine base) between the hours of 7 and 9 A.M. In most parts of the study the applications were made to both eyes, the main reason being that a few instances of possible contralateral effects had been observed after unilateral surface instillation of L-epinephrine. Another reason was that in the majority of patients the abnormality of aqueous dynamics was asymmetrical which made the fellow eye less valuable as a control and more valuable as a test subject.

Pilocarpine in varying dosage was the only previously administered hypotensive medication, and in patients who had received this drug, a minimum of three days was allowed to elapse for evanescence of its effect before L-epinephrine was started.

Observations during the early part of the study suggested variations in the test procedure. The study, therefore, has yielded sev-

From the Department of Ophthalmology, the University of Illinois College of Medicine, Chicago, Illinois.

eral series of observations derived from several different groups of patients, all fairly well matched with regard to age, baseline pressure and outflow facility, and prevalence of visual field defects.

*Test procedures*—All measurements were made with certified mechanical or electronic (V. Mueller) tonometers of the Schiøtz type. The test procedures were as follows:

*Series* 1—Pressure readings were taken hourly from 8 A.M. until 4 P.M. for three consecutive days, a control day, a treatment day, and a post-treatment day. L-epinephrine was administered after the 8 A.M. reading on the treatment day.

*Series* 2—Pressure readings were taken hourly from 8 A.M. until 12 noon for five consecutive days the first three of which were control days. L-epinephrine was administered after the 8 A.M. reading on the fourth day. Tonographies were performed each day shortly after the 12 noon pressure reading.

*Series* 3—Pressure readings were taken hourly from 8 A.M. until 12 noon for five consecutive days the first two of which were control days. L-epinephrine was administered after the 8 A.M. reading on the third day. Tonographies were performed each day shortly after the 12 noon reading.

*Series* 4—Pressure readings were taken hourly from 8 A.M. until 12 noon for three consecutive treatment days (the patient receiving a single dose of the drug after each 8 A.M. tonometry). This was followed by 10 days of rest, after which the whole course was repeated twice.

*Series* 5 *and* 6—Repeated tonometries and tonographies were performed between 11 A.M. and 1 P.M. on patients receiving two self-administered 1-2 drop doses of epinephrine daily for one week (Series 5), or for three weeks (Series 6).

For the same length of time and in rotation the last group of patients was also placed on two other hypotensive medications, pilocarpine 4% and echothiophate 0.25%. Within 18 months each of these therapeutic regimens was repeated at least once and in most patients twice, allowing three weeks for evanescence of the effects of L-epinephrine and echothiophate. Some of the patients (Series 6) required acetazolamide for pressure control during the evanescence periods.

## Results

Hourly pressure measurements after a single dose of L-epinephrine administered at 8 A.M. showed variations in individual response during the early phases. A few eyes passed through a mild hypertensive phase, while in others a drop in pressure was recorded at the end of the first hour. These individual variations were similar in pattern and degree to those reported by Richards and Drance.[7]

When measurements were combined into means, the patients in Series 1 (Table 1) showed a drop in pressure that was gradual and reached a maximum four hours after the early morning treatment. Lower pressures continued during the afternoon and were still clearly demonstrable the next

day. This pointed toward the early afternoon hours of the treatment day as the time of the maximal pressure effect of single doses of L-epinephrine. Procedures used in Series 2 and 3 were, therefore, designed to combine tonography about five hours after treatment with hourly tonometries during the morning. To get more information about the optimal length of the control and post-treatment periods, the control period was extended to three days preceding drug administration in Series 2 and the post-treatment observation period extended to three days in Series 3. The hourly morning pressure readings, excluding the first reading on the treatment day, were combined into means for the individual eye and the individual day.

The data thus obtained (Tables 2 and 3) are indicative of insignificant changes from one control day to the next, of a significant mean pressure drop from the last control day to the treatment day and of an even more significant mean pressure drop from the last control to the post-treatment day. Lower mean pressures than on the last control day still prevailed on the second day after treatment. Since the results in Series 2 and 3 were in essentially good agreement, they were combined in Figure 1 for the presentation of the pressure drops in the individual eyes. Both the treatment day and the post-treatment day data show the approximately linear relationship between pressure drop ($\Delta P$) and starting level ($P_b$) that is known

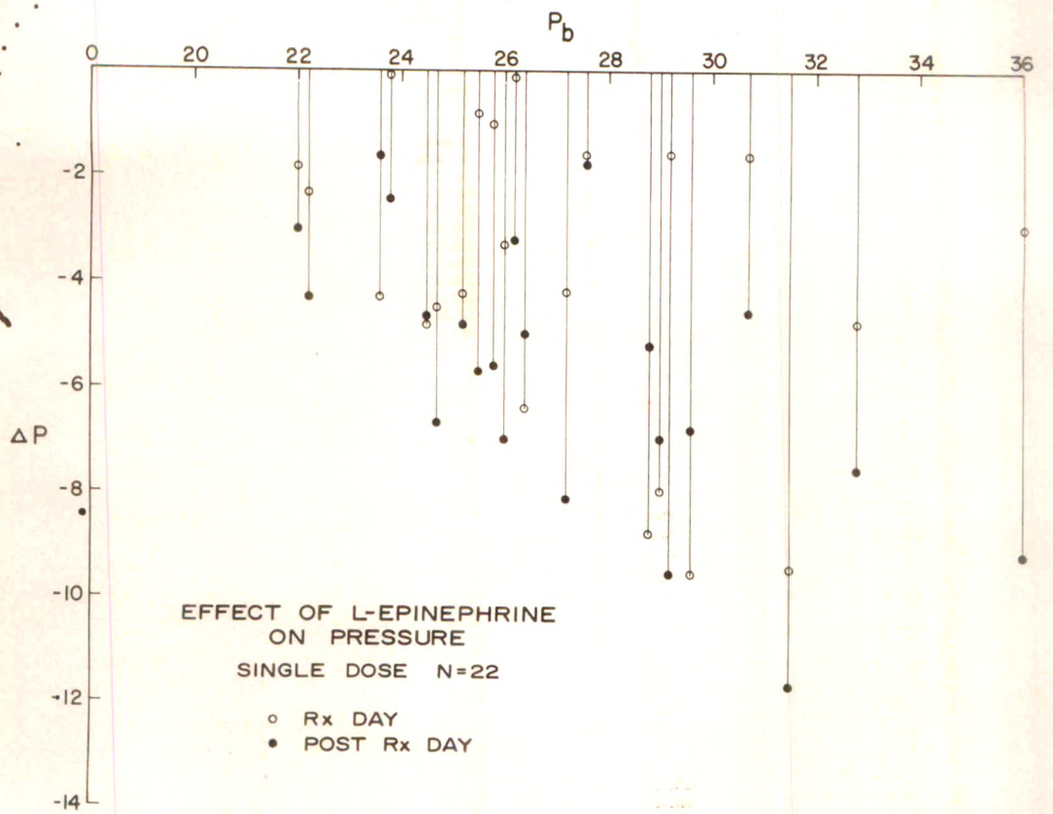

Fig. 1 (Kronfeld). The base line pressures recorded on the abscissa ($P_b$) are the means of hourly morning pressure measurements on the control day preceding the administration of a single dose of 2% L-epinephrine. The ordinates ($\Delta P$) are the differences between $P_b$ and the mean morning pressures on the day of treatment (empty circles) and on the day following treatment (solid circles). The subjects are patients with ocular hypertension or primary open-angle glaucoma (Series 2 and 3).

to apply, within definite limits, to the effects of other hypotensive agents.[8,9] In addition, there is considerable individual variation, with a few eyes standing out by their poor responses.

With the drop in pressure the phenomenon of the early increase in outflow facility is shown in Tables 2 and 3, most pronounced on the treatment day, less so on the post-treatment day, and barely suggested on the second day after treatment. The relationship between base line and drug-response values is made simpler and clearer by conversion of outflow facility into outflow resistance. A linear relationship is known to exist between a pilocarpine-induced drop in resistance ($\Delta R$) and the baseline value ($R_b$).[9-11] In Figure 2 this relationship may also be deduced for single doses of L-epinephrine. There was only one eye that responded poorly in terms of outflow resistance, and in this case it was not associated with a poor pressure response.

Other data regarding single-dose responses were available from Series 4. These patients received single, one-drop doses for three consecutive days, and each three-day course of drug administration on this regimen was repeated three times with 10 days intervening between the courses. The findings on the first day of these courses are shown in Table 4.

### Short-term sustained administration

The effects of L-epinephrine remain es-

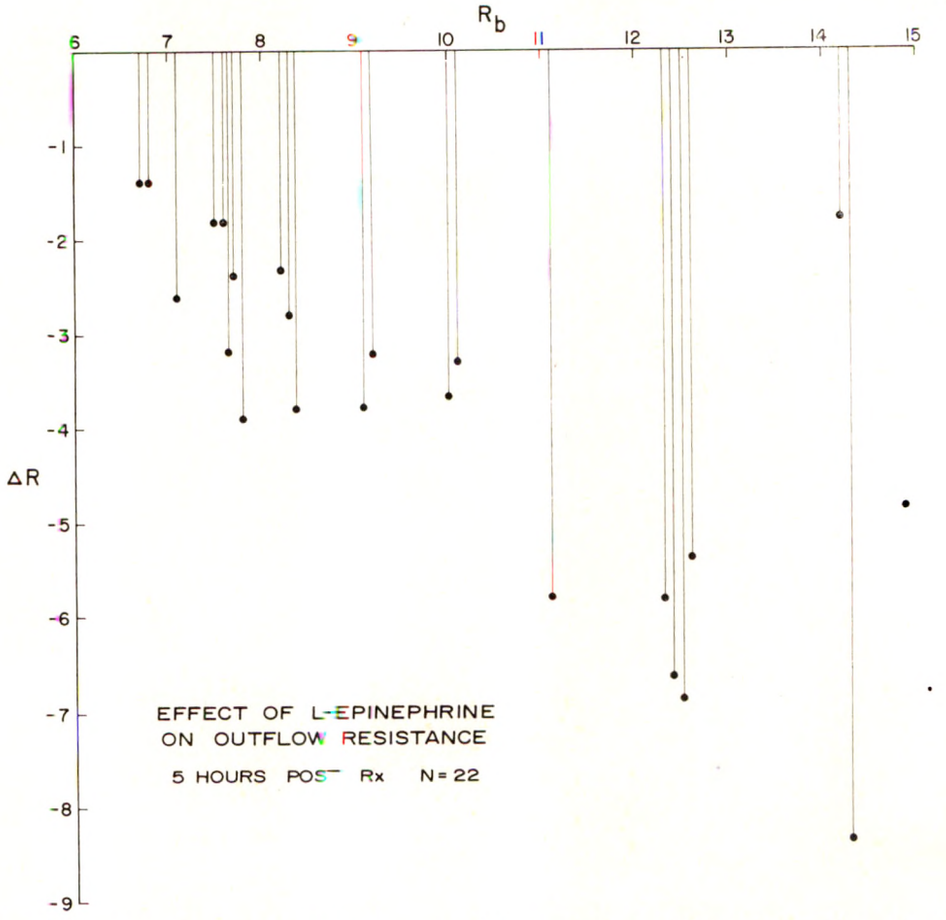

Fig. 2 (Kronfeld). The base line resistances recorded on the abscissa ($R_b$) are the reciprocals of the midday measurements of outflow facility on the control day preceding the administration of a single dose of 2% L-epinephrine. The ordinates ($\Delta R$) are the differences between $R_b$ and the reciprocal of the midday outflow facility on the day of treatment. The subjects are patients with ocular hypertension or primary open-angle glaucoma (Series 2 and 3).

sentially unchanged if two instillations per day are continued for one week (Table 5, Series 5). This finding suggested that sustained medication for a limited period might produce a quasi-steady state which would allow repeated measurements that could be combined into truly representative means. This proved to be the case. Four to six measurements during the second and third week of treatment (Series 6) revealed no systematic upward or downward trend and were, therefore, taken to reflect an at least temporary steady state. These measurements are shown in Table 6 as means and ranges for pressure and facility.

Short-term sustained medication elicited, on the whole, somewhat greater responses than the single doses. In the performance of the individual eyes, a nearly linear dependence of the responses upon their baseline values can again be recognized (Fig. 3 and 4). Comparison with the effects of pilocarpine and echothiophate shows that in the dosages used in this study the response pattern for L-epinephrine was fairly close to that of echothiophate (Fig. 5); a distinguishing feature of the pilocarpine effect was the occurrence of slight responses, both in terms of pressure and of resistance (Fig. 6).

## COMMENT

The search for representative indicators of drug effects had to begin with a search for base lines. The base lines chosen for this study were the means of repeated middle-of-the day tonometries and tonographies done in the outpatient department with only minimal interruptions of the patient's normal

daily activities. The results of these tonographies are normally distributed with standard deviations of the order of 0.010-0.022 µl/minute/mm Hg.[12]

The new data relating to single-dose effects may be compared with the results of the recent studies by Criswick and Drance,[6] and by Makabe.[13] Despite some differences in technique with regard to magnitude and range of responses, the three studies are in good agreement (Table 7).

In the study by Criswick and Drance,[6] and also that by Makabe,[13] only one eye of each patient was studied, with the fellow eye either serving as control or not participating. Most of the data of the present study are derived simultaneously from both eyes of each patient. Because of the well-known similarity of the parameters of aqueous dynamics in the two eyes of the same subject, the use of both eyes in drug studies may add to the strength of the results at the price of reducing the range of interindividual variations. Because of this potential weakness of the present study, the similarity of its results to those of the other two studies is reassuring.

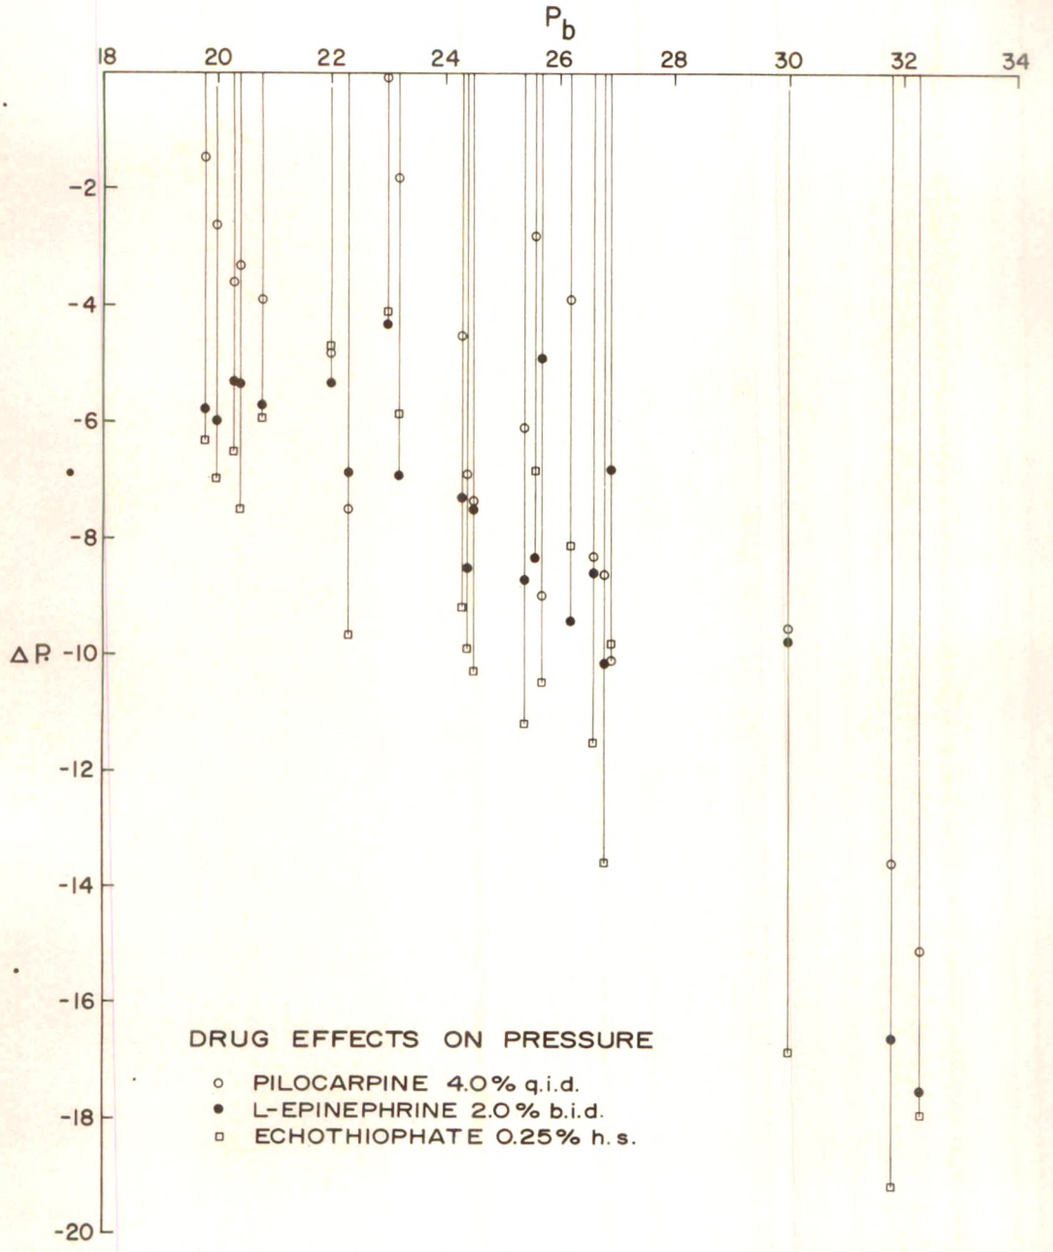

Fig. 3 (Kronfeld). Each vertical line represents the responses of one eye of Series 6. The $P_b$ values on the abscissa are the means of midday pressure measurements without hypotensive medication. The ordinates ($\Delta P$) are the differences between $P_b$ and the means of midday pressure measurements during three-week courses of treatment with the agents indicated in the figure.

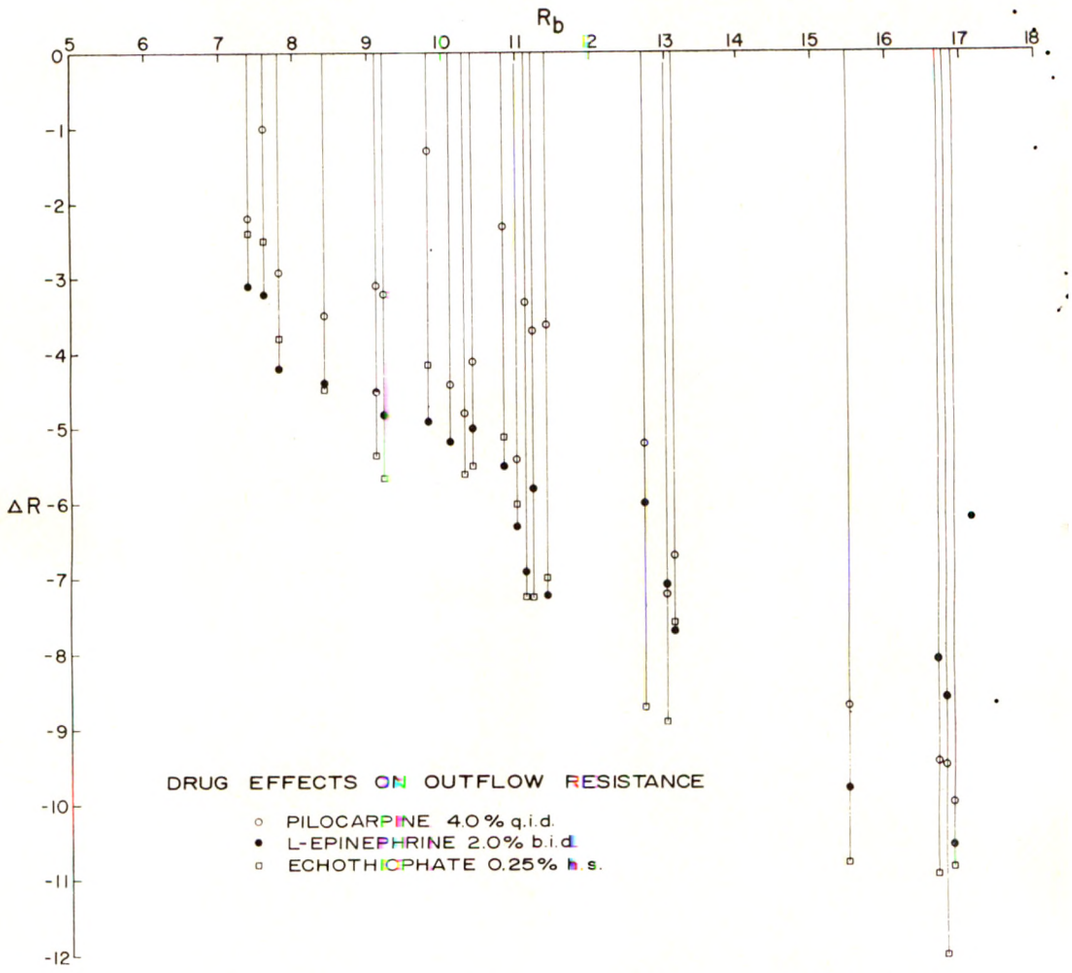

Fig. 4 (Kronfeld). Each vertical line represents the responses of one eye of Series 6. The $R_b$ values on the abscissa are the reciprocals of means of midday measurements of outflow facility without hypotensive medication. The ordinates ($\Delta R$) are the differences between $R_b$ and the reciprocals of means of midday measurements of outflow facility on patients with ocular hypertension or primary open-angle glaucoma (Series 6) during three-week courses of treatment with the agents indicated in the figure.

In the new single-dose data the nearly linear dependence of the pressure and resistance drops upon their respective base line values is in accord with Makabe's study[13] and my own findings in an earlier, unpublished series of cases. This is noteworthy because it brings out a similarity between the effects of L-epinephrine and those of cholinergic hypotensives. The drops in pressure and resistance after single doses could not be correlated with each other, which is in accord with the findings of Criswick and Drance.[6] The lack of correlation suggested significant variations of the other major parameter of aqueous dynamics, the rate of aqueous production. In Makabe's series, the flow rates calculated from the tonographic data appeared to be reduced three hours after single doses in 15 out of 20 glaucomatous eyes. Such effects apparently predominate in normal human eyes (Kupfer,[14] Weekers and associates[15]), and in some forms of ocular disease which will require further study.

In the present single-dose data, no consis-

tent change in the flow rates calculated for the individual eyes could be recognized. The mean facility and pressure responses in Tables 2 and 3 indicate that in the early phase of L-epinephrine effects the gain in facility tends to get ahead of the drop in pressure; this has been interpreted as increased pseudofacility by Duzanec and Leydhecker,[16] and

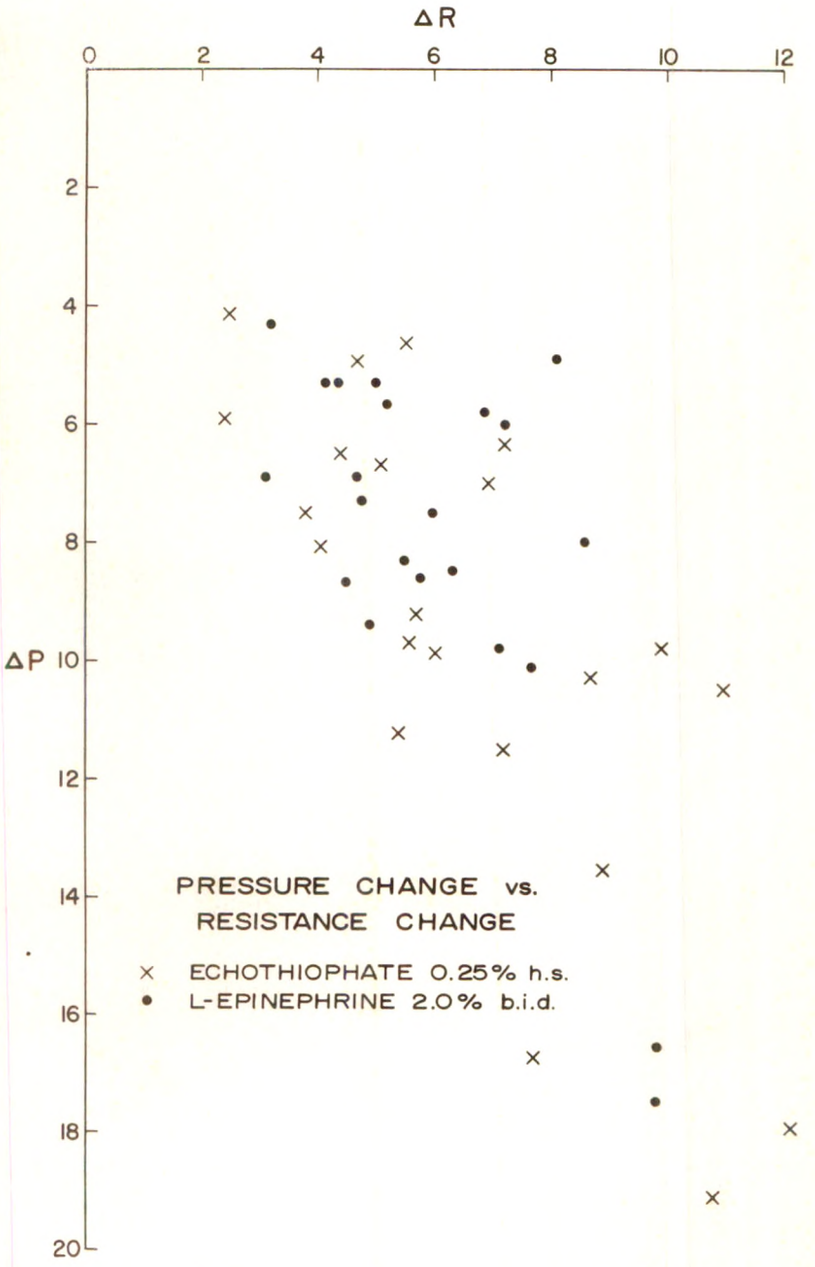

Fig. 5 (Kronfeld). The correlation between the pressure changes and the resistance changes produced by three-week courses of topical hypotensive treatment in patients with ocular hypertension or primary open-angle glaucoma (Series 6).

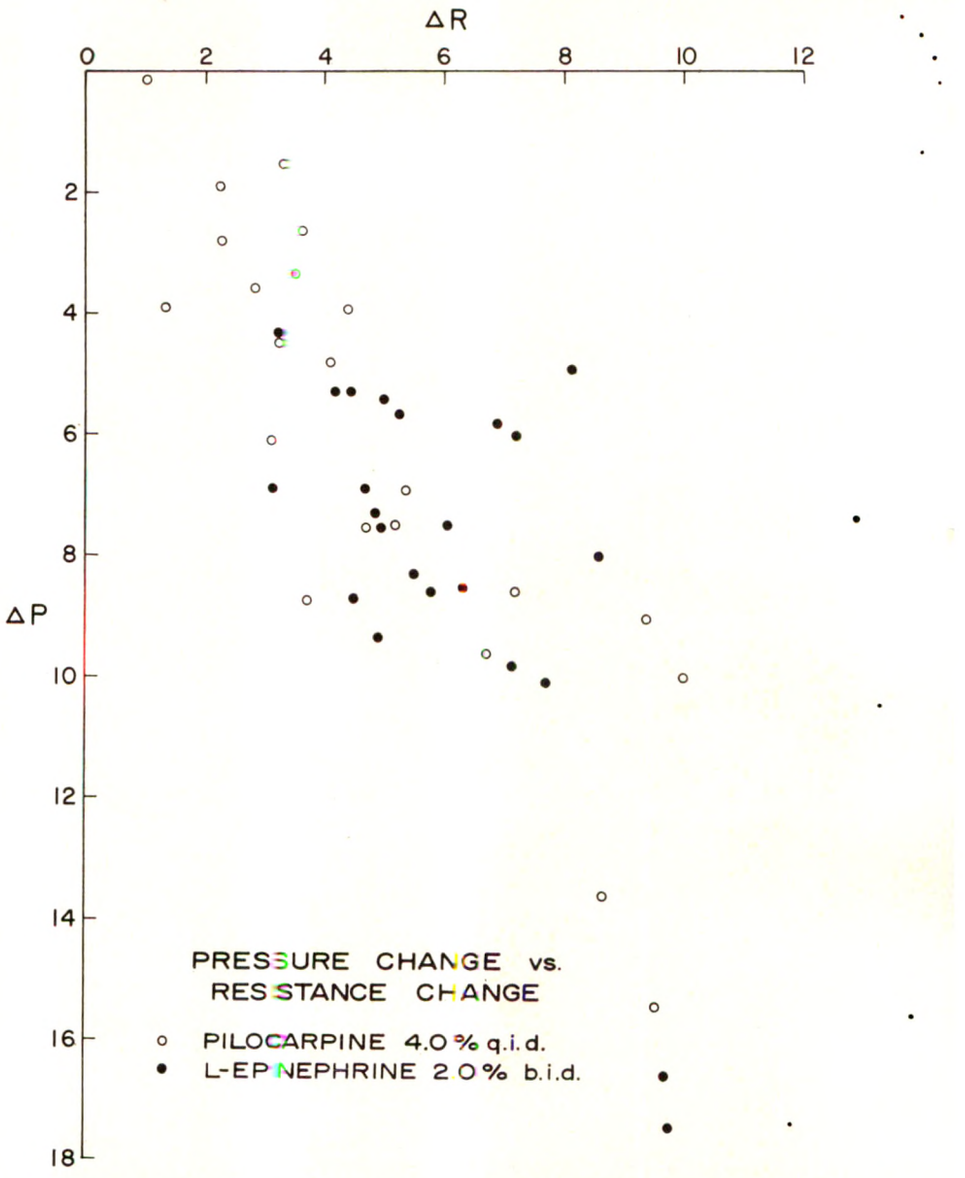

Fig. 6 (Kronfeld). The correlation between pressure and resistance changes produced by three-week courses of topical hypotensive treatment in patients with ocular hypertension or primary open-angle glaucoma (Series 6).

has been observed in monkeys by Bárány.[17] Kupfer's observation in normal human volunteers[14] and Bill's findings in the vervet monkey[18] do not suggest increases in pseudofacility. An initial increase in the rate of aqueous production could explain the discrepancy between outflow facility and pressure.

An increase in the rate of aqueous secretion during the first few hours of L-epinephrine effects was observed by Langham and Weinstein[19] in a sympathetically denervated (that is, supersensitive) human eye.

Abnormalities of sympathetic innervation in glaucoma simplex are by no means clearly established. The usual single dose delivered

TABLE 7

FREQUENCY DISTRIBUTION OF PERCENT OF INCREASE IN OUTFLOW FACILITY IN OCULAR HYPERTENSION OR OPEN-ANGLE GLAUCOMA AFTER SINGLE DOSES OF L-EPINEPHRINE 2%

| Source of Data | Percent Increase | | | | | | | | Total |
|---|---|---|---|---|---|---|---|---|---|
| | Less than −10 | −10 to 10 | 11 to 30 | 31 to 50 | 51 to 70 | 71 to 90 | 91 to 110 | Greater than 110 | |
| Criswick and Drance[6] | — | 2 | 4 | 3 | 5 | 5 | — | 5 | 24 eyes |
| Makabe[13] | 2 | 3 | 3 | 3 | 4 | 1 | 2 | 2 | 20 eyes |
| Present study (Series 2 and 3) | — | — | 3 | 5 | 5 | 4 | 2 | 3 | 22 eyes |

to the eye in the present study (one drop of 2% solution equivalent to about 1 mg of L-epinephrine) is so large in terms of human physiology that initial enhancement rather than the typical inhibition of some aspect of aqueous secretion is conceivable. This could explain the discrepancy between outflow and pressure during the first few hours of the ocular effects of L-epinephrine.

Turning to the effects of sustained L-epinephrine administration, the results in the subjects in Series 6 (Table 6) probably represent the most solid indicators of the early effects of the drug which have emerged from the present study. With regard to magnitude and range of the percent of facility increases, Series 6 differs markedly from the single-dose series 2 and 3. One obvious reason is that the participants in the single-dose studies were selected from a group of patients with ocular hypertension or those with primary open-angle glaucoma whose response to L-epinephrine, at the time of selection, was not known. This group could, and actually did, include poor responders to L-epinephrine. For the three-week sustained administration study (Series 6), some degree of responsiveness to L-epinephrine and to the other drugs was a necessary requirement, so known non-responders were eliminated.

In Series 6, too, there is a nearly linear relationship between the drug-induced resistance and drops in pressure and their base line values (Figs. 4 and 5). Because of the strong correlation between the responses of the patients' two eyes to the drugs used in this study (Fig. 7), it was felt that the sample (Series 6) would become more representative of its population if only one eye of each patient was used in computing the correlation coefficients. This computation for left eyes only (the eyes first tested) yielded correlation coefficients of 0.82 for the L-epinephrine-induced $\Delta P$ versus $P_b$ and of 0.92 for the corresponding $\Delta R$ versus $R_b$, both significant at the 1% level.

In the same sample, a correlation between drops in resistance and in pressure could be demonstrated in a strength of 0.64 for the effects of L-epinephrine and of 0.73 for echothiophate (both significant at the 5% level). Both of these correlations could be made stronger if corrections were applied to the large pressure drops which occurred from starting levels well outside the range of linear relationship between $\Delta P$ and $P_b$.

A search for epinephrine-induced changes in the rate of aqueous production was made by comparing the flow rates calculated from the individual tonographies done under the effect of short-term L-epinephrine therapy with the corresponding base line values. Both sets of values varied within such wide limits for the individual eyes that no consistent effect of the drug on flow rate could be recognized.

Flow rates calculated from the mean pressures and facilities of Table 7 also failed to demonstrate an overall trend toward lower aqueous production rates under short-term epinephrine therapy. In only seven of the 22 eyes listed in Table 7 did the relationship between the rise in facility and the drop in pressure suggest greater than 15% suppression of aqueous production. The dominant effect of epinephrine observed in the present study was clearly the improvement in outflow facility.

### Short-term versus long-term therapy

In Table 8 the two long-term series of Becker and associates[20,21] and the left eyes of the present Series 6 are compared with regard to the percent of improvement in outflow that occurred under L-epinephrine medication. Since in all probability the three series did not differ materially with regard to the condition of the patients' eyes, the gross difference shown in Table 8 (and proved significant at the 0.01 level by the Wilcoxon rank sum test) suggests a rather general

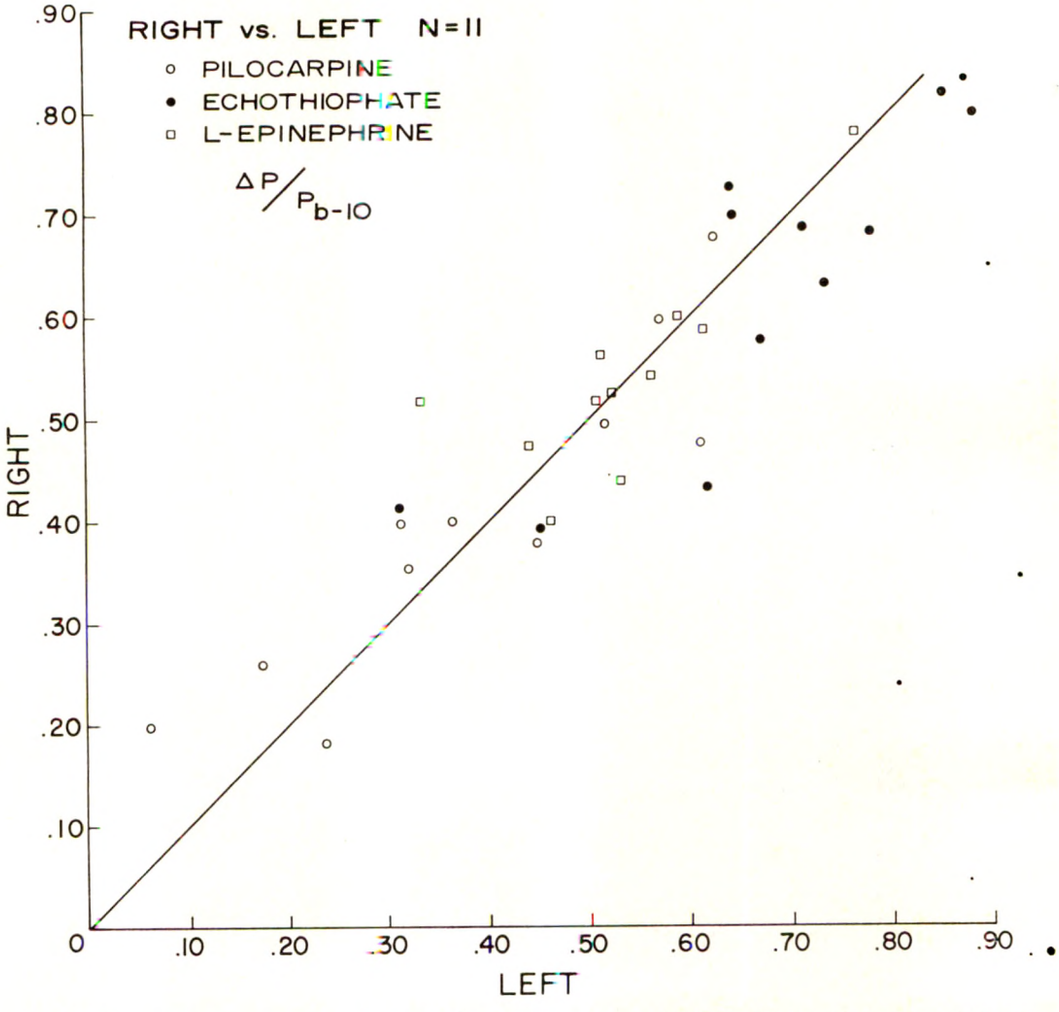

Fig. 7 (Kronfeld). The correlation between the pressure changes ($\Delta P/P_b$-10) in the right and left eye produced in patients with ocular hypertension or primary open-angle glaucoma (Series 6) by three-week courses of treatment with the agents indicated in the figure.

TABLE 8

FREQUENCY DISTRIBUTION OF THE EPINEPHRINE-INDUCED PERCENT OF INCREASE IN OUTFLOW FACILITY IN OCULAR HYPERTENSION OR OPEN-ANGLE GLAUCOMA

| Source of Data | Duration of Treatment | Percent Increase | | | | | | | | | Total No. Eyes |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | −9 to 10 | 11 to 30 | 31 to 50 | 51 to 70 | 71 to 90 | 91 to 110 | 111 to 130 | 131 to 150 | 151 to 170 | |

phenomenon of relative tolerance that sets in after the first three weeks of treatment. A particularly pronounced form of this tolerance may have been the basis of the tachyphylaxis to the drug observed by Krill and Newell[22] in some of their cases. In the large majority of ocular hypertensive patients and those with primary open-angle glaucoma, a certain—and clinically very useful—measure of responsiveness is retained and becomes, in some cases, the starting level for the gradual gain in facility reported to occur on prolonged L-epinephrine therapy.[19,23]

### COMPARISON WITH OTHER HYPOTENSIVE DRUGS

Further characterization of L-epinephrine as a hypotensive agent was expected to derive from comparison of its effect with that of other drugs. The similarity between the effects of epinephrine and echothiophate, as shown in Figures 3 and 4, was closer than expected. In the evaluation of this similarity, allowance should be made for a possible lowering of ocular rigidity by echothiophate. The pressure drops shown in Figure 3 may, therefore, represent slight overstatements and the resistance drops of Figure 4 may be understatements of the actual changes that occurred in response to echothiophate.

Also, the dosages in which the two drugs were used may not have been equally close to the maximum effective dose for all the eyes included in the study. Echothiophate in 0.25% concentration once a day may represent less than the maximum dose, while 2% L-epinephrine twice a day is well in excess of the full dose. Still, in a qualitative and semi-quantitative sense the comparison of the two drugs is probably valid; it again brings out the strength and duration of the outflow-enhancing component in the effect of L-epinephrine. The responses of the individual eyes to the two drugs tend to be close together, suggesting essentially the same degree of responsiveness to both drugs. This probably applies only to eyes with base line pressures within the range represented in this study; in eyes with base line pressures in excess of 35 mm Hg the responses to echothiophate are generally distinctly better than the responses to topical L-epinephrine. This characteristic of the drug, however, does not apply to the massive doses delivered to the eye by subconjunctival injection of 0.1% solutions.

Comparison of the effects of L-epinephrine with those of pilocarpine are valid with regard to dosage; tonography performed four hours after the early morning administration indicated that in none of the patients of Series 6 could the effect of pilocarpine

4% be augmented significantly by 50% increase in dosage. A difference in effective dosage may have been introduced by the fact that most of the patients of Series 6 had been on sustained pilocarpine therapy prior to the study.

The comparison brings out well-known characteristics of pilocarpine—that is, marked individual variations in effect, smaller responses in general and, specifically, very small responses in the range of low base line pressures, a range in which L-epinephrine is conspicuously effective.

## Summary

The early effects of topical L-epinephrine on aqueous dynamics in primary ocular hypertension and primary open-angle glaucoma were studied with single doses and three-week courses of sustained administration. Several phases of the effect of the drug could be recognized, with increases in outflow facility emerging as the dominant response of the type eye under study. During the first three weeks of treatment the magnitude of the facility response was close to that of echothiophate, with suppression of aqueous production making a recognizable contribution to the lowering of intraocular pressure in only one-third of the eyes participating in the study.

The high level of facility response evidenced during the first three weeks of treatment is probably not uniformly maintained as treatment is continued.

# RESULTS OF DEPRESSION BIOMICROSCOPY OF THE POSTERIOR CHAMBER

H. SLEZAK, M.D.
*Vienna, Austria*

The posterior chamber of the human eye has a complicated shape (Fig. 1). Salzmann[1] distinguishes several parts.

The most posterior part (i.e., the slit-shaped orbicular space named after Garnier[2]) extends between the inner face of the pars plana and the orbicular portion of the anterior limiting membrane of the vitreous.

The second part, the system of ciliary valleys, borders on the orbicular space posteriorly. In the posterior pars plicata, the ciliary valleys form closed canals, as the vitreous is adherent to the tips of the ciliary processes. In the anterior pars plicata, by contrast, the ciliary valleys present as grooves opening into the circumlenticular space.

The circumlenticular space itself constitutes the third part of the posterior chamber. Its outer and inner borders are formed by the ciliary processes and the peripheral lenticular zone, while it is delineated anteriorly and posteriorly by the anterior limiting membrane of the vitreous and the anterior zonule fibers.

The extreme anterior part of the posterior chamber (i.e., the prelenticular and prezonular space) extends from the pupil to the iris root. It borders anteriorly on the iris and posteriorly on the lens as well as the anterior zonule fibers.

Biomicroscopy of the posterior chamber in non-aphakic eyes has so far been limited. The prezonular and the circumlenticular space can be examined with the slit lamp only under exceptional circumstances. Such examination is possible (1) if there is a colomba or a dialysis of the iris, or (2) if the pupil can be dilated to the extent of forming an iridolenticular cleft. In this case, the iris contracts into a narrow seam and loses its contact with the anterior lens surface.

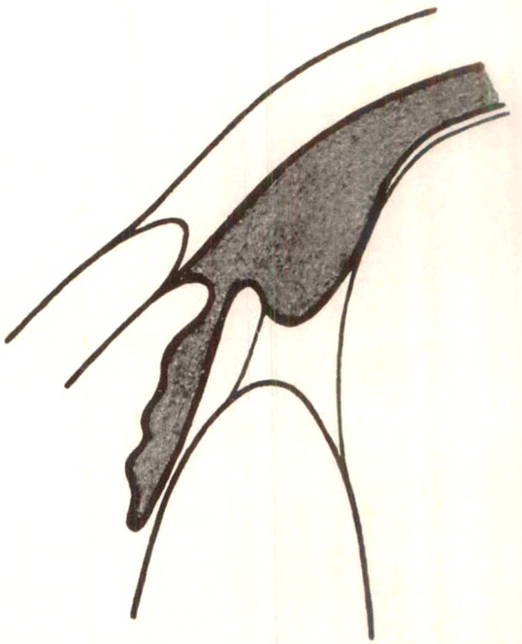

Fig. 1 (Slezak). Posterior chamber of the human eye.

The results obtainable on biomicroscopy of the posterior chamber through the iridolenticular cleft, using mirror contact lenses, are poor for two reasons: (1) The biomicroscopic visual field is narrow; hence, only a slit-shaped section of the posterior chamber can be viewed (Fig. 2). Further (2), the sections of the posterior chamber which are visible through the iridolenticular cleft are not magnified when contact lenses are used. Hence, details go unnoticed.

Visualization can be improved by depressing the sclera above the posterior chamber (Fig. 3). This ensures that the examination

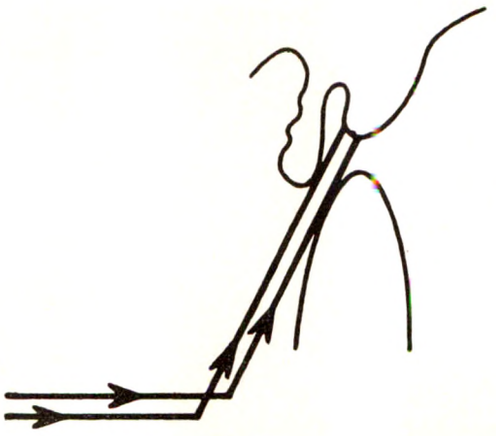

Fig. 2 (Slezak). Biomicroscopy of the posterior chamber through the iridolenticular cleft using a mirror contact glass.

can be done at a smaller angle of incidence, offering the following advantages:

1. The biomicroscopic visual field is considerably expanded, since the examination is no longer confined to the narrow space created by the iridolenticular cleft. Thus posterior chamber sections otherwise inaccessible to biomicroscopy become visible and can be observed with the slit lamp.

2. The size of the image is larger, as the posterior chamber is examined through the lens.

3. Though still necessary, dilatation of the pupil need not be extreme. Thus biomicroscopy of the posterior chamber is no longer confined to exceptional cases.

The auxiliary devices commonly used for slit lamp examinations of the ora serrata and the pars plana of the ciliary body[3-8] have no place in depression biomicroscopy of the posterior chamber, as the depression they make is not sufficiently anterior. These devices reach the orbicular space.

To visualize those parts of the posterior chamber anterior to the orbicular space along the translenticular route, I used a *funnel*, initially, with the three-mirror contact lens[9] (Fig. 4), the depressor of which partially overlapped with the scleral seam of the contact lens. Thus I succeeded in depressing the eyeball anterior to the anterior margin of the pars plana. As experience accumulated, I found that visualization of the posterior chamber is improved when the depressor completely rests on the scleral seam of the contact lens. This ensures that the iris-root recess of the prezonular space can also be observed with the slit lamp. Consequently, I have come to use a contact lens (Fig. 5) with a broad scleral seam, the mirror of which is

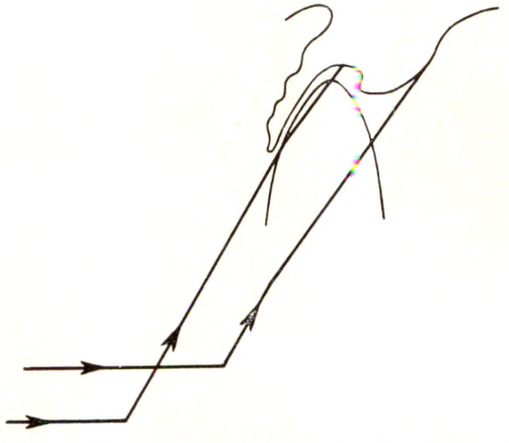

Fig. 3 (Slezak). Translenticular biomicroscopy of the posterior chamber after scleral depression.

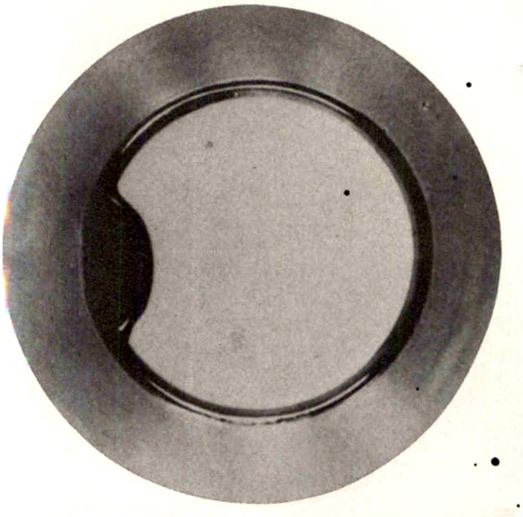

Fig. 4 (Slezak). Ciliary body depression funnel (for biomicroscopy of the pars plicata of the ciliary body).

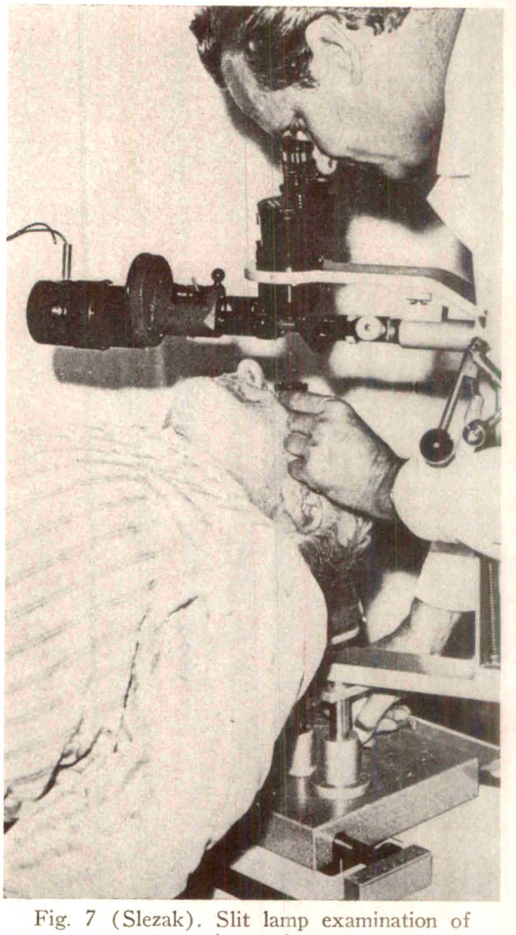

Fig. 7 (Slezak). Slit lamp examination of supine patient.

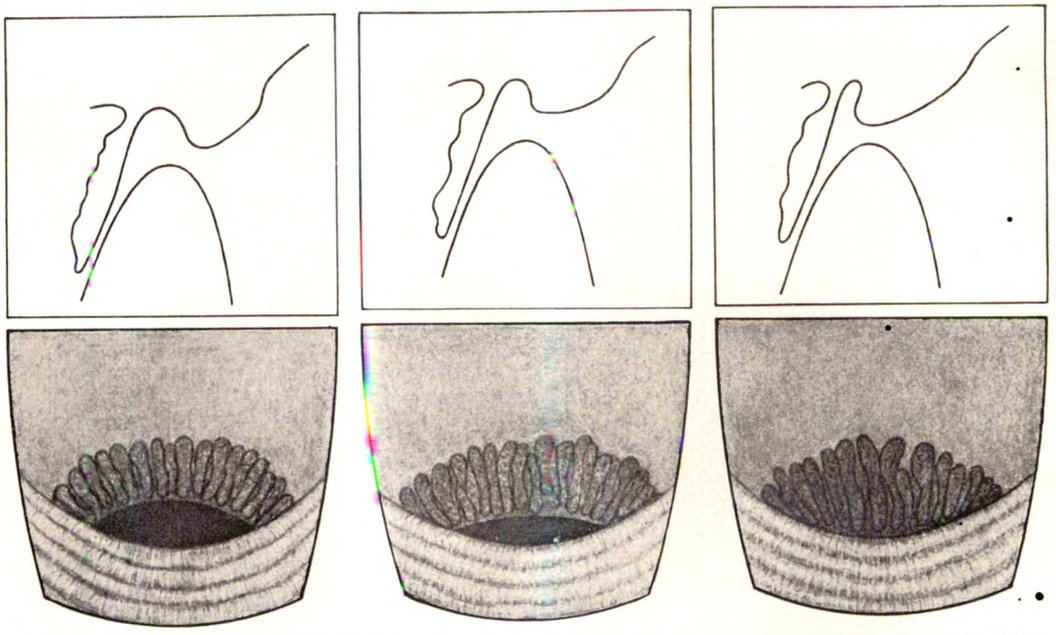
inclined 66 degrees to the anterior surface. Its spherical depressor is embedded in the scleral seam right next to the corneal excavation and impresses the eyeball above the posterior chamber. The depressed area then becomes visible in the mirror of the contact lens (Fig. 6). The pupil of the examined eye is also visualized, but its mirror image is deformed ovally. This oval deformation of the pupillary mirror image at times limits the usefulness of the binocular translenticular slit lamp examinations in the temporal and nasal sections of the posterior chamber. Whenever this occurs the patients are examined in the supine position, using a special version of the slit lamp which I developed in collaboration with Haag-Streit (Fig. 7). The



prototype is still subject to improvements and thus is not yet available on the market.

## Results and comments

Examination with the posterior chamber contact lens supplies information on the topographic relations between the anterior chamber angle and the iris root recess of the posterior chamber. The latter may be wide, of medium width, or narrow. If the recess is wide (Fig. 8), a wide brown area is seen in front of the tips of the ciliary processes. At medium width of the recess (Fig. 9), this area is rather small. It corresponds to the wall of the recess. If the recess is narrow (Fig. 10), its wall can no longer be seen. The image is confined to the anterior margin of the tips of the ciliary processes. The configuration of the iris root recess depends on the width of the anterior chamber angle and the length of the ciliary processes. If the anterior chamber angle is narrow, the recesses should be wide, and vice versa. Discrepancies between the findings of anterior and posterior gonioscopy serve as an indicator for the length of the ciliary processes. Small anterior chamber angles and narrow iris root recesses are associated with relatively long and overhanging ciliary processes, while large angles and wide recesses suggest short and flat processes.

As a rule, the wall of the iris root recess is smooth, but at times it presents a relief of radial ridges and bulges (Fig. 11). Occasionally, an abnormally long ciliary process reaches into the iris root recess.

The posterior chamber contact lens is extremely useful in examining eyes with vitreous opacities of unknown etiology. Recently, I examined a patient with recurring vitreous opacities involving the right eye. Both the choroid and the pars plana of the ciliary body were free from inflammatory lesions. The retinal vessels were also normal. Hence, I initially suspected a serous posterior cyclitis, but depression biomicroscopy of the posterior chamber lead to the right diagnosis: Several tips of ciliary processes inferotem-

Figs. 8-10 (Slezak). Left: Wide iris root recess. Overview (top) and mirror image after scleral depression (bottom). Center: Iris root recess of medium width. Overview (top) and mirror image after scleral depression (bottom). Right: Narrow iris root recess. Overview (top) and mirror image after scleral depression (bottom).

porally had fused into a grayish-yellow nodule (Fig. 12). This suggested a granulomatous anterior cyclitis. About 10 minutes after the intravenous injection of fluorescein the nodule had a patchy green appearance. Shortly afterward, the stain leaked into the vitreous. The nodule was therefore the cause for the recurring vitreous opacities.

I am not aware of any reports on the condition of the posterior chamber in cases of rubeosis iridis. Therefore, I examined patients with this disease at the slit lamp, using the posterior chamber contact lens. Since vascularized tissue is often found in the anterior chamber angle in this condition, I suspected similar changes to be present in the posterior chamber, but, with one single exception, this assumption proved wrong. In all such eyes examined, both the ciliary processes and the iris root recesses were normal, except for one case in which an island of vascularized tissue was seen in the iris root recess (Fig. 13). Further studies will prove whether this finding is more common than our experience seems to suggest.

Conceivably, the posterior chamber contact lens may also be useful for photocoagulation. The technique of photocoagulation as described by Fankhauser and Lotmar[10] has thus far been confined to the peripheral retinal region and pars plana. With the help of the posterior chamber contact lens it can be extended to the pars plicata of the ciliary body. Photocoagulation of the ciliary processes may be tried whenever an operation is indicated in glaucomatous aphakic eyes.

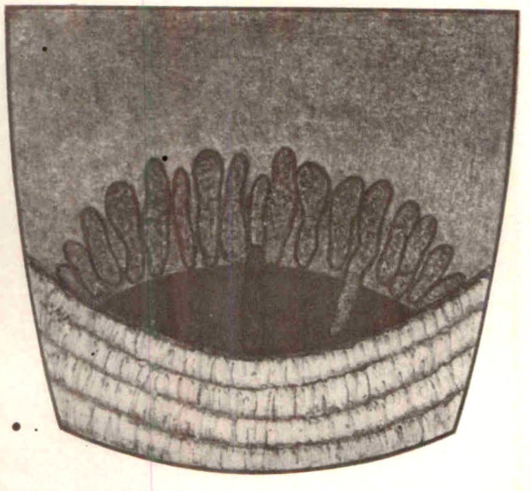


Fig. 11 (Slezak). Wall of the iris root recess with thin radial ridge, radial bulge and abnormally long ciliary process.

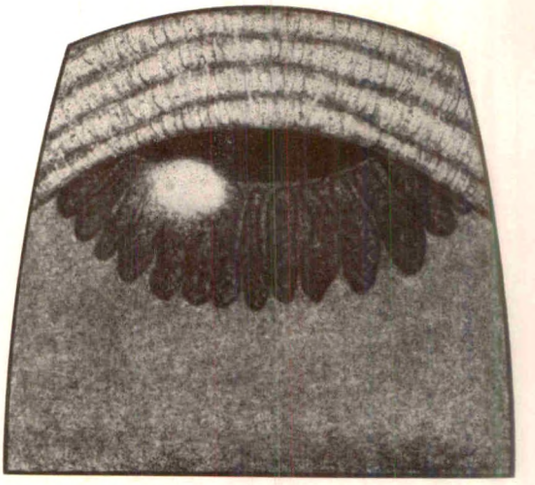

Fig. 12 (Slezak). Granulomatous inflammatory focus in the area of the tips of the ciliary processes.

The posterior chamber in nonaphakic eyes was previously accessible to biomicroscopy only in exceptional cases. Now slit-lamp examination of the posterior chamber is almost always successful.

## Summary

With the help of a depression contact lens, the posterior chamber can now be examined

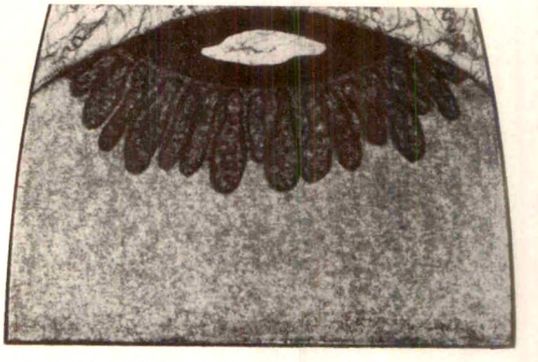

Fig. 13 (Slezak). Vascularized tissue in the iris root recess.

by slit lamp along the translenticular route, even without maximal pupillary dilation. This posterior chamber contact glass for the posterior gonioscopy has a mirror that is inclined 66 degrees to the anterior surface. Its spherical depressor is embedded in the scleral seam right next to the corneal excavation and impresses the eyeball above the posterior chamber. The depressed area then becomes visible in the mirror of the contact lens. Photocoagulation of the ciliary processes through the posterior chamber contact glass can be performed in glaucomatous aphakic eyes.

# AGING CHANGES OF THE CILIARY EPITHELIUM BORDER LAYERS AND THEIR SIGNIFICANCE FOR INTRAOCULAR PRESSURE

J. GÄRTNER
*Mainz, Germany*

With advancing age, alterations in the trabecular meshwork of human eyes include hyalinization,[1] proliferation of long-spacing collagen,[2] and reduction in the number and size of the vacuolated cells in the endothelial lining of the trabecular wall.[3] These alterations are thought to lead to an increase in the resistance to aqueous outflow. However, in aging persons whose eyes are healthy, pressures are not much higher pressures than the norm for younger eyes.[4] Thus, it seems reasonable to conclude that in spite of the increase in the resistance to outflow, intraocular pressure is maintained at about the same level during life by a progressive decline in aqueous secretion.[5]

The present paper deals with some fine structural properties of the external and internal surface of the ciliary epithelium of the human eye. Our observations suggest that aging changes of the extracellular limiting layers of these surfaces, especially at the internal surface of the nonpigmented ciliary epithelium, may be due to a progressive diminution in the rate of formation of the aqueous humor. The fine structural alterations are already present in young adult eyes and these proceed in the later decades of life.

## MATERIALS AND METHODS

Materials were obtained from eyes which were surgically removed from patients aged nine months, 29, 31, 34, 58, 61, 77, and 78 years with retinal or uveal tumor. In all cases, the tumor was situated at the posterior pole or opposite the excised tissue. The appearance of the disk clinically and histologically was normal. In one case (the nine-month-old child), ocular tension was not measured. The intraocular pressure of the other eyes used for this investigation ranged between 14 and 19 mm Hg.

The specimens to be studied by electron microscopy were prepared in the same way as described in previous papers[6,7] and examined in a Zeiss EM 9-A or EM 9-S electron microscope.

## OBSERVATIONS

In early childhood there is no fundamental difference between the basement membranes (basal lamellae) of the ciliary capillaries and those on the outer (base of the pigment epithelium) and inner (area lining the posterior chamber) surface of the ciliary epithelium. Furthermore, there is no difference between these ciliary basement membranes and the basement membranes covering the outer and inner surface of the neural retina, i.e., posterior to the ora serrata.

Both in the pars plana and in the pars plicata, the basement membranes of the capillaries and of the pigmented and nonpigmented ciliary epithelium consist of only one sheet, a lamina densa of the usual appearance. From the adjacent cells it is mostly separated by a light zone up to 50 nm wide (lamina rara). Occasionally, no lamina rara exists and the lamina densa immediately

follows the contour of the adjacent cell membrane.

At the capillary wall, and at the outer surface of the ciliary epithelium, the average thickness of the lamina densa is 55 nm. At the inner surface of the ciliary epithelium the basement membrane seems to be thinner. The average thickness is 33 nm, both in the pars plicata (Fig. 1) and in the pars plana (Fig. 2).

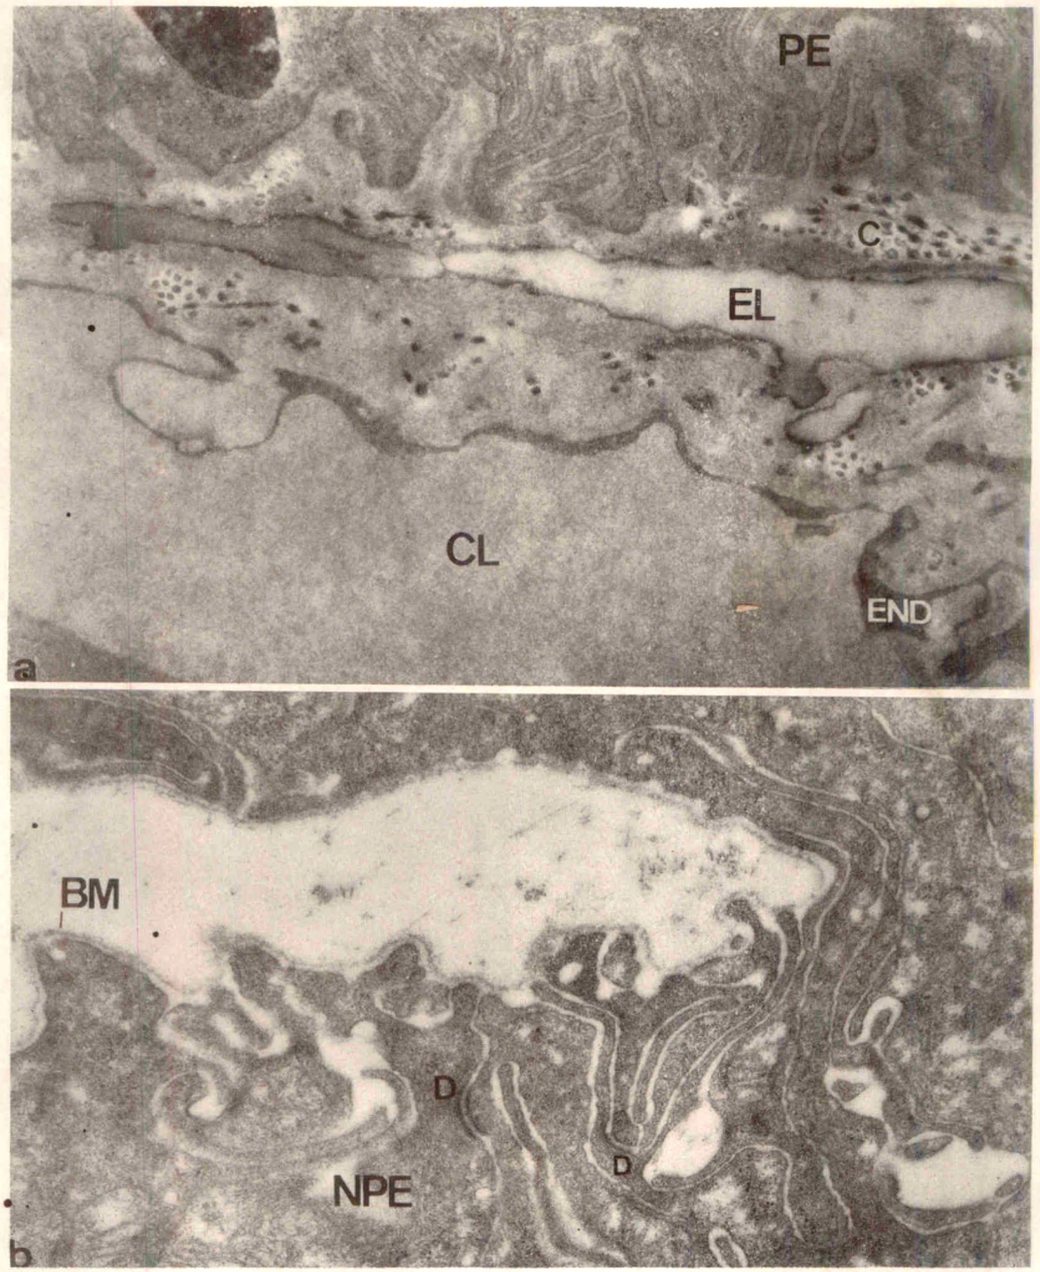

Fig. 2 (Gärtner). Girl, aged nine months. Pars plana. (a) External surface of the ciliary epithelium. Perivascular extracellular space between a capillary and the pigment epithelium, filled with a homogeneous substance (×23,000). (b) Internal surface. The basement membrane is single-layered.

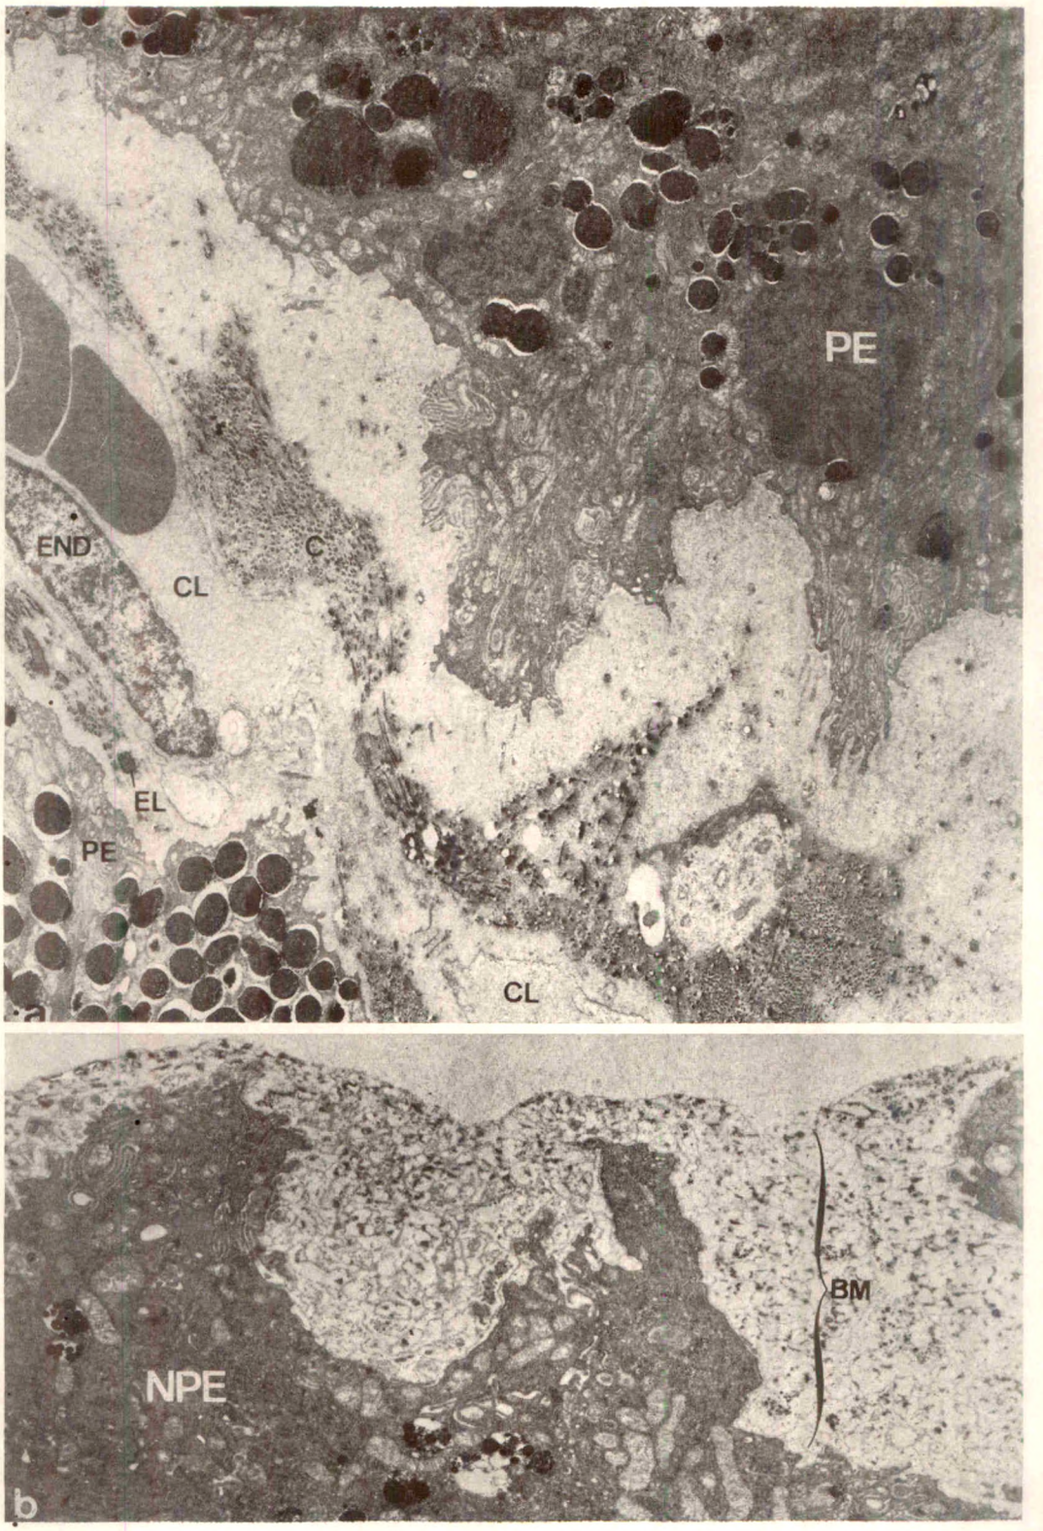
In many areas between the capillary wall and the pigment epithelium it is impossible to demarcate the laminae densae adjacent the capillary wall and the pigment epithelium from the mean rest of "unformed" contents of the perivascular extracellular space. These contents are a lightly staining, homogeneous, fine granular or filamentous substance, which encloses collagen fibrils, cellular components, and occasionally elastic fibers. The described substance has a very similar aspect to the fluid portion of blood within the capillary lumina. It may be present both in the pars plicata and in the pars plana (Fig. 2).

In the adult eye, the perivascular extracellular space between the capillary wall and the pigment epithelium widens considerably. The lightly staining homogeneous substance may reach a thickness of several microns (Fig. 3-A). Also the basement membrane material at the inner surface of the ciliary epithelium has a very different appearance from that in early childhood. It forms a marked network, especially in the pars plicata, but also within the bays of the pars plana. As already described in previous papers,[6,8] most of the meshes of this network are occupied by osmiophilic granular and lamellar deposits, probably lipid-containing substances (Figs. 3-B and 4). At higher magnifications, the deposits show a fine parallel striation that consists of alternating light and dense lines. The periodicity of the striation varies about a mean value of 3.4 nm. Like the homogeneous substance in the extracellular space between the ciliary capillaries and the pigment epithelium, the basement membrane network already in young adult eyes may reach a thickness of several microns.



In the cytoplasm of the nonpigmented ciliary epithelium vacuoles and lipid-containing granules of different size occur.

Unlike the basement membrane network at the inner surface of the ciliary epithelium, the perivascular extracellular space between the ciliary capillaries and the pigment epithelium usually does not contain granular or lamellar accumulations of the described type. At higher resolution, this space has a fine granular or filamentous appearance; it is exactly like the common basement membrane material. On the other hand, it is hardly distinguishable from the fluid contents of a capillary lumen, filled with plasma proteins (Fig. 5).

With increasing age the basement membrane network at the inside of the ciliary epithelium becomes thicker. In an eye that was 73 years of age, it measured twice the thickness than in eyes that were 29 and 34 years old. The meshes of the network contain much more granular and lamellar deposits than can be found in young adult eyes. Also, the perivascular extracellular space between the ciliary capillaries and the pigment epithelium further increases in thickness. Osmiophilic granular and lamellar deposits either lack or are visible only at a very few places within this space (Figs. 6 and 7).

The cytoplasm of the nonpigmented ciliary epithelium of senile eyes shows marked changes from that observed in young adult eyes. They are due to an increase in the number and size of intracytoplasmic vacuoles and especially to an enormous increase in the number of the lipid-containing compound granules (Figs. 7 and 8). These granules may be membrane-bounded, but some differ from the others in their lack of an encirculing membrane. Their dense contents

are formed of round, sometimes dust-like particles, and of lamellae which may be arranged in form of myelin figures. Most of the otherwise dense compound granules contain vacuoles of low density. These are of different size, and usually placed in the periphery. Within the dilated intercellular spaces near the inner surface of the nonpigmented epithelium myelin figures were observed, which may be fragments of the compound granules (Fig. 8).

Osmiophilic granular and lamellar material is also present within degenerating or necrotic cells outside the ciliary epithelium; apparently fibroblasts of the zonular apparatus. These cells occur in various stages of disintegration, sometimes immediately adjacent to the basement membrane network at the inner surface of the ciliary epithelium (Fig. 9).

## Discussion

The sponge-like structure of the basement membrane at the internal surface of the ciliary epithelium is a usual finding in adult human[5,8,9,10,11] and in bovine[12] eyes. In the early stages of life it could not be observed, at least not in our material. There is a distinct accentuation of this structure in advanced age. We believe that the transformation of the originally single-layered basement membrane into a multilayered network is mainly caused by biomechanical forces exerted by the adhering zonular fibers.[8,13] The common aging processes, leading in most tissues to a well-known augmentation of basement membrane material, may be an additional factor.

The external surface of the ciliary epithelium of the adult human eye is completely different from the internal surface. At the external surface no sponge-like basement membrane is visible, but only a rather homogeneous substance in the perivascular extracellular space between the capillary wall and the pigment epithelium. Like the basement membrane network at the internal surface, the homogeneous substance may reach a thickness of several microns with advancing age. At most places it is not possible to recognize a distinct demarcation between this substance and the sheets of basement membrane material adjacent to the endothelial cells, the pigment epithelium, or protruding into the perivascular extracellular space between them. On the other hand, both in the perivascular extracellular space and in the capillary lumina, the same fine granular material may be observed. It must be called to mind that the endothelial cells of the ciliary capillaries are fenestrated like the endothelia of the plexus chorioideus,[14] the choriocapillaris,[15,16] the glomerulum,[17] the sinusoides of the liver,[18] and of other areas with increased transport functions. On the basis of these fine structural conditions, the perivascular extracellular space between the ciliary capillaries and the pigment epithelium may be regarded as a part of the blood space, as it is proposed also for Disse's space in the liver,[18] (e.g., as in Disse's space, the abundance of a homogeneous fine granular material in the extracellular space between ciliary capillaries and pigment epithelium could be the result of a more solid condition of aggregation of the substances passing this space during the processes of metabolism and aqueous humor formation). Our electron microscopic findings suggest that these substances might be plasma proteins.

Experiments with $^{131}$I-labeled albumin, which were performed to study the protein exchange in the eye, have shown that in the ciliary processes the perivascular albumin space is much larger than in the rest of the anterior uvea and that the main blood aqueous barrier to proteins is not located in the capillary walls. As only 10% of the albumin that leaves the vessels appears in the aqueous humor, it is assumed that the rest has to be metabolized, return into the vessels, or pass out of the eye by other routes.[19] Thus, it seems reasonable to conclude that the gel-like structure visible by electron microscopy in the extracellular space between the ciliary capillaries and the pigment epithelium, usu-

ally designated as thickened basement membrane, is not exclusively the basement membrane material pre-existing and augmented here, but also a variable symptom of aqueous secretion. The amount, the composition, and the condition of aggregation of all the contents of this space must be influenced by the protein concentration between capillary wall and pigment epithelium—that is, by the actual transport of water from this space into the ciliary epithelium. This could explain the changing fine structural aspects of the space —sometimes "empty," but mostly filled with the described gel-like structure.

It is a very interesting finding that in the extracellular space between the ciliary capillaries and the pigment epithelium practically no lipid-containing deposits are present. This is a marked difference from the basement membrane network at the inside of the ciliary epithelium, which is packed with such deposits, especially in senile eyes. With regard to this localization of the deposits, one might suggest that they originate from the compound granules within the nonpigmented ciliary epithelium. Fragments of these granules could be pushed out through the widened intercellular spaces together with the fluid of aqueous and trapped within the meshes of the network. As to the nature of the compound granules, it seems likely that they are lipofuscins according to the description of these elements given for the nervous system,[20] the retina,[21] and other tissues.[22] Lipofuscin granules constitute a type of residual body. They are now generally considered to be a form of lysosomes.[23] As the localization of acid phosphatase is the most important identifying characteristic of these particles, it must be stressed that the nonpigmented ciliary epithelium contains much acid phosphatase activity.[24,25] There might be some connection between lysosomes and melanin. The presence of acid phosphatase recently was demonstrated in neuromelanin granules, and electron microscopy reveals what appears to be lipid globules in neuronal melanin. It seems that lipofuscin and neuronal melanin are not as distinct as thought previously.[26] Furthermore, the possibility that some of the compound granules might be phagocytosed or even synthesized[8] melanin granules, cannot absolutely be ruled out.

The deposits could also originate in a second way, namely by the detachment of distal parts of nonpigmented epithelium cell processes or from disintegration of degenerating fibrocytes of the zonule. An analogous mechanism is believed to be responsible for the deposition of lipid debris within the aged cartilage matrix, which undoubtedly originate from necrotic chondrocytes.[27] Finally, the deposits may be the result of a biochemical disturbance leading to changes in the basement membrane synthesis.[8] It is well known that normal basement membrane material contains lipid substances. In the isolated basement membranes of the renal cortex of the rat, for example, 16.9% total lipids were found.[28]

Whatever explanation might be the most probable, our findings suggest the possibility that outflow facility from the ciliary epithelium into the posterior chamber may be decreased by changes occurring at the internal surface with advancing age. These changes are thickening of the basement membrane material as a whole, and interposition of lipid deposits within the meshes of its unique network. It seems obvious that especially the age-dependent interposition of lipids may influence the permeability of the basement membrane barrier at the ciliozonular border area, both in the pars plicata and in the pars plana. At the external surface also, a thickening of the homogeneous substance in the perivascular extracellular space between the ciliary capillaries and the pigment epithelium is observed with increasing age. However, even in senile eyes, we could not find in this substance the amount of lipid deposits occurring in the basement membrane network at the internal surface of the ciliary epithelium. In our opinion, there seems to be little doubt that the decrease in outflow in Schlemm's channel with advancing age is compensated

by a lower aqueous secretion caused by an increase in the resistance to aqueous outflow from the nonpigmented ciliary epithelium.

## Summary

In an electron microscopic examination of the fine structure of the ciliary epithelium of the human eye, mainly basement membranes, the changes that are observed are attributed to aging. With advancing age, the cytoplasm of the nonpigmented ciliary epithelium contains vacuoles and numerous compound granules, probably lipofuscins. The basement membrane at the inner surface is single-layered in early childhood, whereas in the adult eye it forms a multilayered network. At the external surface of the ciliary epithelium, a rather homogeneous substance in the perivascular extracellular space between the ciliary capillaries and the pigment epithelium is visible. This substance is considered not exclusively as basement membrane material, but also as a gel condition of plasma proteins leaving the capillaries. The basement membrane network at the internal surface contains lipid deposits which are not observed within the homogeneous substance at the external surface. Especially in senile eyes, the meshes of the network are packed with such deposits.

The findings suggest an age-dependent increase in the resistance to aqueous outflow from the ciliary body into the posterior chamber, localized in the basement membrane network at the internal surface of the nonpigmented epithelium.

OPHTHALMIC MINIATURE

"It wasn't what she said," he reported later. "It was simply her attitude. There was something sly and suspicious about her. She just couldn't meet my eye. She wouldn't look at me."

"In Puerto Rico, a nice girl, a good girl," he explained, "does not meet the eyes of an adult. Refusing to do so is a sign of respect and obedience. It would be as difficult for Livia to look you in the eyes as it would be for her to misbehave, or for her mother to come to you with a complaint. In our culture, this is just not accepted behavior for a respectable family."

# ELECTROCAUTERY PUNCTURE OF THE TRABECULAR MESHWORK IN ENUCLEATED HUMAN EYES

ROBERT A. MOSES, M.D.
*St. Louis, Missouri*

In 1958, Grant[1] systematically studied the microsurgery of the trabecular meshwork in enucleated human eyes, using the anterior chamber route. He found that the incised meshwork had no tendency to retract, and that simple incision into Schlemm's canal had little effect on the facility of outflow. Grant suggested that the flaps of incised mesh fell against the outer wall of the canal, blocking the ostia of the collector channels. This hypothesis was strengthened by the fact that excision of the meshwork did increase the facility of outflow. Total excision of the mesh decreased the resistance to outflow some 75%.

However, partial excision of the trabecular meshwork reduced the outflow resistance only in proportion to the amount of mesh removed, suggesting that there was little or no flow from the surgical site along Schlemm's canal. Grant proposed that the lax intact meshwork occluded the canal, preventing circumferential flow.

If there was a free path from anterior chamber to canal, the canal itself should offer very little resistance to circumferential flow. The present research was designed to establish the presence such a free communication path.

## MATERIALS AND METHODS

The basic method described by Grant[1] was used. A 5-mm trephine hole in the cornea of the enucleated human eye allowed access to the trabecular meshwork and observation under 25- or 40-power magnification. A small piece of fine polyethylene tubing was placed between the iris and lens to prevent their retrodisplacement, creating a consequent tension on the meshwork during perfusion. The hole was closed by a stainless steel fitting[1] through which the eye was perfused at known constant pressure. The steel fitting was removed, microsurgery of the trabecular meshwork was performed, and the fitting was replaced for test of the surgical result.

Electrosurgery of the trabecular meshwork was accomplished with a Cameron 225 radio frequency cautery. A bipolar electrode was made from a 23-gauge, 1.5-inch hypodermic needle with a 32-gauge copper magnet wire threaded through the bore and held in place with epoxy resin adhesive (Fig. 1). The needle was connected to the ground and the central wire to the coagulation outlet. The coagulation control was set at 2.5. Under visual control the electrode was introduced through the corneal aperture and placed against the trabecular meshwork. The foot switch was depressed for about two to three seconds. This treatment had three results: (1) A definite hole in the mesh was produced (Fig. 2); (2) permanent gas bubbles were evolved (occasionally a bubble in Schlemm's canal had to be milked through the diathermy puncture by stroking the mesh

with a blunt probe); (3) the cornea was distorted in the region of the burn.

A small iridodialysis was produced by grasping the iris with a fine forceps, the steel fitting was repositioned, and the eye again perfused through the fitting.

Detection of leaks around the steel trephine hole seal was by inspection through the microscope and by application of fluorescein solution as in Seidel's test.

## Results

Successful trabecular perforation increased the outflow facility by as much as 0.44 µl/min./mm Hg. Additional perforations did not usually increase the facility further (Table 1). The augmented facility tended to decrease with time. In one eye, for instance, the facility decreasing from 0.57 to 0.45 µl/min./mm Hg during 30 minutes, but remained constant at the lower figure for the next 15 minutes.

Marked increase of facility was finally achieved in seven of 13 eyes. From one to six electrocautery applications were required. In another eye (E71-249, Table 1), high facility (0.62 µl/min./mm Hg) was obtained initially after cautery, but in this eye was reduced after further cautery application.

## Discussion

The facility achieved by total removal of the trabecular meshwork, by one electrosurgical puncture, or by several electrosurgical punctures of the trabecular mesh is about 0.6 µl/min./mm Hg in those eyes in which the trabecular cautery appeared to function, suggesting that 0.6 µl/min./mm Hg is the facility of the collector channels and associated veins in the enucleated human eye. The fact that one perforation by heat can effectively remove the total resistance of the trabecular meshwork indicates: (1) that the perforation tends to remain patent in some eyes under

* All perfusions were at 30 mm Hg and at room temperature.

the present experimental conditions, and (2) that flow along Schlemm's canal is free and of very low resistance when a free communication to the anterior chamber exists.

Schlemm's canal may break up into several channels[2] or may be occluded by endothelial proliferations in places.[3,4] The presence of these structural variations may account for some of the failures in this series.

## SUMMARY

Perforation of the trabecular meshwork by radio frequency electrocautery markedly increased the facility of outflow in seven of 13 enucleated human eyes. The facility achieved (0.40 to 0.70 μl/min./mm Hg) was of the same order as that found in an earlier investigation after complete removal of the trabecular meshwork by dissection, suggesting that flow along the canal of Schlemm is of low resistance.

# LATE ENDOPHTHALMITIS AFTER FILTERING SURGERY

JOHN M. HATTENHAUER, M.D., AND MICHAEL P. LIPSICH, M.D.
*Chicago, Illinois*

Endophthalmitis occurring many years postoperatively is a little-emphasized, yet nearly always disastrous, complication of filtering surgery. The purpose of the present report is to describe nine such cases seen at the University of Illinois Eye and Ear Infirmary between 1966 and 1970, as well as two additional cases seen by staff consultants.

## SUMMARY OF CASES

The variety of types of underlying glaucoma present in our series of 11 cases is shown in Table 1. Seven had had thermal sclerectomies performed by alternately incising sharply and cauterizing the limbal wound until a fistula is made into the anterior chamber. Three patients had posterior lip sclerectomies performed with a Holth punch. Two or three bites of sclera were taken from the posterior lip in the manner described by Haas and Iliff.[1] A single pillar iridencleisis operation was performed on one patient. Tenon's capsule resections were not performed in any case. Ten of the 11 filtering blebs were described postoperatively as thin-walled and cystic, and their size ranged from one and one-half to three clock hours. Postoperative tensions ranged from 5 to 22 mm Hg with two eyes in chronic hypotony (Cases 7 and 8). The time elapsing between surgery and the onset of infection was from four months to 11 years. The average was 45 months.

From the Department of Ophthalmology, University of Illinois Eye and Ear Infirmary, Chicago, Illinois. This study was supported in part by Public Health Service Training Grant EY 24-13 and by the Illinois Eye Bank. Presented at the meeting of the Central Section of the Association for Research in Vision and Ophthalmology, Madison, Wisconsin, April 2, 1971.

Reprint requests to John M. Hattenhauer, M.D., Eye Clinic of Wausau (S.C.), 614 First Street, Wausau, Wisconsin 54401.

Eight patients presented with a one-day history of symptoms, usually consisting of pain, swelling, and redness of the affected eye. Although visual outcome was poor in all patients, the best final acuity among the three patients (Cases 1, 2, and 9) who waited three or more days before seeking medical attention was counting fingers at 10 inches. On initial examination, six patients had anterior chamber hypopyon and two had a hypopyon level in the bleb itself. There was anterior chamber flare and cells (but no keratic precipitates) in all cases. In one patient (Case 9), panophthalmitis with a fixed globe was present when he was initially seen. It was felt that the initial infection in this case occurred in the bleb and that panophthalmitis developed subsequently.

Cultures of the surface of the infected blebs were taken on all patients. Three of them grew staphylococci-coagulase positive, and one grew pneumococcus. The remainder of the cultures either grew diphtheroids or nothing. A diagnostic anterior chamber paracentesis was performed in one patient, but failed to reveal any organisms after culture.

Final visual acuity was markedly worse in all but three cases. In the eight in whom it worsened, the best final acuity was 20/100, while in the remainder it ranged from hand motions to no light perception. One eye was enucleated.

No other site of infection, trauma, or other intercurrent disease was detected by history or physical examination in this series of patients, with the exception of one patient who had well-controlled, adult-onset diabetes.

## DISCUSSION

Intraocular infection after filtering surgery has generally been thought to be associ-

ated primarily with the trephine operation. Indeed, most of the relevant literature[2-4] describes cases of this type. All but two of Sugar and Zekman's[2] reported 26 cases had been filtered by corneoscleral (Elliot) trephination. McGrand[5] reported two cases of infected blebs occurring three to four years after surgery. One of these patients had had a trephination (type unspecified), the other an anterior lip sclerectomy. Christensen and Robinson[6] reported nine cases of infected filtering blebs, but they did not indicate the type of surgery performed. One of their patients developed a filtering bleb following cataract surgery.

Since trephination is a procedure which has not been done in this institution for more than 10 years, no precise comparison could be made between the incidence of infection after trephination and after other types of fistulizing operations. It is sufficient to emphasize that intraocular infection is a very real late complication of any filtering operation and one that requires the prompt institution of the most vigorous antibiotic therapy.

The pathogenesis of this complication seems to be related directly to the type of filtering bleb produced and only indirectly to the type of fistulizing operation performed. Haas[7] has classified functioning filtering blebs into two types: Type I blebs are thin-walled and cystic, contain many septae, provide mainly transconjunctival drainage, have a positive Seidel test, and are very subject to breakage and infection. Type II blebs, on the other hand, are thick-walled, pale, with no visible vascularization, have a negative Seidel test, and provide mainly subconjunctival drainage.

Type I blebs are thought to be more frequent with an anterior dissection of the conjunctival flap, and this may be the reason for the association of the corneoscleral (Elliot) trephine operation with bleb infection in previous reports. Alternatively, this was the

most common type of operation performed at that time.

Older patients are thought to be more prone to the development of thin-walled blebs, since they have thinner Tenon's capsules. Anterior dissection of the conjunctival flap, so that it extends past the insertion of Tenon's capsule, will also increase the probability of a Type I bleb. In addition, the thermal sclerectomy has been implicated in the production of thin-walled blebs through the thermal destruction of Tenon's plexus at the time of surgery.[8]

In reviewing his results from filtering surgery, Haas[7,8] found an incidence of thin-walled blebs of 51% in posterior lip sclerectomies and 66% in iridencleisis operations. Exact figures indicating the incidence of thin-walled blebs in thermal sclerectomies are not available. However, since 10 of our 11 patients had thin-walled blebs, this suggests that they may have a much higher incidence of infection than thick Type II blebs.

The reported incidence of infection after filtering surgery ranges from 1% to 18%.[4] There were 520 filtering procedures performed at the University of Illinois Eye and Ear Infirmary from 1961 through 1970. Of this total, 302 were thermal sclerectomies, 182 were posterior lip sclerectomies, and 35 were done by iridencleisis. The incidence of infection was 1.5% for both thermal and posterior lip sclerectomies. The incidence following iridencleisis was 3%, but this is probably not significant statistically in view of the small number performed. More significant is the fact that all but one of these infections occurred in patients with thin-walled blebs.

While the Type II bleb is the one considered desirable, the Type I bleb is often obtained. Review of this series of patients suggests that it is this type which is most likely to provide a pathway for the entrance of microorganisms into the eye. It is apparent that the interior of the eye is in direct communication with the conjunctival sac through the Type I bleb, even though the way may be somewhat labyrinthine because of the septae in the blebs. Thus, any episode of conjunctivitis or blepharitis presents a serious threat to the eye of the patient with a Type I filtering bleb.

Elliot[9] felt that "an abrasion of the surface of the membrane" (of the filtering bleb) was necessary, in the presence of a conjunctival infection, to allow passage of microorganisms into the subconjunctival tissues. Robinson and Christensen[6] thought that the manipulation of gonioscopy was a contributing factor in one of their cases. In the case reported by Ashline and Ellis,[10] contact lenses were being worn by the patient at the time intraocular infection occurred.

None of the patients in our series were wearing contact lenses at the time infection occurred, nor had any of them been recently subjected to ophthalmic manipulation. No history of antecedent trauma of any sort was elicited. While manipulation or trauma may be a contributing factor in some cases, it is by no means a prerequisite for the development of these infections.

Leopold[11] has enumerated several nonocular conditions which may be contributory in the development of intraocular infection. These are: severe metabolic disease (such as uncontrolled diabetes), neoplastic disease, advanced age, or poor general health. None of these factors appear to be operative in our series. In addition, none of our patients had multiple surgical procedures or excessive surgical trauma, either of which might also predispose them to infection.

Prompt institution of treatment of even the mildest conjunctivitis is certainly mandatory in these patients, after obtaining a specimen for Gram stain, culture, and sensitivity. Control of chronic blepharitis should also be maintained. Patients with thin-walled blebs should be advised to contact their ophthalmologist at the earliest signs of redness or soreness of these eyes.

At the earliest suggestion of chemosis, pain, or unusually severe injection—and by all means if anterior chamber reaction is

present or purulent material is in the bleb—systemic as well as subconjunctival and topical antibiotic therapy should be instituted. Hospitalization affords a surer means of obtaining intensive therapy systemically as well as topically.

For the initial treatment of these patients, our present choice of systemic antibiotics is ampicillin or cephaloridine (methicillin should be added if there is suspicion of this being a resistant staphylococcal infection). Subconjunctival cephaloridine or gentamicin should be administered on daily or every other day basis, as well as a combination antibiotic solution such as Neosporin* at two-hour intervals. We believe this intensive initial antibiotic regimen is necessitated by the almost uniformly grim prognosis, as suggested by our cases.

Chandler[12] has recommended the use of prophylactic antibiotics twice daily in patients with thin-walled blebs and hypotonous eyes. Another prophylactic regimen might include the use of an antiseptic such as zinc sulfate 0.25% or benzalkonium chloride (Zephiran) 1:3000, or sulfa drops prophylactically.

Chandler considers hypotony to be a contributory factor in the development of these infections. However, in our series only two patients could be considered to have hypotonous eyes.

Arruga,[13] in discussing infection of filtering blebs, has stated, "seriousness is the characteristic of this complication." In our experience this is certainly not an understatement. Only three patients in our series escaped a marked loss of vision as a result of their infection. Two of these three cases had a pre-infection acuity of 3/200 and light perception, respectively, which remained unchanged; the other (Case 11) went from 20/20 with a functioning bleb to 20/40 with a scarred nonfunctioning bleb.

Although anterior chamber hypopyon is an ominous finding, we were not able to correlate its presence or absence with ultimate visual results as has been indicated in a previous study.[6] One of our patients (Case 8), who presented with hypopyon, had no change in visual acuity whereas two patients (Cases 1 and 3), who did not have hypopyon when originally seen, suffered marked loss of visual acuity.

In this article we have enumerated and reviewed only cases of late intraocular infection in patients whose surgery was intended to produce a filtering bleb. We have, in addition, seen six additional patients with intraocular infection which developed in eyes with filtering blebs which were the unplanned sequelae of cataract surgery. Ashline and Ellis[10] reported the development of endophthalmitis in such a patient who was, in addition, wearing contact lenses. An enucleation was the final result of a similar case reported by Dixon and his associates.[14] We feel, in view of this experience, that the possibility of an intraocular infection may be the strongest indication for repair of an unintentional filtering bleb following cataract surgery. This repair may be undertaken either surgically or, as Kirk[15] has recommended, by hyphrecation.

Although written in the pre-antibiotic era, Elliot's words regarding late infection following fistulizing operations serve as an appropriate reminder of the seriousness of this complication: "Under energetic treatment, full vision may, in rare cases, be restored; more often sight is permanently damaged, while a not uncommon event is the loss of all or nearly all vision, and even the eye as well."

## Summary

In 11 cases, intraocular infection occurred an average of 44 months after filtering surgery. Eight of these cases developed marked loss of vision. A thin-walled filtering bleb is thought to be the most common contributing factor to the development of infection. Anterior flap dissection, the use of thermal cau-

* Burroughs Wellcome and Co., Research Triangle Park, New Jersey.

tery, and advanced age of the patient are all factors thought to increase the incidence of thin-walled blebs. Trauma to the bleb was not a factor contributing to infection in this series of patients. Early, vigorous treatment of bleb infections is urged in order to prevent the disastrous result of intraocular infection. There is merit in the consideration of repair of large unintentional thin-walled blebs following cataract surgery to avoid this complication.

# SERRATIA MARCESCENS ENDOPHTHALMITIS

JOHN F. BIGGER, M.D., GERALD MELTZER, M.D., ALAN MANDELL, M.D., AND RONALD M. BURDE, M.D.

*St. Louis, Missouri*

Serratia marcescens was first described by Bizio in 1823.[1] Subsequently, it became known as Bacterium prodigiosum because it produces a red pigment (prodigiosin). Recently, it has been recognized that nonpigment producing strains of Serratia marcescens also exist. The organism is a Gram-negative coccobacillus, presently classified in a division of the Enterobacteriacea with Klebsiella and Enterobacter. Criteria for identification of Serratia marcescens were established by Edwards and Ewing.[2]

Initially considered saprophytic for man, Serratia marcescens has in the past been intentionally sprayed in hospital environments to study airborne spread of bacteria.[3] Its red pigment has also been a useful marker in the study of bacteremia after dental extractions,[4] and bacteriuria after urinary tract procedures.[5] In recent years, however, Serratia marcescens has been increasingly implicated as an etiologic agent in severe human infections. It has been reported to cause respiratory and urinary tract infections, wound infections, meningitis, osteomyelitis, endocarditis, and septicemia.[6,7]

Reports of ocular infections by Serratia have been confined to purulent conjunctivitis,[8,9] lacrimal duct infections,[7] and corneal ulcers.[9,10] This paper reports two cases of severe purulent endophthalmitis from which Serratia marcescens was isolated.

## CASE REPORTS

*Case* 1—A 44-year-old man was hospitalized on September 1, 1970, with an intraocular foreign body of the left eye. Six hours before admission he was struck in the left eye by a metal fragment while hammering a metal bolt. X-ray examination revealed a 4 × 7 × 2 mm foreign body located just beneath the wound of entry, 2 mm posterior to the nasal limbus. Vision was hand movements. A hyphema occupied approximately 15% of the anterior chamber and the intraocular pressure was 3 mm Hg. A vitreous hemorrhage obscured visualization of the retina. Operative exploration and foreign body extraction with a magnet through the site of entry was accomplished without difficulty. The wound was sutured. The patient was given an injection of aqueous penicillin, 100,000 units, and gentamicin sulphate, 6.8 mg, subconjunctivally at the conclusion of the procedure.

Thirty hours postoperatively the patient developed severe pain in his left eye, with a purulent conjunctival discharge, hypopyon, and drainage of purulent material from the wound site. In spite of therapy with methicillin and gentamicin systemically, and chloramphenicol and neomycin-polymixin-bacitracin topically, the infection continued to progress. Twenty-four hours later there was no light perception in the left eye, an early orbital cellulitis was present, and the patient was febrile. Enucleation was performed, the orbit was packed, and with continued antibiotic therapy the patient recovered and was discharged on September 10, 1970.

Cultures from the conjunctival sac and from the intraocular contents grew a nonpigmented organism identified as Serratia marcescens. The organism was sensitive in vitro to ampicillin, tetracycline, gentamicin, chloramphenicol, streptomycin, kanamycin, and polymixin B, and was resistant to cephalothin and cephaloridine.

Histologic examination (Fig. 1) revealed infiltrations of acute inflammatory cells within the cornea, anterior chamber, iris, ciliary body, vitreous, choroid, and retina. Blood was present in the anterior chamber and vitreous. There was severe destruction of the retina by the inflammatory process. Gram stains revealed large numbers of Gram-negative rods within the vitreous.

*Case* 2—An 85-year-old woman was admitted on September 16, 1970, for a cataract extraction in the left eye. Intracapsular cataract extraction was accomplished without vitreous loss. At the conclusion of the procedure a subconjunctival injection of aqueous penicillin, 100,000 units, and gentamicin sulphate, 6.8 mg, was given. Twenty-four hours after surgery the cornea had minimal striate kerato-

tions during or after the use of antibiotics, including antibiotics to which the organism is susceptible, in vitro, may necessitate re-evaluation of the concept of prophylactic antibiotics if such infections become common in ophthalmology.

The second feature of Serratia which is of considerable significance is the in vivo resistance of the organism to antibiotic therapy. The high mortality rate of Serratia septicemia attests to the significance of this fact.[6] In vitro testing of antibiotic sensitivity may reveal multiple sensitivities, most commonly to gentamicin and kanamycin,[6] and these are recommended as the antibiotics of choice. In our cases, however, in spite of antibiotic therapy there was rapid progression of the infection. The in vivo resistance of Serratia marcescens is attributed by Miller and Buckler[12] to the ability of the organism to continue to proliferate intracellularly after phagocytosis by white blood cells. The proliferating organism intracellularly is thus not affected by the extracellular concentration of antibiotics. This feature of intracellular survival is apparently responsible for the virulence of the infecting organism and its in vivo resistance to therapy.

## Summary

In two cases reported, severe purulent endophthalmitis was caused by Serratia marcescens. Serratia infections are prone to occur in individuals with debilitating conditions, with altered host resistance, following surgery, and where antibiotics have been in use. Infections with this organism show an in vivo resistance to antibiotic therapy. Although reports of ocular involvement are rare, three instances of Serratia infection have been associated with the use of the soft contact lenses.

# HETEROGENEITY OF DISORDERS IN PATIENTS WITH CORNEAL CLOUDING, NORMAL INTELLECT, AND MUCOPOLYSACCHARIDOSIS

GEORGE CONSTANTOPOULOS, PH.D., AND ANATOLE S. DEKABAN, M.D.
*Bethesda, Maryland*

AND

HAROLD G. SCHEIE, M.D.
*Philadelphia, Pennsylvania*

Eight years ago, we reported a series of patients with corneal dystrophy, excessive excretion of urinary acid mucopolysaccharides (AMPS) and variable, although generally not severe, systemic abnormalities.[1] Certain of their clinical manifestations had a considerable resemblance to the sublethal hereditary syndrome of Hurler. However, most of our patients displayed no features tending to affect longevity and usually they had normal intelligence; some were married and gainfully employed despite their visual impairment.

With a renewed interest in the mucopolysaccharidoses, several investigators attempted to subdivide these disorders into distinct genetic types.[2-4] McKusick and associates,[4] in their classification, referred to our series of patients (adding their own cases) as mucopolysaccharidosis type V, or Scheie's syndrome. Recently, Wiesmann and Neufeld[5] stated that the patients with type V mucopolysaccharidosis are biochemically indistinguishable from patients with Hurler's syndrome. It became, therefore, important to reevaluate those of the currently available patients whom we originally described, utilizing recently developed biochemical methods and bringing up to date radiological and clinical findings.

From the Section on Child Neurology, National Institute of Health (Drs. Constantopoulos and Dekaban), and the Department of Ophthalmology, University of Pennsylvania Hospital (Dr. Scheie).

## MATERIALS AND METHODS

Four patients whose initial diagnosis was corneal dystrophy are the subject of this study. Refrigerated (0–4°C) 24-hour urine specimens without addition of preservatives were used for the isolation of AMPS. From the undialyzed urine, AMPS were precipitated with cetyl pyridinium chloride (CPC) and also by chromatography of Ecteola (chloride form).[6] The differences in recovery of AMPS by these two methods was never greater than 10%.

Hexuronic acid content of the isolated AMPS was measured by the carbazole reaction,[7] the orinol method,[8] and the borate-modified carbazole method.[9] Hexosamine was determined by the Elson-Morgan reaction[10] and galactosamine was assayed enzymatically.[11] Sulfate was determined by the method of Antonopoulos[12] and N-sulfate hexosamine according to Lagunoff and Warren,[13] without prior hydrolysis of AMPS. The AMPS were subjected to paper electrophoresis.[14] Construction of elution diagrams by gel filtration on Sephadex G-200 and determination of the distribution of molecular weights of the AMPS was performed as previously described.[15] The conditions for the enzymatic hydrolysis of chondroitin sulfate A (CSA), chondroitin sulfate B (CSB) and chondroitin sulfate C (CSC) with chondroitinase-AC and -ABC were those used by Saito, Yamagata, and Suzuki[16]; heparitin sulfate (HS) is not affected by these enzymes.

## Case reports

*Case* 1—This 39-year-old man (T.L., Fig. 1) and his married sister (R.L.W.) were described previously.[1] His general health was good in all respects until he reached five years of age, when he gradually developed what was considered to be arthritis of the hands and feet. Inguinal herniorrhaphies were performed at the age of four and eight years. Impairment of vision was first noticed in his early twenties; this was soon followed by complete inability to read. Examination disclosed cardiac enlargement with harsh systolic and diastolic murmurs and also enlargement of the liver and spleen. The interphalangeal joints (particularly the terminal) of both hands were swollen and ankylotic (Fig. 2), and the wrists were deformed. The findings were not compatible with those of the carpal tunnel compression of the median nerve. Similar, although less marked, abnormalities were present in his feet. The acuity of vision in 1958 was RE: 6/150, LE: 6/100 without correction, but in 1970 he could perceive only hand movements (Fig. 3). Slit-lamp examination revealed diffuse stromal corneal clouding, most marked at the periphery of the corneas. The deeper layers seemed more involved than the superficial. Epithelial edema was absent, but the corneas were at least one-fourth more than normal thickness. During 12 years of observation the central haziness became more marked. Pigment changes were never seen in the fundi. Visual impairment was attributed to the corneal changes. Visual fields were full to 5/330 white. Electroretinography was never done. The patient's hearing was serviceable, although the audiogram showed 45% loss of pure tones between 3000 and 6000 frequencies. Intelligence examination gave him verbal quotient above 120.

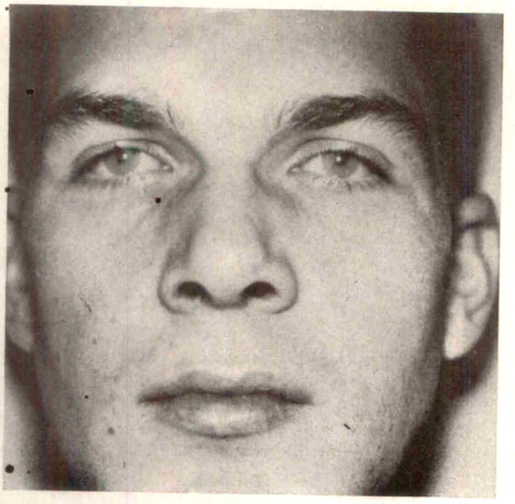

Fig. 1 (Constantopoulos, Dekaban, and Scheie). Case 1 in 1958 when referred for consideration of keratoplasty because of a diagnosis of familial corneal dystrophy.

Fig. 2 (Constantopoulos, Dekaban, and Scheie). Case 1. Patient's hands showing deformity of fingers.

The x-ray films of the skeleton were unusual: distal articular surfaces of radii were deformed; the carpal bones were small and contained cystic lesions; the distal ends of the metacarpals had curious pyramid-shaped deformities and the phalanges showed flexion-type deformities (Fig. 4-A). Similar, although less severe, abnormalities were present in his feet (Fig. 4-B). In addition, the vertebral bodies were moderately flattened (Fig. 5) and ribs were considerably widened (spatulated) posteriorly. The abnormalities in the wrists and hands were considered unique and not typical of Hurler's syndrome.

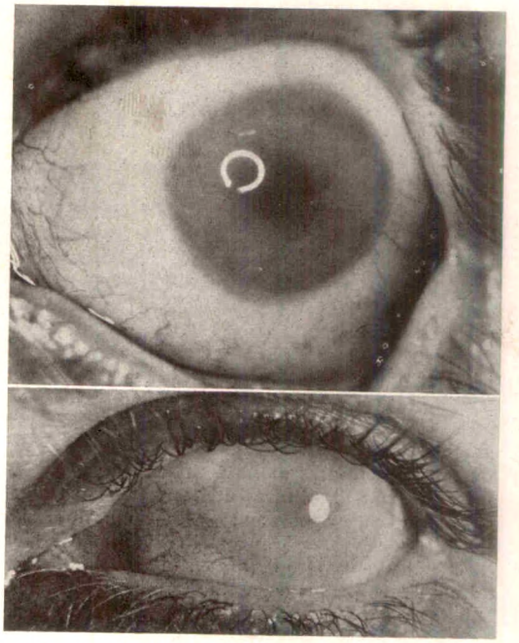

Fig. 3 (Constantopoulos, Dekaban, and Scheie). Case 1. Top: Left eye of patient in 1958, showing diffuse corneal haze. Bottom: Left eye of patient in 1970, showing more marked central haziness.

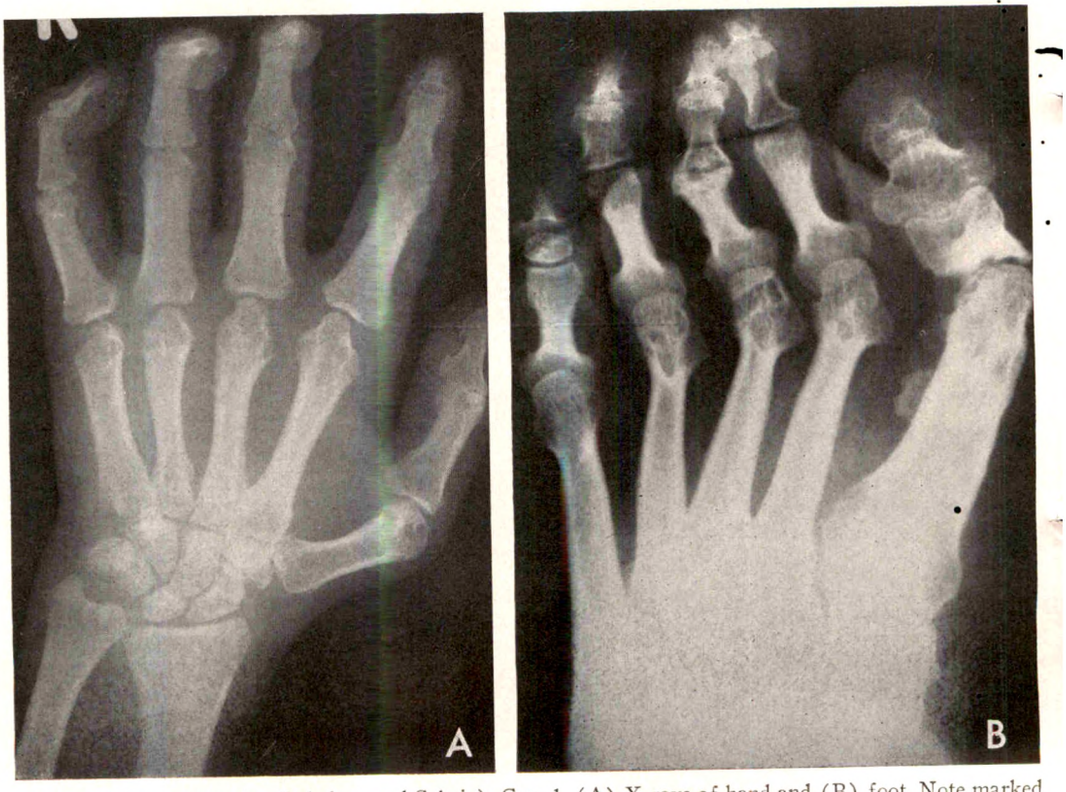

Fig. 4 (Constantopoulos, Dekaban, and Scheie). Case 1. (A) X-rays of hand and (B) foot. Note marked contracture deformities of terminal phalanges, unusual pyramid-like distal ends of metacarpals, cystic lesions, especially in the carpal bones, and growth abnormalities. However, tapering of proximal ends of metacarpals and other abnormalities typical of Hunter-Hurler's syndrome are absent.

*Case 2*—This 37-year-old woman (Fig. 6) is the affected sister of T.L. (Case 1) and has impaired vision from long-standing corneal opacities. In 1958, after an unsuccessful keratoplasty, her vision was RE: hand movements, LE: 6/24, and she had taken to counting fingers. The ocular findings and their subsequent course (Fig. 7) were identical to those of her brother, except for an opaque corneal graft. For a number of years she has had considerable limitation of movement in hands and feet. Her menses began at the age of 12 years and have been regular. Currently, she is married and has done some gainful work intermittently. On examination, she was found to have an excessive number of pigmented moles with some areas of depigmentation and a few cutaneous telangiectases. She had apical systolic and diastolic murmurs and markedly enlarged spleen and liver (Fig. 8). Her hands and wrists were deformed (Fig. 9) with typical ankyloses in flexion of the terminal phalanges. Radiologic surveys of the skeleton revealed essentially similar findings as in her older brother. The carpal bones were cystic in appearance and the metatarsals were short, but they did not have the characteristic proximal tapering usually seen in Hurler's syndrome. The metacarpal heads were conical and contained small cystic lesions; the terminal phalanges were in flexion ankylosis (Fig. 8). The radial styloid processes were underdeveloped bilaterally. The ribs had broad, spatulated midportion segments; the spine and skull were essentially normal. Except for the spatulate appearance of the ribs, it was the conclusion, on radiologic evidence, that the bony lesions were quite unique in both siblings and not typical of Hunter-Hurler's syndrome.

*Case 3*—This patient (A.B.[3]) is a white girl currently 12 years of age. She has developed somewhat coarse facial features, with thick lips, flattened bridge of the nose and prominent eyebrows (Fig. 10). Her gestation, delivery, and infancy were normal. She sat alone at six months, walked at 13 months and spoke in sentences at three years of age. At about that time she developed contractures in her finger joints and limitation of movement in elbow and shoulder.

While her maternal great-grandmother and great-grandfather are second cousins, this child's parents and younger sibling are alive and well.

On examination, both corneas were diffusely hazy. Her vision in 1961 was RE: 6/12, LE: 6/12, and in 1970, RE: 6/150, LE: 6/20. Findings on slit-lamp examination were identical to those in Cases 1

and 2, except that in this patient the corneal clouding seemed more uniform peripherally and centrally (Fig. 11). Fundi were normal. She had a Grade II systolic murmur over the precordium and a small umbilical hernia. Her liver was moderately enlarged. Her fingers, and especially the terminal phalanges, were in flexion deformity (Fig. 12), and she had limitation of movement in elbow and shoulder joints. Radiologic examination in 1960 showed flexion deformities in the phalangeal joints (Fig. 13) and evidence of delayed maturation of bones. The vertebral bodies were normal.

*Case 4*—This boy (J.M.[1]) is currently 18 years of age (Fig. 14). He was first examined at the age of 10 months for haziness of both corneas; this was considered then to represent congenital idiopathic edema of the corneas. At the age of one year, bilateral inguinal hernias were repaired. At the age of 10 years his height was 56.5 inches and his weight was 69 pounds. He had a Grade II apical systolic murmur, and his hands were somewhat broad (Fig. 15). Both corneas had a diffuse haze with the density greater in the deeper layers. Visual acuity as-

Fig. 5 (Constantopoulos, Dekaban, and Scheie). Case 1. Note some flattening of vertebral bodies and increase in concavity of intervertebral surfaces. There is no kyphosis and only mild spur formation.

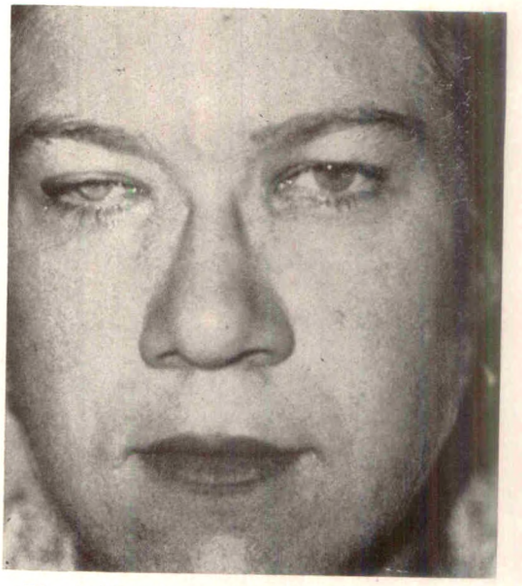

Fig. 6 (Constantopoulos, Dekaban, and Scheie). Case 2, sister of patient T.L. (Case 1), seen in 1958 becaused of so-called corneal dystrophy.

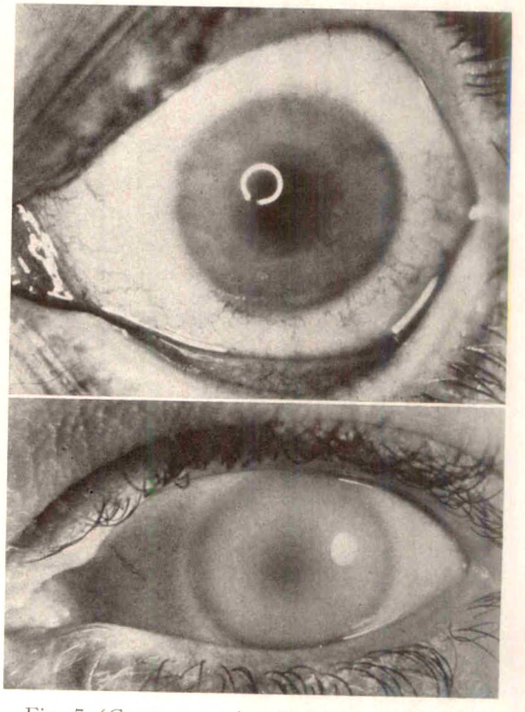

Fig. 7 (Constantopoulos, Dekaban, and Scheie). Case 2. Top: Left eye of patient in 1958, with evident cloudiness of cornea. Bottom: Same eye in 1970, showing opaque corneal graft.

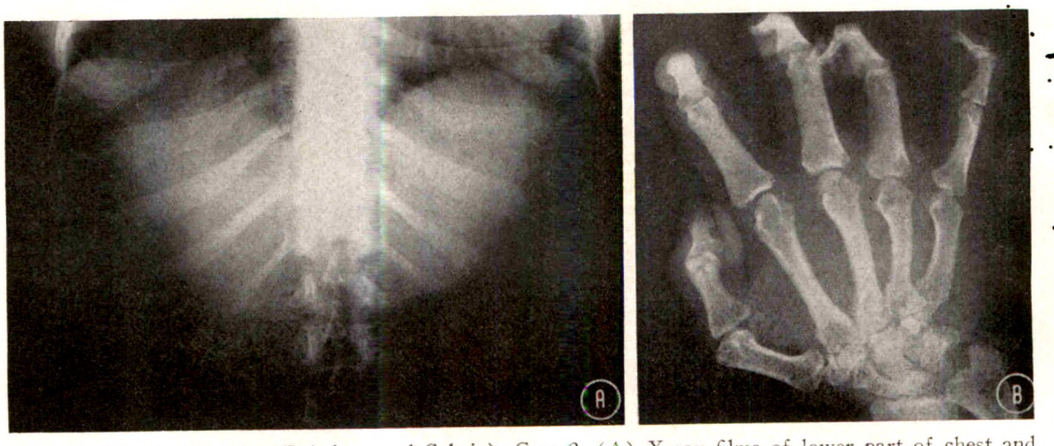

Fig. 8 (Constantopoulos, Dekaban, and Scheie). Case 2. (A) X-ray films of lower part of chest and upper part of abdomen. Note greatly enlarged liver and spleen and spatulate midportion of ribs. The spine is normal. (B) X-ray films of hand showing similar, although slightly milder, abnormalities as seen in patient's older brother (Case 1).

sessment in 1956 was unreliable; in 1970, it was RE:6/60 and LE: 6/100 with a more marked corneal haze (Fig. 16). The boy's mental status is normal. The parents and two siblings are alive and well.

## Discussion

The first three patients have remarkably similar clinical features. They share, in common with Hurler's patients, corneal opacity and hepatosplenomegaly, but differ from them in having normal intelligence, essentially unaffected longevity, relatively normal height and distinct skeletal abnormalities.

The fourth patient is essentially healthy in all respects, except for corneal opacity discovered when he was one year of age. Thus, this patient may represent an entirely different diagnostic problem.

The visual acuity in all four of these patients has diminished due to increased corneal clouding. Pigmentary degeneration of the retina was not seen, nor was optic atrophy. Visual fields were not studied, except by confrontation, nor was electroretinography performed. The fundi were normal when these could be visualized; in Cases 1 and 2 marked blurring of vision precluded good visualization.

In Table 1, the content and composition of urinary AMPS are analyzed and the results in our four patients are compared with those of 11 normal controls and a patient with proven Hurler's syndrome. In normal controls the average content of 24 hour urinary AMPS was 10.1 mg (range 4.5–16.5) and in the patient with Hurler's syndrome it was 117.0 (range for six similar Hurler's patients was 100–125 mg). The first three patients (Case 1–3) had currently 137, 108, and 162 mg AMPS in 24-hour urine, respectively while the fourth (Case 4) had only 9 mg AMPS. Thus, the total urinary AMPS in the patient with Hurler's and in the first three of our four patients was greatly elevated and within the range seen in Hurler's syndrome, whereas the total urinary AMPS of the fourth patient (Case 4) was within normal range.

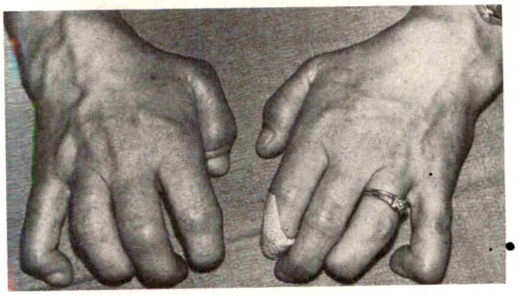

Fig. 9 (Constantopoulos, Dekaban, and Scheie). Case 2. Patient's hands and wrists in 1970, with typical ankyloses in flexion of terminal phalanges.

Fig. 10 (Constantopoulos, Dekaban, and Scheie). Case 3. Left: Patient as first seen in 1966. Right: Same patient when seen in 1970.

The composition of AMPS (Table 1) in the normal controls consisted of about 72% of CSA + CSC, 21% HS, 3.6% CSB and a small remainder of KS, the carbazole/orcinol ratio (C/O) being 1.31. In the patient with Hurler's syndrome, the greatest contribution to the urinary AMPS was by CSB (68.5%) and HS (26.5%); the CSA+CSC amounted to only 4.9% and C/O ratio was 0.65. The siblings (Cases 1 and 2) had quite similar composition of AMPS, and in both cases, the composition was not very much different than that seen in Hurler's disease patients, but the patient identified as Case 3 had grossly different composition of AMPS,

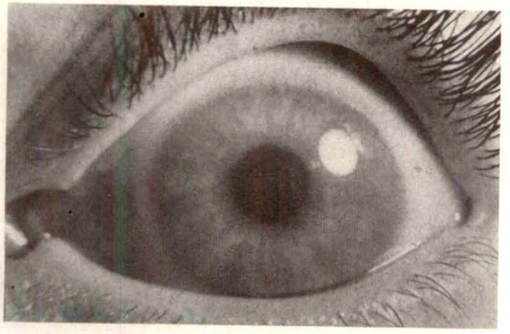

Fig. 11 (Constantopoulos, Dekaban, and Scheie). Case 3. Left eye showing uniform corneal clouding peripherally and centrally.

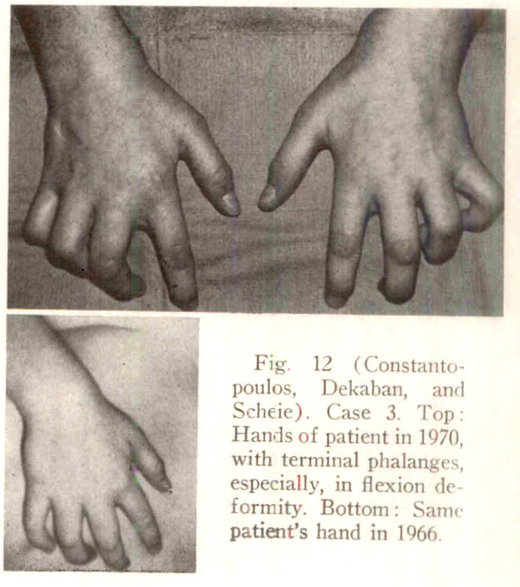

Fig. 12 (Constantopoulos, Dekaban, and Scheie). Case 3. Top: Hands of patient in 1970, with terminal phalanges, especially, in flexion deformity. Bottom: Same patient's hand in 1966.

Fig. 13 (Constantopoulos, Dekaban, and Scheie). Case 3. X-ray film of right hand and wrist. The flexion deformities of phalanges are pronounced. The elongation of distal ends of metacarpal is in an early phase as compared to older patients (Figs. 4 and 8). Also there is evidence of delay in bony maturation.

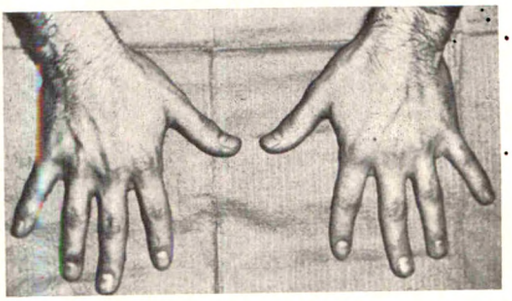

Fig. 15 (Constantopoulos, Dekaban, and Scheie). Case 4. Broad, spadelike hands.

with HS amounting only to about 8% while CSB constituted about 90% of the total. The composition of urinary AMPS of the fourth patient (Case 4) was similar to that of the normal controls.

Complete analytical data of the urinary AMPS in the normal controls and in the patients studied are given in Table 2. It may be seen that the contents of galactosamine, glucosamine and N-sulfate hexosamine, as well as the C/O ratios indicate the substantial presence of HS (about 30% of the total urinary AMPS) in the first two patients

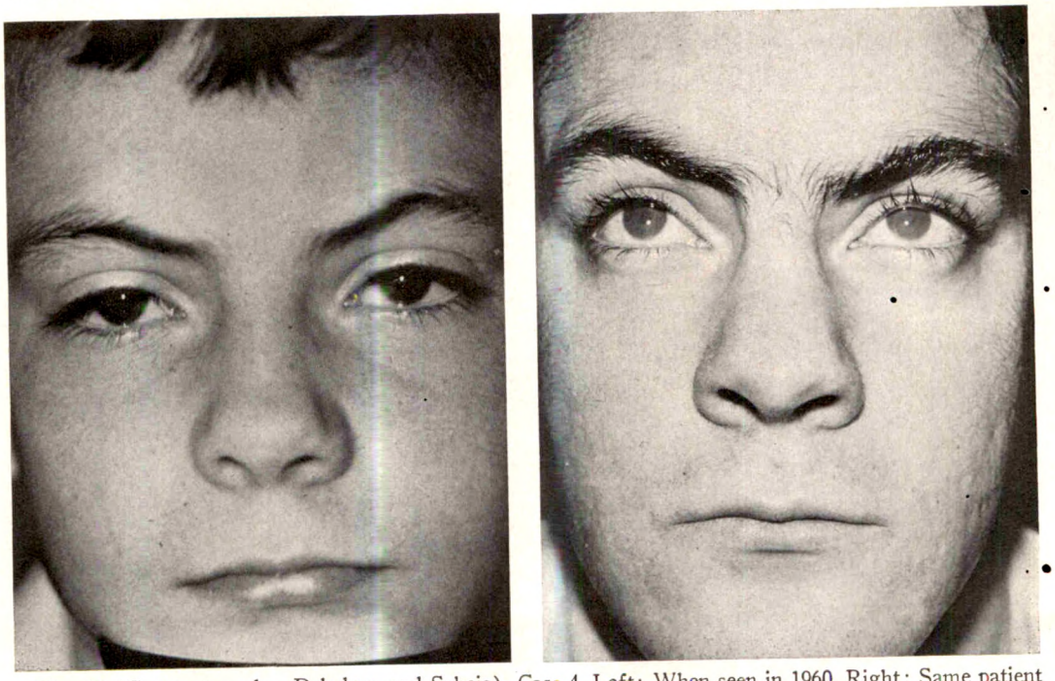

Fig. 14 (Constantopoulos, Dekaban, and Scheie). Case 4. Left: When seen in 1960. Right: Same patient in 1970.

(Cases 1 and 2), while the third patient (Case 3) excretes very little HS (less than 10% of total AMPS).

Five mg of urinary AMPS from all patients except Case 4 were incubated in total volume of 2.5 ml, with 0.5 units chondroitinase-ABC for three hours. At the end of the incubation, the mixture was inactivated for three minutes in boiling water and the AMPS were isolated with the aid of 1.0 g Ecteola chloride column. The recovered AMPS (measured as uronic acid) were 38, 34, 7.5, and 19% of the AMPS from Cases 1–3 and the patient with known Hurler's disease (Case 5), respectively. The carbazole/orcinol ratio was 1.4, 1.3, 1.8, and 1.45, compared to 0.76, 0.75, 0.47, and 0.65 of the original AMPS. The last values (except the third one) are much lower than the values obtained with standard heparitin sulfate and the urinary HS from Sanfilippo (ratio 1.8–2.5). After a second digestion with chondroitinase-ABC, the AMPS mixture was applied to a Sephadex G-200 column, but no further production of unsaturated acetylgalactosamine-containing disaccharides was noted. In separate experiments it was found that the molecular weight distribution of HS after incubation with chondroitinase-ABC was not changed; finally, after incubation of 250 μg of urinary AMPS from Case 4 with the above enzymes, only a small amount of a

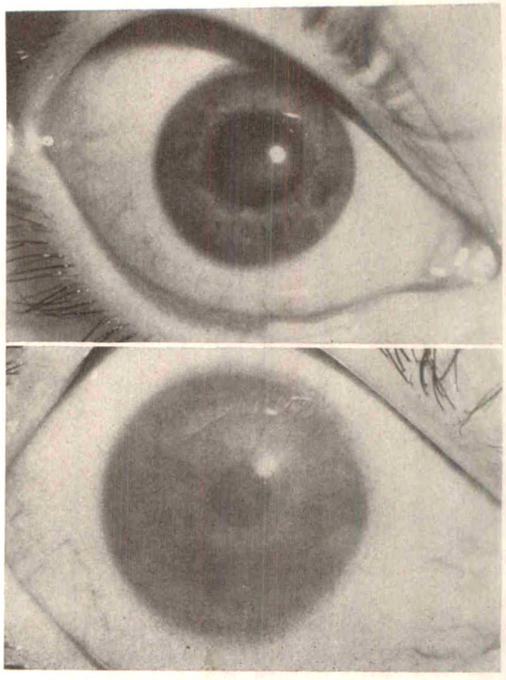

Fig. 16 (Constantopoulos, Dekaban, and Scheie). Case 4. Top: Left eye of patient showing diffuse corneal haze in 1960 (visual acuity unreliable). Bottom: Same eye in 1970, with corneal haze considerably more marked.

substance with electrophoretic mobility of heparitin sulfate was left intact.

A recently developed method[15] of gel filtration for the determination of molecular weight distribution and composition of the AMPS was applied to the isolated AMPS from the patients' urines.

Figure 17 shows the elution diagram profiles and chemical reactivities of the urinary AMPS from our patients and from normal controls. Urinary AMPS from normal subjects give the elution pattern shown in the bottom panel. The average molecular weight is about 14,000 and the distribution is fairly symmetrical on both sides of the peak. The chemical reactivities reflected those of the predominant components (CSC and CSA). The elution diagram from the urinary AMPS of patients with Hurler's syndrome is bimodal (second panel from bottom). The peak at the left is about 40% of the total AMPS, consists of CSB, and has an average molecular weight about 18,000. The larger peak at right is about 50% of the area of the diagram and its AMPS consist of CSB and HS. The average molecular weight is about 6,000. The average molecular weight of the total AMPS from this patient is about 11,500. The upper two panels represent the elution diagrams of the two siblings (Cases 1 and 2). It is of interest that they are *not* bimodal and that they show considerable shifting towards the small molecular weights. About 80% of the AMPS, consisting of CSB and HS, are highly degraded. The rest is mainly CSB of intermediary molecular weight. The average molecular weight of the total AMPS from these two patients is about 8,000. In contrast to these, the urinary AMPS of Case 3 (third panel from top) are of large molecular weight; about 60% of the AMPS are pure CSB, with an average molecular weight of about 20,000. There is, however, some HS as indicated from the C/O ratio at the extreme right end of the elution diagram. The average molecular weight of the AMPS from this patient is about 15,500. Thus, the AMPS of the two siblings (Cases 1 and 2) and the patient identified as Case 3 differ from those of the patients of Hurler, Hunter, and Sanfilippo.[15] Finally, the elution diagram of the urinary AMPS from the fourth patient (Case 4) closely resembles the diagram of normal controls.

## CONCLUSIONS

Detailed evaluation of the clinical and biochemical data on the four patients reported here, in whom the common denominator of corneal opacity, indicates that we are probably dealing with heterogeneity. It is unlikely that mucopolysaccharidosis is the cause of the corneal opacity in Case 4, and the etiology in this case remains to be determined. It is evident that the clinical and radiologic findings in the remaining three patients are similar, while the composition and molecular weight distribution of their urinary AMPS are different. Three clearly evident problems require more detailed consid-

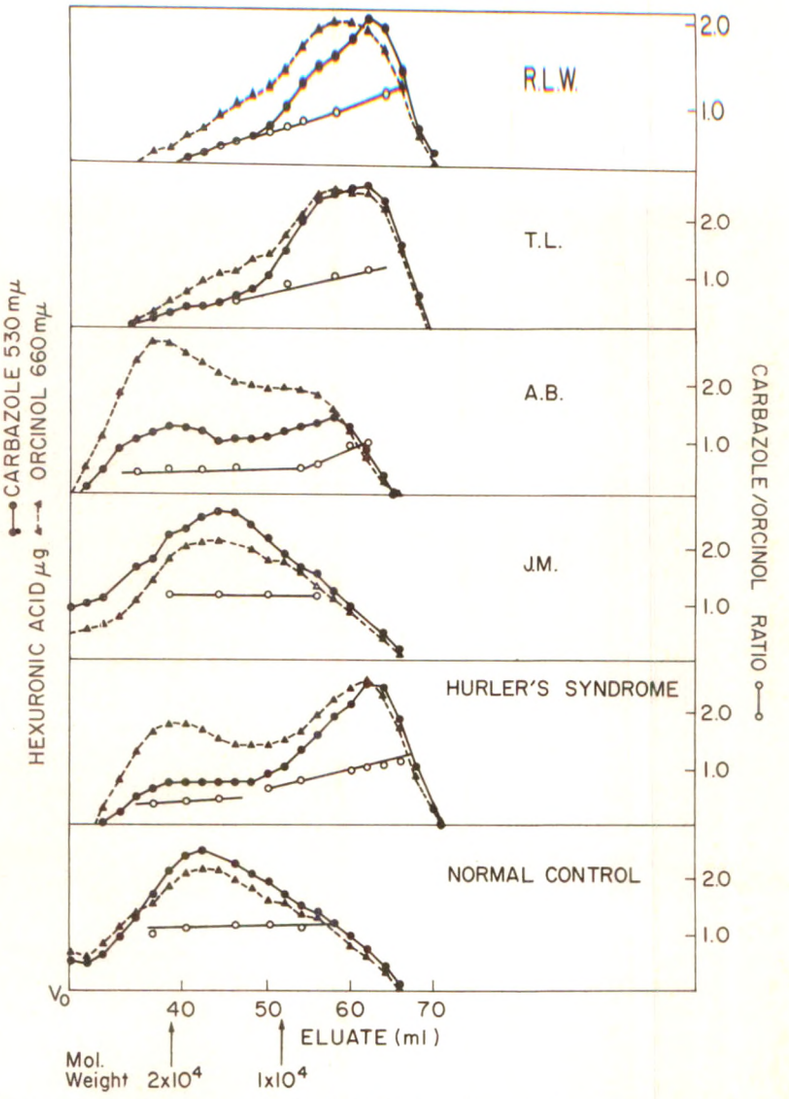

Fig. 17 (Constantopoulos, Dekaban, and Scheie). Elution diagrams in a normal control, typical Hurler's disease patient, and in the four patients reported here.

eration: (1) There is a need to determine the composition and characterization of urinary AMPS in the patients generally classified as having mucopolysaccharidosis V or Scheie's syndrome (Cases 1–3). (2) The question of nosological relationship between mucopolysaccharidoses I and V must be resolved. (3) The significance of the different composition and distribution of molecular weights of AMPS in Cases 1 and 2 as compared to Case 3 requires clarification.

In this study it was found that the urinary AMPS of the two siblings (Cases 1 and 2, the classic Scheie patients) consist of CSB and HS in the ratio of about 70:30, which is characteristic of the Hurler patients. The presence of HS in the urinary AMPS of these two patients was noticed by Terry and Linker,[2] and by Kaplan.[17] The low carbazole-to-orcinol ratio of the HS isolated by us after removal of other AMPS by enzymatic hydrolysis is similar to that of the HS from

the urinary AMPS of a patient with polydystrophic dwarfism,[18] but we have no explanation for this. Of special interest is the drastic shift of the urinary AMPS towards the low molecular weights in these two siblings. The fact that the CSB from their urine is of very small molecular size could explain why Terry and Linker[2] were unable to demonstrate the presence of CSB that precipitates, as the calcium salt with 10 and 20% alcohol concentration, as was the case with the CSB from their Hurler patients.

The second problem is the relationship of the type V mucopolysaccharidosis, as exemplified by the first three patients, to Hurler's syndrome. The elution patterns obtained by gel filtration of the urinary AMPS of the two siblings (Cases 1 and 2) are different not only from those of patients with mucopolysaccharidoses types I, II, and III,[19] but we have found in our laboratory (unpublished data) that they are unique among many such patterns from other mucopolysaccharidoses and from those of patients with various other diseases. If these questions were resolved, the elution pattern could then be a useful tool for characterization and classification of disorders with abnormal metabolism of AMPS. The experiments in tissue culture fibroblasts from the skin of these two siblings and from the skin of patients with Hurler's disease performed by Wiesmann and Neufeld[5] must be taken into consideration, but the definitive decision about nosological identity of these disorders cannot depend on this finding alone. Apparently, the fibroblasts from these two variants behaved metabolically as if they were lacking the same agent. However, the question remains: How far can one generalize from the experiments with mixed populations of fibroblasts in tissue cultures to the metabolic complexity of the human organism? The clinical and laboratory differences between the cases currently classified as type I and V mucopolysaccharidosis appear to be too great to consider types I and V as the same disease. A majority of patients with Morquio's syndrome have normal mentality, and a small proportion may have fine corneal opacity; their clinical features, however, are quite different from those of patients with other mucopolysaccharidoses. Likewise, Maroteaux-Lamy syndrome is clinically and radiologically distinct.

The third problem relates to the differences of physical characteristics of AMPS between Cases 1, 2, and 3. The presence of difference in composition and elution patterns between Cases 1 and 2, on the one hand, and Case 3 on the other, complicates further existing classifications. The possible explanation of this particular discrepancy could be the age difference; the siblings (Cases 1 and 2) are in their late thirties while the other patient (Case 3) is presently only 12 years of age. Unfortunately, we do not know the composition of urinary AMPS in Cases 1 and 2 prior to their adult years. Kaplan[18] computed the ratio of CSB : HS as 65 : 35 and 68 : 32 at their respective ages of 32 and 30 years; currently this ratio for both the brother and sister was determined to be 64 : 31. Possibly, with increasing age and after reaching adulthood, both the composition and molecular weights of AMPS could become altered; no information on this aspect is available. Other explanations, such as a presence of particular modifying genes in certain families with this syndrome, or altered general body metabolism, should also be considered. Our finding that the AMPS are of small molecular size in these patients could conceivably lead to easier elimination from their organs of excessive amounts of AMPS and thus could affect the manifestation of the disease. However, the CSB in Case 3 is of large molecular size, and yet this patient has normal mentality.

Since our knowledge of life histories, pathology, biochemistry, and enzymatic defects involved in various mucopolysaccharidoses is incomplete,[20] it appears advisable to exercise considerable conservatism in proposing further classifications of these syndromes. Accumulation of a larger pool of patients with

these disorders, along with detailed clinical and pertinent laboratory data, will eventually permit resolution of existing controversies. We feel that for the time being it is advantageous to retain types I (Hurler) and V (Scheie) of mucopolysaccharidosis as possibly separate syndromes, since they differ markedly in their clinical manifestations, radiologically demonstrable skeletal abnormalities, and in the distribution of molecular weights of urinary AMPS.

## Summary

Four patients from an earlier series, and classified at that time as having type V mucopolysaccharidosis, were re-evaluated, using currently available, newer techniques. In this original series of patients the common denominator was corneal opacity and normal intelligence. On the basis of marked differences in the clinical manifestations and laboratory findings, it is suggested that for a defined portion of these patients the classifications of type I (Hurler's disease) and type V mucopolysaccharidosis (Scheie) be retained as possibly separate syndromes. The elution diagrams of molecular weight distribution of acid mucopolysaccharides provide a useful tool for characterization of various mucopolysaccharidoses.

# CARCINOID SYNDROME WITH BILATERAL ORBITAL METASTASES

F. M. Honrubia, M.D., Wilkes H. Davis, M.D., M. Kent Moore, M.D., and James H. Elliott, M.D.

*Nashville, Tennessee*

Carcinoids are slowly growing malignant neoplasms which metastasize in 21 to 75% of the cases. They originate from the enterochromaffin or Kultschitsky cells in the intestinal tract; other primary sites include the bronchi, bile ducts, pancreas, and ovary.[1]

Wong and Melmon[2] have previously reported the ophthalmic manifestations of the carcinoid syndrome. These consist of flushing of the head, neck, and arms after a provocative intravenous injection of epinephrine. Associated conjunctival vascular dilatation and lacrimation are constant early signs of the flush. Ten of 16 patients had a variety of fundus changes which were attributed to carcinoid syndrome.

The present case report is of interest because the presenting ophthalmic complaint of the patient was diplopia and a mass under her right eye. Subsequently, a diagnosis of an unsuspected carcinoid tumor with bilateral orbital metastases was made by histopathologic examinations, provocative epinephrine tests, and chemical assays of tissue specimens and urine for either serotonin (5-hydroxytryptamine) or 5-hydroxyindoleacetic acid (5-HIAA).

Fig. 1 (Honrubia, Davis, Moore, and Elliott). Note fullness of both lower eyelids, greater on patient's right.

## Case report

*Case* 1—This 74-year-old white woman was first seen in the Vanderbilt University Hospital Eye Clinic on April 17, 1968, complaining of diplopia of approximately 13 months' duration and a mass under her right eye of four months' duration.

Four years earlier, the patient had a "gastric ulcer" which presented with massive melena and responded to medical therapy. Over the past 18 months, she had a 60-pound weight loss. Seven months before being seen, she had a "malignant tumor" removed from her left neck, with subsequent cobalt therapy to the operative field. Shortly thereafter, she had some "scalp masses" excised. These two specimens were interpreted initially as "adenocarcinoma of sweat glands."

Visual acuity was RE: 20/30 and LE: 20/25-2. Tension was 17.3 mm Hg (Schiøtz) in each eye. Bilateral firm nodular masses were palpated at the inferior orbital rims which extended back into the orbits. The right mass was more prominent (Fig. 1). The masses moved with movement of the globes. Eyelids, conjunctiva, cornea, anterior chamber, iris, and pupils were within normal limits in both eyes. Each lens had a mild nuclear and cortical opacities. Ophthalmoscopy revealed two small, healed chorioretinitic scars in the periphery of the right eye at 3 and 5 o'clock. Limited abduction and a hypertrophia were present in the right eye (Fig. 2). The patient had diplopia in all fields of gaze. Exophthalmometer readings were 19 mm bilaterally. Orbital x-ray studies, including optic foramina

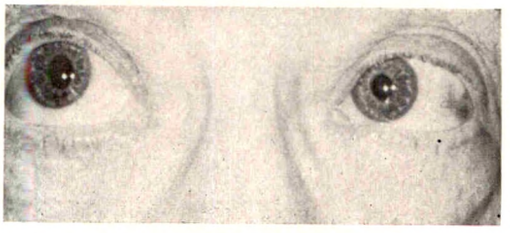

Fig. 2 (Honrubia, Davis, Moore, and Elliott). Patient with bilateral orbital metastases. On right conjugate gaze there is a right hypertropia and limitation of abduction.

Fig. 3 (Honrubia, Davis, Moore, and Elliott). Biopsy of right orbital mass. The tumor is highly cellular with connective tissue septa and capsule (hematoxylin-eosin, ×10).

views, were unrevealing. The orbital masses were thought to represent metastases from the same tumor which had involved the scalp and neck.

The patient was admitted for biopsy of the orbital masses. A general physical examination revealed a small, movable, firm nodule in the posterior triangle of the right neck and small mass in the left breast. A biopsy of the right orbital mass and a needle biopsy of the left breast mass revealed similar tumors. Microscopically, the specimens were composed of nests of cells with pale, eosinophilic cytoplasm and uniform nuclei. The nuclear chromatin was clumped and dispersed. The most peripheral cells in the nest had darker, more eosinophilic cytoplasm and the nuclei in this peripheral layer were oriented away from the basement membrane (Figs. 3 and 4). The peripheral cells were argentaffin-positive as indicated by reduction of silver leaving brownish-black deposits in the cytoplasm (Fig. 5). The diagnosis was argentaffinoma (malignant carcinoid). Comparisons were then made with the scalp and left neck specimens obtained in 1967. All were thought to represent the same tumor type, argentaffinoma.

With this diagnosis, further studies were undertaken to ascertain if there was involvement of other systems. Chest films, metastatic bone series, upper gastrointestinal series, small bowel series, barium enema, liver scan, and liver function studies were all non-revealing.

Although a vague history of recent episodes of flushing was obtained, the patient had never experienced the dramatic attacks of classic carcinoid syndrome. Therefore, a provocative epinephrine test was done. Four minutes after intravenous injection of 0.5 μg of epinephrine the patient noted a warm feeling over her face and a facial flush could be observed. With a 4.0 μg dose, a generalized flush was noted. There was no marked change in the patient's blood pressure or pulse and she had no asthmatic symptoms. The results of the test were felt to be abnormal, but of a mild degree.

The 24-hour urinary levels of 5-hydroxyindoleacetic acid (5-HIAA) ranged from 9.2 to 12.6 mg. Although not extremely high, these values were definitely increased. The nodule in the right posterior triangle of the neck was biopsied on August 8, 1968, and was the same type as the other specimens —argentaffinoma. An assay for serotonin was made on a portion of the biopsied neck mass and showed a very high value of serotonin, 1.4 mg/g of wet tissue. This further confirmed the diagnosis of argentaffinoma.

When last seen in the Eye Clinic on July 28, 1970,

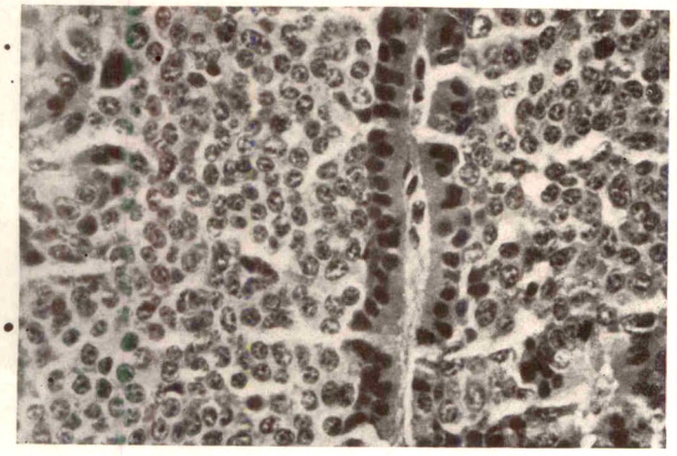

Fig. 4 (Honrubia, Davis, Moore, and Elliott). Photomicrograph of right orbital mass. The tumor is composed of two cell types. The major portion of the cells have a pale cytoplasm, uniform nucleus and dispersed chromatin. Other cells forming the boundary of cell nests have a darker cytoplasm with a prominent nucleus. This latter type of cell shows a palisading pattern with the nucleus oriented away from the basement membrane (hematoxylin-eosin, ×400).

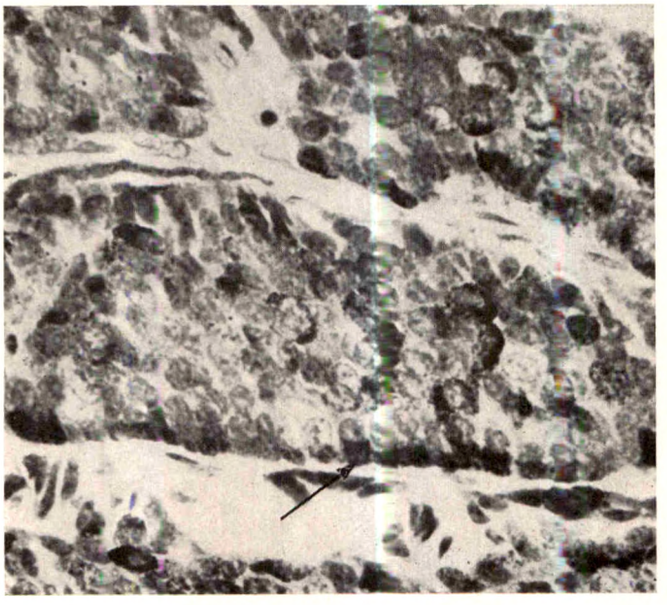

Fig. 5 (Honrubia, Davis, Moore, and Elliott). Photomicrograph of right orbital mass. Cytoplasm of cells exhibit dark granules indicating a positive argentaffin reaction after silver staining (arrow) (Fontana-Masson, ×400).

the patient's ocular examination was essentially unchanged. She was experiencing flushes every day and she had additional masses in the right orbit superiorly, the right triceps area, and the left axillary area.

## Comment

One case of unilateral orbital metastasis of carcinoid has been reported.[3] However, in the patient reported here, the orbital metastases were bilateral. Although the primary site of the carcinoid tumor was not found, the diagnosis was made from the clinical symptomatology and the histopathologic study of biopsies taken from the orbit, neck, and breast. This was further substantiated by: (1) the positive argentaffin reaction in the orbital tumor, (2) the high levels (9.2-12.6 mg/24 hours) of 5-HIAA in the urine (normal, 1-9 mg), (3) the high level of serotonin in the biopsy specimen from the nodule in the posterior triangle of the neck (usual levels in gastrointestinal carcinoid range from 10 to 60 μg/g wet tissue).

From the literature it must be concluded that the incidence of metastatic orbital carcinoma is quite uncommon. When orbital metastasis does occur, the site of the primary tumor is usually the breast or lung.[4] It has been estimated that metastatic carcinoma to the orbit is only one-fifth as frequent as metastatic involvement of the globe.[5] Hart[6] reviewed a total of 133 cases of carcinoma metastatic to the eye and orbit in the registry of the Armed Forces Institute of Pathology up to 1958; he found orbital involvement in only 14 cases. Other authors reporting large series of orbital tumors also show that metastatic carcinoma to the orbit is infrequent.[7-9]

Bilaterality in metastatic carcinoma to the orbit would appear to be an exceedingly rare event. Haye[10] states that only four cases have been described. By constrast, bilateral orbital metastases of tumors other than carcinoma is more common; Albert, Rubenstein, and Scheie[11] found that 56% of children with orbital metastases from neuroblastoma had bilateral involvement. Cases of intraocular metastases from all types of tumors are seen more frequently and 20–25% are bilateral.[12]

We agree with other authors who have suggested that the reason for the low reported incidence of metastatic orbital carcinoma is that patients with metastatic disease are rarely treated in eye hospitals and orbital tissues are infrequently submitted for pathologic examination.[4]

## Summary

A case of bilateral orbital metastases from a carcinoid tumor is reported. The ophthalmic findings prompted biopsy and histopathologic studies which resulted in the diagnosis of argentaffinoma, which was further confirmed by a positive argentaffin reaction in the orbital tumor, the elevated level of 5-HIAA in the urine, and the high concentration of serotonin present in the tumor. Reevaluation of previously biopsied masses also revealed the argentaffinoma pattern. Following pathologic diagnosis, the patient later developed the classic syndrome.

## Acknowledgments

The serotonin assay of tumor tissue and 5-HIAA level in the urine were performed in the laboratory of John A. Oates, M.D., Professor of Pharmacology and Medicine, Vanderbilt University Medical School. We thank John L. Shapiro, M.D., Professor of Pathology, and Barton McSwain, M.D., Professor of Surgery, Vanderbilt University Medical Center, who reviewed the histopathologic sections.

# AXIAL TOMOGRAPHY OF OPTIC CANALS IN DIAGNOSIS OF CHILDREN'S EYE AND OPTIC NERVE DEFECTS

S. MERIN, M.D., D. C. HARWOOD-NASH, M.D., AND J. S. CRAWFORD, M.D.
*Toronto, Canada*

Axial tomography of the optic canals is the only method by which the entire length of both optic canals can be visualized on one x-ray film. Both sides can be viewed simultaneously to compare minor changes and demonstrate pathology affecting only one part of the optic canal. This method was recently standardized by examination of 50 normal children.[1]

We have used axial tomography for diagnosis of several congenital conditions, tumors and injuries to the globe and optic pathways.

## MATERIAL AND METHODS

Forty-five children between the ages of two months and 17 years were examined by axial tomography of the optic canals. Patients selected for the study had one of the following conditions: a tumor affecting the optic nerve, a congenital eye disease possibly connected with changes in the optic nerves, or an injury of the orbit which might involve the optic canal.

We followed the method of axial hypocycloidal tomography as suggested by Dilenge, Metzger, and Simon,[2] and Harwood-Nash.[1] The child was placed supine on a padded box with the head over one edge, the neck extended maximally (Fig. 1). In each case, six hypocycloidal tomograms were taken about the optic canals in the axial plane to include the anterior and posterior clinoids,

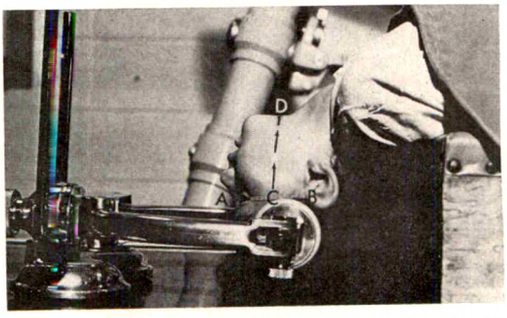

Fig. 1 (Merin, Harwood-Nash, and Crawford). Position of child for axial tomography of the optic canals. Line A-B (from the outer canthus of the eye to the ear) is parallel to the tabletop. A perpendicular line to C (the middle of A-B) fixes the point D, on the sagittal line, on which the tube is focused.

the tuberculum sellae, and the body of the sphenoid. Figure 2 is an axial tomogram of a normal optic canal.

The optic canals were stated to be normal if they were identical to one another, normal in shape, and the transverse diameter at the mid-portion was within the normal values

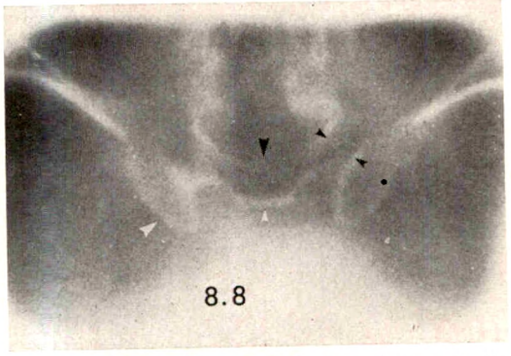

Fig. 2 (Merin, Harwood-Nash, and Crawford). Axial tomogram of a normal optic canal at its mid-level (in this case, 8.8 cm from the vertex of the head). The structures which can be seen are the optic canals (left canal indicated by small black arrows), the sphenoid body (indicated by large black arrow), tuberculum sellae (indicated by small white arrow), anterior clinoid processes (right process indicated by large white arrow).

From the Departments of Ophthalmology and Radiology, The Hospital for Sick Children, Toronto 101, Ontario, Canada. Dr. Merin is on leave from the Hadassah University Hospital Jerusalem, Israel.

This paper was read in part before the 107th annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, May 24-26, 1971.

Reprint requests to Department of Ophthalmology, The Hospital for Sick Children, 555 University Avenue, Toronto 101, Ontario, Canada.

(Table 1). Canals were considered abnormal if the diameter was larger or smaller than the above values, if there was a segmental narrowing or widening in one or both canals, if a canal was occluded, or if a fracture was seen.

## Results

The results are shown in Table 2.

We present here a brief description of the findings for each diagnosis and add some illustrative case reports.

### Glioma

Enlargement of one optic canal was found in all seven patients with optic nerve glioma. In five, both canals were affected. In all cases, subsequent neurologic and radiologic examinations and, later, surgery and biopsy confirmed the diagnosis.

#### Case report

*Case* 5—A four-and-one-half-year-old girl had a right exotropia for two years. Visual acuity was limited to finger counting. The optic disk was pale. The left eye appeared normal. Routine roentgenograms showed the right optic foramen enlarged and the left normal (Fig. 3). Axial tomograms showed the right optic canal enlarged to 10 mm in diameter and the funnel-shaped left optic canal 6 mm in diameter (Fig. 4). A preoperative diagnosis of bilateral glioma of the optic nerves was made. At operation the right optic nerve was five times its normal diameter and the tumor extended back into the chiasm and forward into the left optic canal. No radical excision was performed and the patient was sent for radiologic treatment.

### Craniopharyngioma

Six cases were examined. All showed scalloping of the sphenoid, clawing of the medial side of both anterior clinoids, and funnelling of the intracranial portion of one or both optic canals.

#### Case report

*Case* 12—A nine-year-old boy had been suffering from growth retardation for several years. He discovered accidentally that he could not see with his right eye. The right eye did not perceive light, owing to total optic atrophy. The left eye had visual acuity of 20/40, pallor of the disk and temporal hemianopsia. Roentgenograms showed normal optic foramina, but axial tomograms showed an invasion of both optic canals by tumor (Fig. 5). A subtotal excision of a craniopharyngioma was performed.

| Age in Years | Transverse Diameter of Optic Canal | |
|---|---|---|
| | Minimum | Maximum |
| Under 1 | 3 mm | 5 mm |
| 1 to 3 | 4 mm | 5 mm |
| Over 3 | 4 mm | 7 mm |

* Measured on roentgenograms, and so about one-third larger than the actual size.

### Other tumors

One patient (Case 13) had neuroblastoma and meastasis to the left orbit. Tomograms of the orbit showed destruction of the lateral wall, but axial tomograms of the optic canals showed that the canal was not involved.

### Anophthalmus

Five cases of anophthalmus were examined. Three were congenital, and on palpation of the socket under anesthesia no vestigial eye was found. The optic canal on the affected side was narrow in all three and occluded in two of them.

#### Case reports

*Case* 14—A two-and-one-half-year-old boy was examined because of bilateral congenital anophthalmus, had palpebral fissures measuring 15 mm each. Roentgenographic examination of the optic foramina showed them to be slightly flat in the vertical diameter (Fig. 6). Axial tomograms showed the optic canals to be small and occluded (Fig. 7).

Clinical anophthalmus had been diagnosed in one patient (Case 17), but palpation under anesthesia revealed a small pea-size eye. The axial tomograms showed normal optic canals.

*Case* 18—In this seven-year-old girl with acquired anophthalmus, the optic canals were normal. Because of retinoblastoma she had her right eye removed at the age of eight weeks and her left eye at the age of two-and-one-half years. After the enucleation, each socket was treated by a plastic ball and conformer. Axial tomograms showed normal optic canals.

## TABLE 2

TOMOGRAPHY OF THE OPTIC CANALS IN CHILDREN

| Case No. and Age (in years) | Clinical Diagnosis | Optic Canals: Diameter (in mm) | | Remarks |
|---|---|---|---|---|
| | | Right | Left | |
| 1–11 | Glioma of both optic nerves | 5.5 | 5.5 | Optic foramina normal, funnelling of proximal part of both canals |
| 2–10 | Glioma of both optic nerves | 7.0 | 8.0 | Enlarged |
| 3– 6 | Glioma of left optic nerve | 5.0 | 8.0 | Enlarged |
| 4– 2 | Glioma of both optic nerves | 8.0 | 9.5 | Enlarged |
| 5– 4½ | Glioma of both optic nerves | 10.0 | 6.0 | Figures 3 and 4 |
| 6– 7 | Glioma of right optic nerve | 8.0 | 6.0 | |
| 7– 2 | Glioma of both optic nerves | 7.0 | 8.0 | |
| 8–15 | Craniopharyngioma | 6.0 | 6.0 | See text |
| 9–15 | Craniopharyngioma | 5.5 | 6.0 | See text |
| 10–14 | Craniopharyngioma | 6.0 | 6.0 | See text |
| 11–13 | Craniopharyngioma | 7.0 | 7.0 | See text |
| 12– 9 | Craniopharyngioma | 6.0 | 5.0 | Figure 5 |
| 13– 2½ | Neuroblastoma with metastasis to the left orbit | 5.0 | 5.5 | Normal |
| 14– 2½ | Bilateral congenital anophthalmus | 3.5 | 0 | Small on right side, blind pouch on left |
| 15– 3 | Right congenital anophthalmus | 0 | 4.0 | Blind pouch on right side |
| 16– 1½ | Left congenital anophthalmus (Weyers-Thier syndrome) | 6.0 | 3.5 | Small on left |
| 17– 6 | Left congenital extreme microphthalmus (to the extent of anophthalmus) | 4.5 | 4.5 | Normal |
| 18– 7 | Bilateral anophthalmus, postenucleation | 5.0 | 5.0 | Normal canals |
| 19– 1 | Bilateral congenital microphthalmus and cataract | 7.5 | 7.0 | Large, bilateral |
| 20– 4 | Right congenital microphthalmus and cataract | 5.0 | 5.0 | Normal |
| 21– 4½ | Bilateral microphthalmus and uveal coloboma | 5.0 | 4.0 | Normal |
| 22– 6 | Bilateral congenital microphthalmus uveal coloboma | 4.5 | 5.0 | Normal |
| 23– 3 | Bilateral hypoplastic disk | 3.5 | 3.0 | Small, bilateral |
| 24– 7 | Right hypoplastic disk | 4.0 | 6.0 | Small, right |
| 25– 6 | Left hypoplastic disk | 6.0 | 3.5 | Small, left |
| 26– 9 | Right negalopapilla | 6.0 | 6.0 | Normal |
| 27–17 | Coloboma of right optic disk | 6.0 | 6.0 | Normal |
| 28– 3½ | Bilateral congenital optic atrophy | 3.0 | 3.0 | Small, bilateral |
| 29– 2 | Right congenital optic atrophy | 4.5 | 5.5 | Slightly small, right |
| 30–12 | Left post-traumatic optic atrophy | 6.0 | 5.5 | Normal |
| 31– 1 | Leber's amaurosis congenita | 5.5 | 5.5 | Normal |
| 32–14 | Leber's amaurosis congenita | 4.0 | 4.0 | Lower limits of normalcy |
| 33– 2 | Right microphthalmus with persistent hyperplastic primary vitreous | 5.0 | 4.5 | Normal |
| 34– 2 | Left microphthalmus with persistent hyperplastic primary vitreous | 5.0 | 4.5 | Normal |
| 35–16 | Congenital nystagmus with hyperopia | 6.0 | 6.0 | Normal |
| 36 | Congenital nystagmus with hyperopia | 5.0 | 5.0 | Normal |
| 37–3½ | Congenital nystagmus with hyperopia | 4.5 | 4.5 | Normal |
| 38–10 | Congenital nystagmus with hyperopia | 4.0 | 4.0 | Slightly small |
| 39– 1 | Congenital glaucoma | 5.0 | 4.0 | Normal |
| 40– 2 | Congenital toxoplasmosis | 3.0 | 3.0 | Normal |
| 41–10 | Right high myopia | 5.5 | 5.5 | Normal |
| 42– 1 | High hyperopia | 6.0 | 6.0 | Normal |
| 43– 9 | Trauma | 5.5 | 5.5 | Broken bone |
| 44–12 | Trauma | 5.0 | 5.0 | Broken bone blocking optic canal |
| 45– 7 | Trauma | 6.0 | 6.0 | Broken bone blocking optic canal |

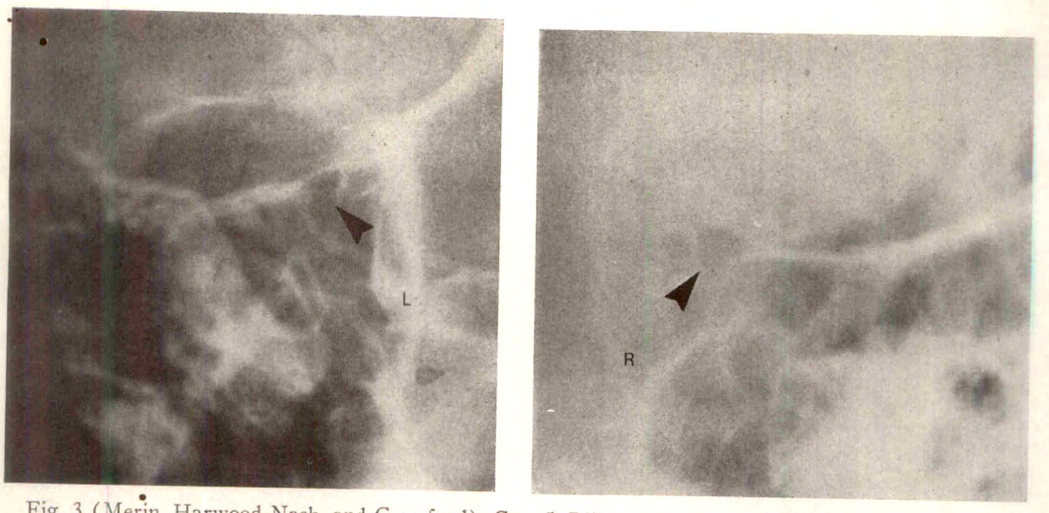

Fig. 3 (Merin, Harwood-Nash, and Crawford). Case 5. Bilateral glioma of the optic nerves and chiasm. Right: Plain roentgenograms showing right optic foramen enlarged. Left: Left optic foramen is normal.

### Congenital microphthalmus

Four cases were examined, two had an associated congenital cataract and two had an associated uveal coloboma. In three, the optic canals were within normal limits and in the following case (Case 19) they were unusually large.

#### Case report

*Case* 19—This one-year-old boy, blind since birth, had bilateral microphthalmus, the cornea measuring only 8 mm in diameter. Bilateral mature congenital cataracts did not allow us to visualize the fundus. The child and his mother showed some signs of abnormal development of the first two branchial arches and she, too, had a congenital microphthalmus with cataract of her right eye, which was blind since birth. The boy's axial tomograms showed unusually wide optic canals (Fig. 8).

### Hypoplasia of optic nerves

Congenital hypoplastic disk was diagnosed in three cases. In all three, axial tomograms of the optic canals showed them to be abnormally narrow on the affected side, for example, in Case 25.

#### Case report

*Case* 25—This six-year-old boy had been examined for exotropia of his left eye since infancy. The right eye was found normal, its visual acuity

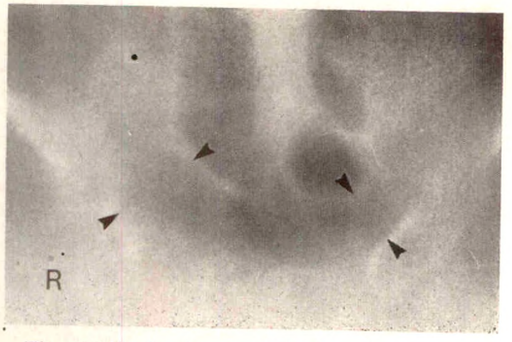

Fig. 4 (Merin, Harwood-Nash, and Crawford). Case 5. Axial tomogram showing wide optic canal on right (R), normal mid-portion of left optic canal (black arrows), and a funnel widening of the posterior part of the left optic canal.

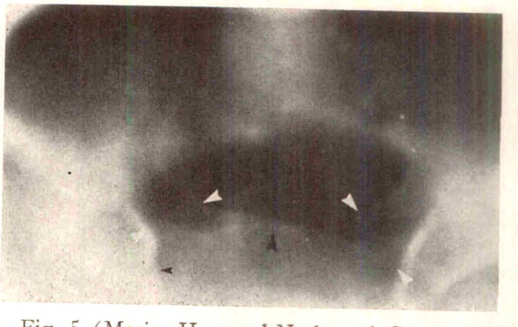

Fig. 5 (Merin, Harwood-Nash, and Crawford). Case 12. Craniopharyngioma with bilateral extension into the optic canals. Axial tomogram showing clawing of anterior clinoid process (small black arrow). The posterior part of each canal is widened (white arrows). The larger black arrow indicates scalloping of the sphenoid.

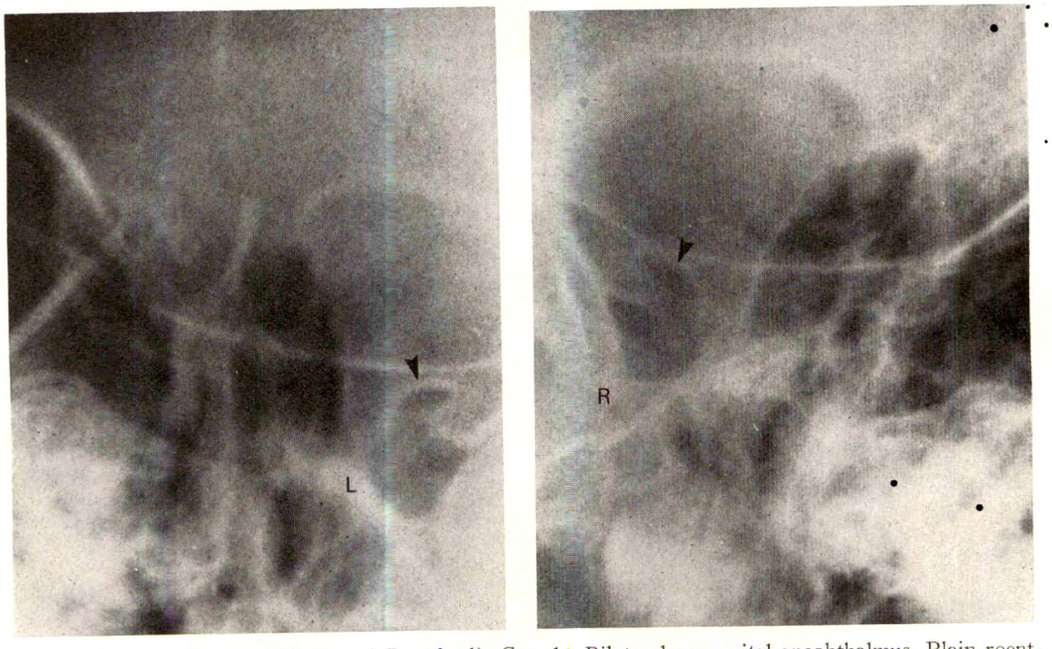

Fig. 6 (Merin, Harwood-Nash, and Crawford). Case 14. Bilateral congenital anophthalmus. Plain roentgenograms showing optic foramina slightly flattened in the vertical diameter and elongated in the horizontal diameter.

being 20/20 (with −1.0 sph. ⊃ −0.50 cyl. ax. 188°). The left eye had constant exotropia of 15Δ. Visual acuity was 20/50 (with −0.50 sph. ⊃ −0.50 cyl. ax. 90°). The pupils were normal and their direct and consensual response to light was normal. The fundus showed a small hypoplastic disk (Fig. 9). Roentgenograms showed normal and equal optic foramina. Axial tomograms of the optic canals showed a narrow optic canal on the left side (Fig. 10).

### Megalopapilla

One case of megalopapilla showed normal optic canals.

#### Case report

*Case 26*—This nine-year-old boy was referred to us after routine eye examination revealed an abnormal right optic disk. The visual acuity was 20/20 in

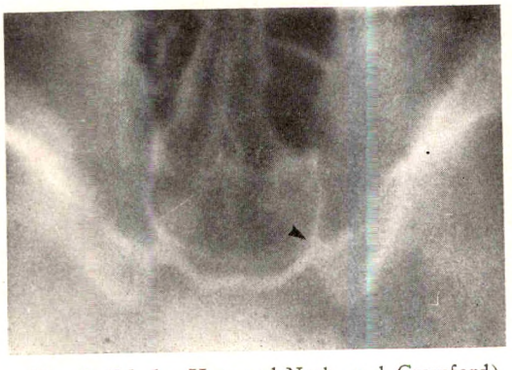

Fig. 7 (Merin, Harwood-Nash, and Crawford). Case 14. Axial tomogram showing occluded midportion of left optic canal (arrow) and narrowed right optic canal.

Fig. 8 (Merin, Harwood-Nash, and Crawford). Case 19. Bilateral microphthalmus. Axial tomogram showing large optic canals (right, 7.5 mm; left 7.0 mm).

Fig. 9 (Merin, Harwood-Nash, and Crawford). Case 25. The right (A) and left (B) fundus of a patient with a left hypoplastic disk. The white mark at the bottom of B is a light reflex.

each eye. The right optic disk was enlarged by about 50% (Fig. 11), and had some temporal pallor. Intraocular pressure was normal. The blind spot was enlarged with a partial supratemporal quadrantanopsia. Axial tomograms showed normal optic canals. Neurologic examinations were negative.

### Coloboma of optic disk

One case of coloboma of optic disk showed normal optic canals.

### Optic atrophy

Three patients with optic atrophy were examined. In one of the two congenital cases, the optic canals were small; in the other they were within normal limits though smaller on the affected side. In Case 30, optic atrophy resulted from injury in the first year of life. At 12 years of age the optic canals appeared normal and practically equal.

### Miscellaneous congenital conditions

The optic canals were normal in two patients with Leber's congenital amaurosis, two with hyperplastic persistent primary vitreous with microphthalmia, four with congenital nystagmus and hyperopia, and one each with congenital glaucoma, congenital toxoplasmosis, congenital high myopia, and congenital high hyperopia.

### Trauma

Axial tomograms showed fractures of the wall of the optic canal in three patients with trauma.

### Case report

*Case* 44—A 12-year-old girl, brought to the emergency department after a snowmobile accident, had no light perception in either eye. The right globe was ruptured and the central retinal artery on the left was occluded. Tomograms of the optic canals showed a fragment of bone penetrating into the right optic canal (Fig. 12).

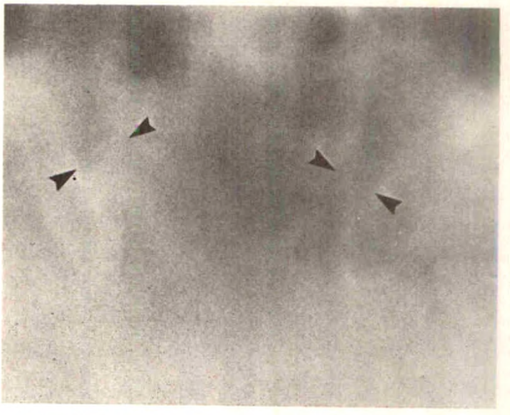

Fig. 10 (Merin, Harwood-Nash, and Crawford). Case 25. Axial tomogram showing left optic canal (L) narrower than the right (patient 25).

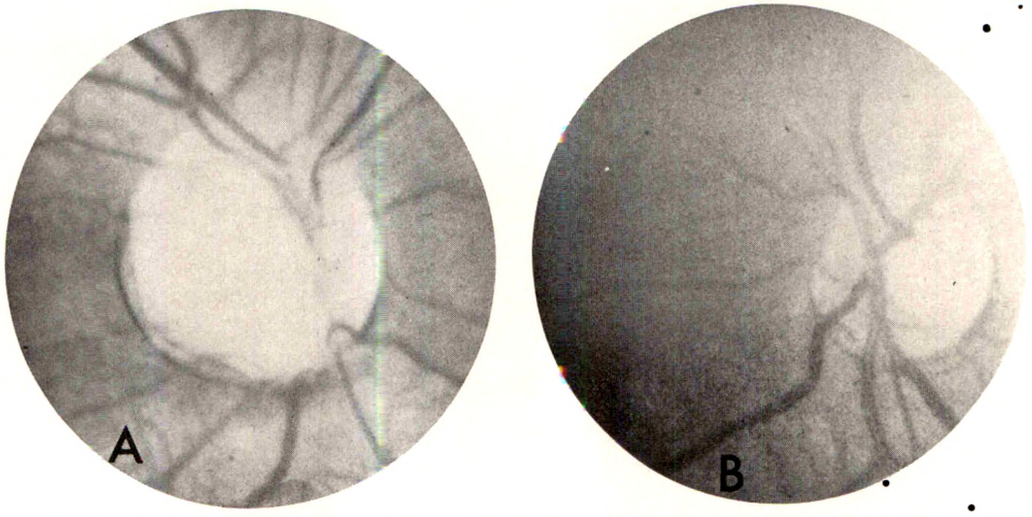

Fig. 11 (Merin, Harwood-Nash, and Crawford). Case 26. Right megalopapilla. The right disk (A) is enlarged, the left disk (B), normal.

## Discussion

Axial tomography of the optic canals is simple to perform in children. The necessity for hyperextension of the neck might make this type of tomography difficult to perform in adults.

The widening of an optic foramen seen on a plain roentgenogram is considered pathognomonic or glioma of the optic canal. A tumor, however, may be in the canal behind the foramen and hence only demonstrable by tomography. In Case 1 the foramina were normal but the axial tomograms showed an intrusion of both optic canals by the tumor from the direction of the chiasm. In Case 5, when plain roentgenograms showed only an abnormal right optic foramen, the axial tomograms showed that the left optic canal was involved as well.

Craniopharyngioma can readily be diagnosed by axial tomography. The clawing of the anterior clinoids, the scalloping of the body of the sphenoid and the proximal funnelling of the optic canals found concurrently in all cases were not seen in any other pathologic condition.

Anophthalmus, congenital or surgical, in a young child retards development of the orbit and the optic canal on the affected side.[3] The degree of this retardation depends on the age of the child and it is much less if an implant is inserted.[4] In all cases of microphthalmus the optic canals were normal; in all cases of anophthalmus they were abnormal. The only case diagnosed as congenital anophthalmus in which axial tomography showed no abnormality of the optic canals proved later to be congenital microphthalmus. Thus axial tomography may distinguish between true anophthalmus and microphthalmus.

Controversy exists about the value of plain roentgenograms of the optic foramina

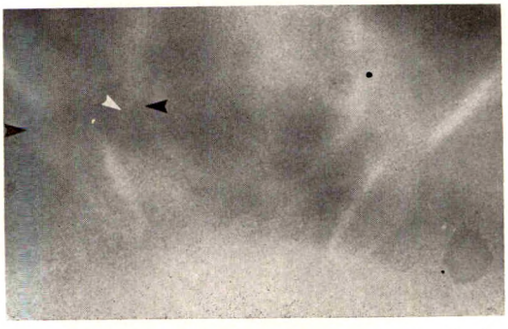

Fig. 12 (Merin, Harwood-Nash, and Crawford). Case 44. Trauma. Axial tomogram showing fracture of medial and lateral walls of right optic canal and across base of right clinoid process (black arrows) with a fragment of bone penetrating the canal (white arrow).

in diagnosis of hypoplasia of optic nerve, a condition in which the optic nerve contains fewer nerve fibers.[5] Several authors found the optic foramen small on the affected side,[6,9] others[10] found it normal. Recently, in two large series[11,12] plain roentgenograms were reported to be of no value. Axial tomography of the optic canal, however, clearly demonstrated narrowing of the canal in all three cases we examined. This narrowing may be a pathognomonic sign of hypoplasia of the optic nerve.

In a single case of the rare megalopapilla (Case 26) our findings of a normal canal confirm those of Franceschetti and Bock.[13]

Small optic canals were demonstrated in two cases of congenital optic atrophy. In one case of early acquired optic atrophy (Case 30), tomograms were normal. More cases will have to be examined in order to find out if this difference is always found.

A fracture of the optic canal is often difficult to demonstrate in plain x-ray films, but shows up clearly in axial tomograms.

Potter and Trokel[14-15] recently advised the use of anterior-posterior (A-P) hypocycloidal tomography of the optic canals and proved its superiority over plain roentgenograms of the optic foramina. However, A-P tomography, unlike axial tomography, does not show the whole length of the optic canal on one film and can be inaccurate when the angle of tomography does not correspond to the angle of the optic canal. Whereas A-P tomography is done always at a fixed angle, the average angle of the optic canal to the sagittal line is 36[16] or 37 degrees[14,15] with frequent individual variations which are greater and more common in children than in adults.[1]

## Summary

Hypocycloidal axial tomography of the optic canals was used to examine 45 children with various congenital and acquired diseases of the globe and optic nerve. It provided accurate assessment of unilateral or bilateral involvement in cases of glioma, craniopharyngioma, congenital anophthalmus, congenital optic atrophy, and congenital hypoplasia of the optic nerve; showed fracture in the wall of the optic canal in cases of injury; and revealed normal optic canals in cases of microphthalmus, coloboma of optic disk, Leber's congenital amaurosis, congenital nystagmus, congenital glaucoma, congenital toxoplasmosis, high myopia, and high hyperopia.

# SACCADIC VELOCITIES IN INFANTS AND CHILDREN

HENRY S. METZ, M.D., ALAN B. SCOTT, M.D., AND DAVID O'MEARA
*San Francisco, California*

Previous investigations in adults[1,2] indicate that abnormal recovery saccades of optokinetic nystagmus are elicited in lateral rectus muscle palsy. The antagonist medial rectus performed the recovery saccade normally. The value of studying ocular saccades in other neurologic diseases has been pointed out.[3,4] Voluntary saccadic movements are easily elicited in adults, and less easily, these command movements can also be obtained in young children. Saccades generated by optokinetic nystagmus (OKN) are reflex saccades; these have the same characteristics as voluntary saccades, but can be easily elicited in children.

It was the purpose of this study to determine to what extent the reflex saccades of optokinetic nystagmus (OKN) may be of diagnostic value in infants and young children.

## MATERIALS AND METHODS

Seven infants with ocular motility problems were tested. The child was seated comfortably on his mother's lap at the center of a drum 0.85 meter in height and 0.75 meter in diameter (Fig. 1). Vertical black stripes, 12 mm wide, alternating with 36 mm vertical white stripes, covered the inside surface of the drum. The speed of rotation was 60 degrees per second, which resulted in eight black and eight white stripes passing a given point in one second. The drum could be rotated in either direction. Each eye was studied separately as the drum was rotated first in one direction and then reversed.

Eye movements were recorded by electrooculography (EOG), as previously described.[2] Miniature skin electrodes (Beckman) were placed on the medial canthus and lateral canthus and the indifferent electrode centrally over the brow (Fig. 2).

Fig. 1 (Metz, Scott, and O'Meara). Infant on mother's lap inside large drum used to generate optokinetic nystagmus.

Within several minutes, even in a difficult child, one can get an adequate record of the eye movements. The tracing was considered valid when three patterns of following movements—recovery (saccadic) movements were noted in a three-second interval.

Optokinetic nystagmus was recorded by electrooculography on cooperative adults to establish both the normal pattern and the

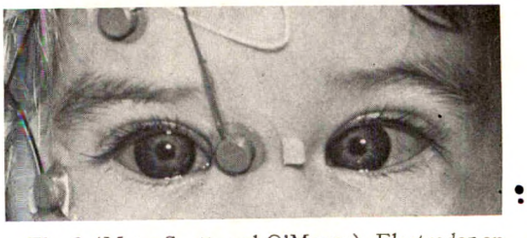

Fig. 2 (Metz, Scott, and O'Meara). Electrodes on medial and lateral canthi and centrally above the brow on infant.

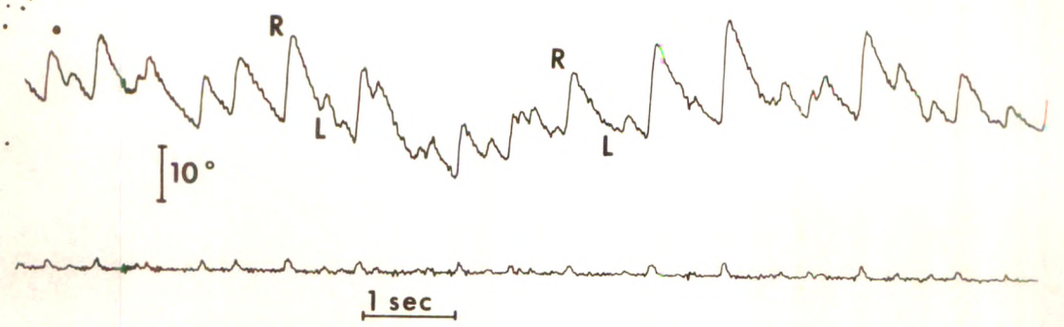

Fig. 3 (Metz, Scott, and O'Meara). EOG, left eye. Upper trace: Eye position and movement. Lower trace: Velocity. Movements generated to optokinetic nystagmus, drum rotated right (R) to left (L). Saccades to right are normally rapid suggesting normal medial rectus function.

pattern produced by a paretic muscle. Figure 3 demonstrates normal optokinetic nystagmus with a slow following and sharp recovery phase. A healthy medial rectus was responsible for the normal saccades obtained. Figure 4 displays abnormal optokinetic nystagmus as produced by a paretic lateral rectus muscle. The following and recovery movements are both slow. The saccades of optokinetic nystagmus produced by a normal and palsied muscle are easily differentiated by their different velocities.

## Case reports

*Case* 1—Moebius syndrome. This nine-month-old girl had had esotropia since birth (Fig. 5). Bilateral facial paralysis was present. Development was otherwise normal.

A V-pattern esotropia was present, measuring 80 prism diopters in downgaze, 60 prism diopters in primary gaze and 45 prism diopters in upgaze. Abduction did not bring either eye quite to the midline. Upward and downward gaze were mildly limited in each eye. Ophthalmoscopic examination was normal. In tests of this child, Figures 6 and 7 (upper trace) display normal recovery saccadic movements generated by the medial rectus. Figures 6 and 7 (lower trace) show recovery movements generated by the lateral rectus.

*Interpretation*—Abduction saccades bilaterally are slow and rolling and do not have normal saccadic velocity. These abnormal saccadic movements are similar to those seen in adults with known lateral rectus palsy. Normal horizontal saccadic movements have a velocity of above 250 degrees per second. These reflex saccades are about 50 degrees per second and indicate lateral rectus palsy in each eye. The EOG tracing resembles that of the adult sixth-nerve palsy with slow abduction saccades (Fig. 4), and shows that muscle paresis can be demonstrated in infants using this technique. When drum rotation is reversed, the direction of nystagmus is reversed. The medial rectus now functions as the agonist muscle for recovery movements, producing normal appearing optokinetic saccades. When the agonist muscle is normal, the saccadic velocity resulting from contraction of that muscle can serve as a control.

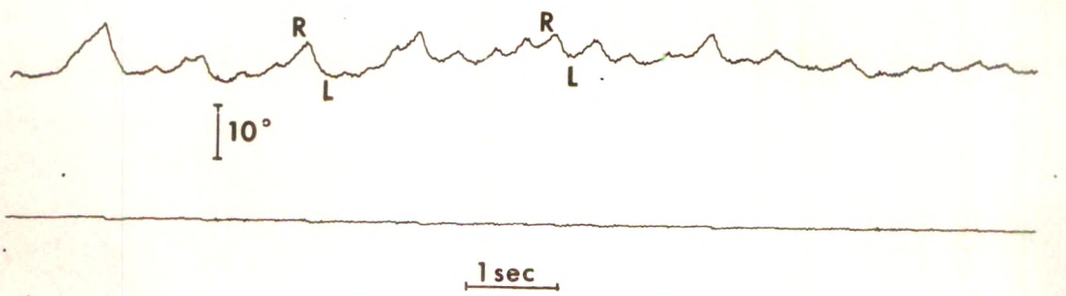

Fig. 4 (Metz, Scott, and O'Meara). EOG, left eye. Upper trace: Eye position and movement. Lower trace: Velocity. Movements generated by optokinetic nystagmus, drum rotated left (L) to right (R). Saccades to left are slow suggesting paresis of the lateral rectus muscle.

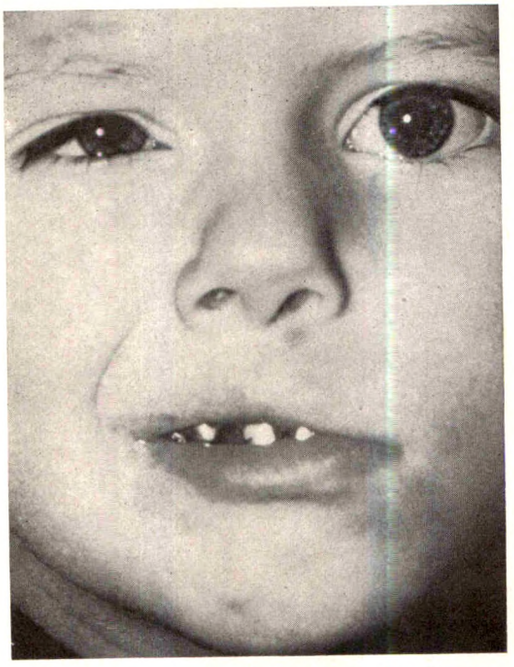

Fig. 5 (Metz, Scott, and O'Meara). Moebius syndrome. Bilateral sixth and seventh nerve palsy with esotropia.

*Case 2*—Limitation of abduction. This 21-month-old boy had been normal until five weeks of age. Following an automobile accident, he developed a subdural hematoma, hydrocephalus, and esotropia. A shunt procedure was performed to relieve the hydrocephalus. His mental and motor development were estimated at about the nine-month level. Examination revealed an alternating esotropia of 75 prism diopters (Fig. 8). Abduction was limited to almost 10 degrees lateral to midline in each eye and was not improved by patching. Vertical movements were full. Ophthalmoscopic examination was normal bilaterally. OKN saccades were observed and recorded in the area where movements were possible (i.e., nasal to the midline).

*Interpretation*—In Figures 9 and 10, the upper traces demonstrate recovery saccades generated by the medial recti and the lower traces, saccades generated by the lateral recti. In both instances, saccades are rapid and sharp. They suggest normal function of each lateral rectus muscle in the presence of diminished voluntary abduction bilaterally.

At surgery, the forced duction test revealed significant restriction to abduction in each eye. Bimedial rectus recessions of 5 mm and bilateral rectus resections of 7 mm were performed. Two months following surgery, the eyes were straight and abduction was full in each eye.

The status of the lateral recti in this patient was not certain prior to saccadic testing. History suggested lateral rectus paresis resulting from trauma. The marked esotropia persisted since the injury and there may have been little or no recovery of the lateral recti. The rapid saccades generated by the lateral recti in each eye suggested normal function. The return of full abduction following surgery confirmed the absence of lateral rectus palsy. The forced duction test at surgery confirmed the presence of mechanical restriction to abduction bilaterally.

## Discussion

Ocular saccades, whether voluntary or induced reflexly by optokinetic nystagmus, provides a stress test for the oculomotor system. Comparison of normal saccades with saccades of patients with motility defects is a simple yet accurate way of uncovering paresis of an extraocular muscle.

The drum used to produce optokinetic

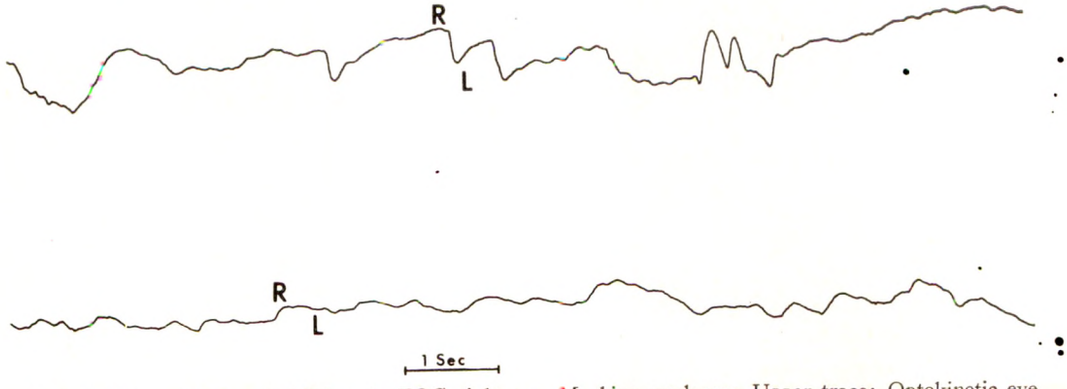

Fig. 6 (Metz, Scott, and O'Meara). EOG right eye, Moebius syndrome. Upper trace: Optokinetic eye movements, drum rotated left (L) to right (R). Recovery saccades to left are rapid. Lower trace: Optokinetic eye movements, drum rotated right (R) to left (L). Recovery saccades right are slow, suggesting paretic right lateral rectus muscle.

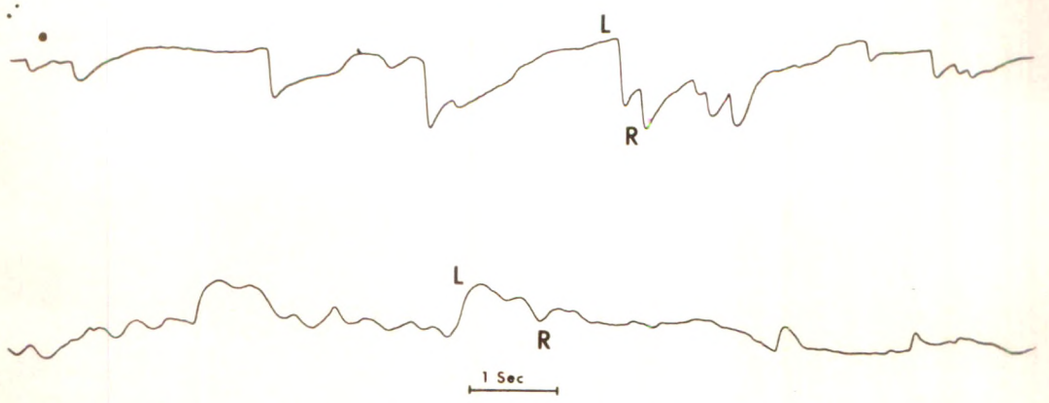

Fig. 7 (Metz, Scott, and O'Meara). EOG left eye, Moebius syndrome. Upper trace: Optokinetic eye movements, drum rotated right (R) to left (L). Recovery saccades to right are rapid. Lower trace: Optokinetic eye movements, drum rotated left (L) to right (R). Recovery saccades left are slow, suggesting paretic left lateral rectus muscle.

nystagmus should be large and encircle the patient to form a large field of moving stripes. This provides greater assurance that the child will be stimulated visually by the rotating stripes, wherever he looks. The stripes should be wide enough to be seen with reduced visual acuity. The object is to produce good OKN. Whatever speed of drum rotation, number of stripes in the visual field, or ratio of the size of the black and white stripes that does this, will be satisfactory.

Recording the eye movements of induced optokinetic nystagmus has several advantages over visual observation alone. A permanent record is acquired, the pattern of movement can be studied more completely at a later time and body and head movements need not be restricted nor the lids held apart to inspect the eyes. EOG equipment is often available at centers that perform electronystagmography.

The speed of a saccadic eye movement is not under voluntary control. A subject cannot purposely produce a slow saccade. The physician thus assumes control of the testing situation and the velocity of the saccadic eye movement is representative of the active force which can be generated by the agonist muscle.

It has been previously pointed out that resection of a paralytic extraocular muscle, even with recession of a contractured antagonist, cannot be expected to either maintain ocular alignment in the primary position or to increase the range of motility.[5] If the antagonist is not contractured or if it has been significantly recessed, it may be possible to provide greater range of motion by extraocular muscle transplantation surgery. It therefore becomes important to know about the mechanical forces in the orbit and the active forces capable of being generated by certain muscles. The former will be revealed by the forced duction test which can be done in infants while under anesthesia just prior to surgery. The active forces can be estimated in adults by use of the Scott active force test[5] and by ocular electromyography.[6] These tests cannot readily be done in infants or young children, so other objective recording techniques must be used.

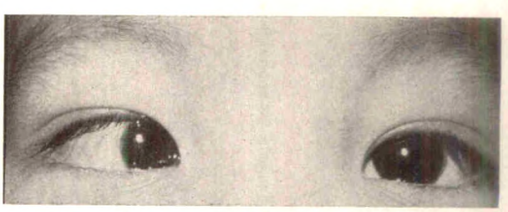

Fig. 8 (Metz, Scott, and O'Meara). Bilateral abduction limitation with large angle esotropia.

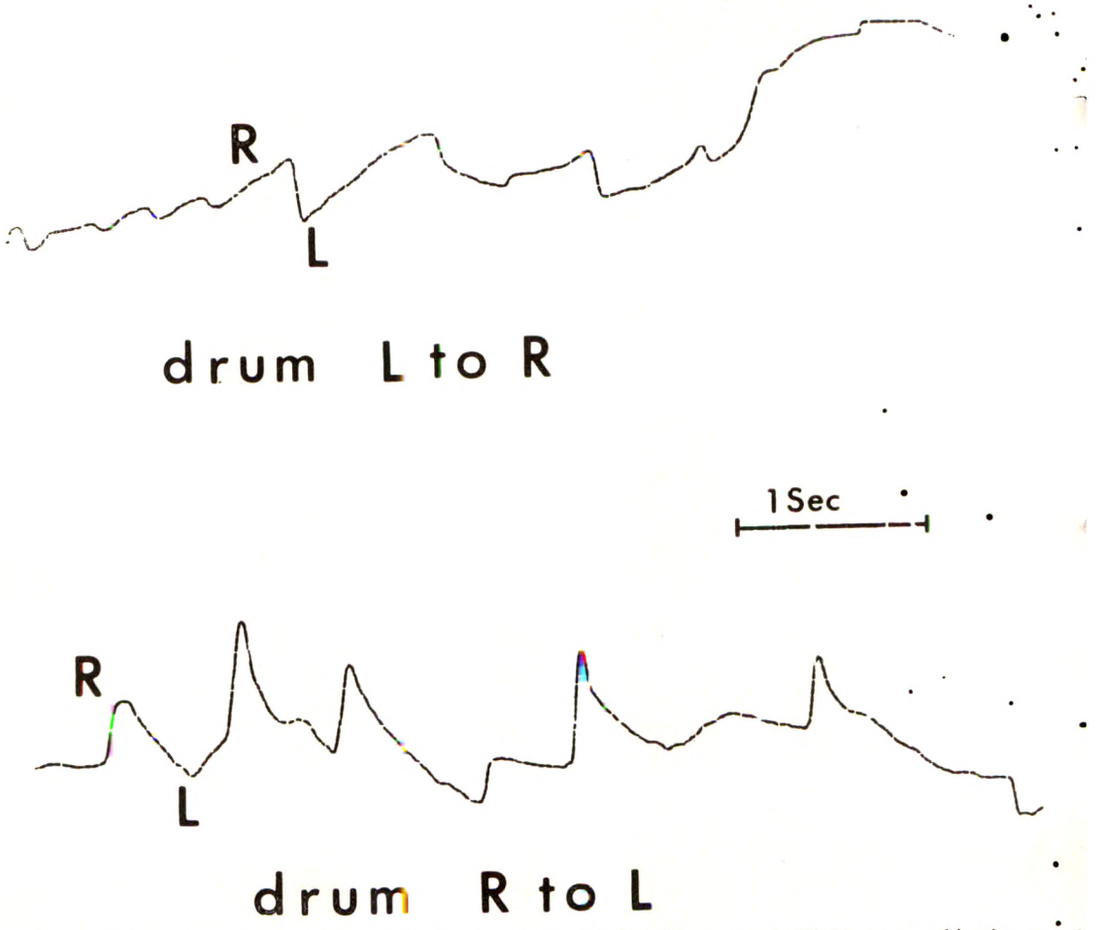

Fig. 9 (Metz, Scott, and O'Meara). EOG, abduction limitation. Upper trace: Right eye, optokinetic eye movements, drum rotated left (L) to right (R). Recovery saccades to the left are rapid. Lower trace: Left eye, optokinetic eye movements, drum rotated right (R) to left (L). Recovery saccades to the right are rapid. Normal medial recti in each eye.

When muscle surgery is performed without knowledge of the innervational status of the ocular muscles, the decision concerning which muscles to operate upon and the amount of surgery required is necessarily based on guess work. We believe the method of generating saccades with optokinetic nystagmus while recording eye movements with EOG can provide useful information to the ophthalmologist in diagnosis, prognosis, and surgical planning.

## Summary

Ocular saccades were generated in infants and children by optokinetic nystagmus. These movements were recorded by means of electrooculography.

A normal saccade was generated by a normal extraocular muscle while an abnormally slow saccade is produced by a paretic extraocular muscle. By comparing the saccade produced by a suspected paretic muscle with normal saccades, paresis can be detected in young patients. The test is useful for diagnosis, prognosis and surgical planning in infants and children with paralytic strabismus. In children, where there are limitations in doing the forced duction test and ocular electromyography, one can use electro-oculography and generate reflex saccades with opto-

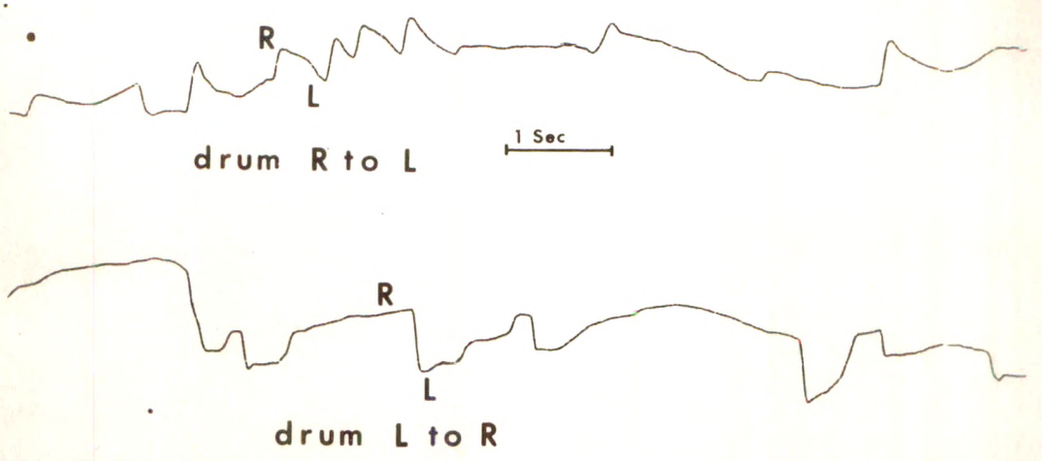

Fig. 10 (Metz, Scott, and O'Meara). EOG, abduction limitation. Upper trace: Right eye, optokinetic eye movements, drum rotated right (R) to left (L). Recovery saccades to right are rapid. Lower trace: Left eye, optokinetic eye movements, drum rotated left (L) to right (R). Recovery saccades to left are rapid. Normal lateral recti in each eye.

kinetic nystagmus in perplexing problems where paresis is suspected.

ACKNOWLEDGMENT

We thank Dr. Arthur Jampolsky for his advice and encouragement in this study and Mr. Robert Bowen for preparation of the photographic illustrations.

# REVERSAL OF SYSTEMIC TOXIC EFFECTS OF SCOPOLAMINE WITH PHYSOSTIGMINE SALICYLATE

SUE ELLEN YOUNG, M.D., RICHARD STRANAHAN RUIZ, M.D., AND JOHN FALLETTA, M.D.

*Houston, Texas*

With the widespread use of cycloplegic agents, mydriatics, and preanesthetic medications, anticholinergic intoxication occurs fairly frequently in ophthalmic patients. Physostigmine salicylate offers a readily available and rapidly effective treatment for the central anticholinergic syndrome. The following case reports illustrate our experience with this antidote.

## CASE REPORTS

A 75-year-old white woman in good general health was admitted for retinal detachment surgery. To dilate the pupils, one drop of 0.25% scopolamine and one drop of 10% phenylephrine was instilled in each eye every 10 minutes for two hours. Approximately 30 minutes following the final instillation of drops (calculated total dose: 3 mg scopolamine; 120 mg phenylephrine), the patient became somnolent and confused. The blood pressure was 150/80 mm Hg, the pulse rate was 66/minute with a regular rhythm, and they remained stable. Temperature was normal. She was oriented to time, place, and person although she was drowsy. Intermittently she picked at her clothes and brushed imaginary ashes into an ashtray. The skin was of normal color and the mucous membranes were dry. Deep tendon reflexes were normal and no pathologic reflexes were elicited. A diagnosis of toxic reaction to scopolamine was made. Despite the mildness of the reaction, physostigmine salicylate, 1 mg, was administered subcutaneously. Within five minutes the patient's sensorium had cleared significantly. Ten minutes after the injection of physostigmine, tearing and salivation were evident, and shortly thereafter, the patient urinated. She had no recollection of her behavior prior to the administration of physostigmine. The remainder of this patient's hospital course was uneventful.

A four-year-old black boy in previously good health was brought to the emergency room because of bizarre and unusual behavior originating several hours earlier. The child was irritable, combative, and disoriented. There was generalized muscular hypertonicity with sporadic, gross, nonrhythmic tremors of all extremities. Blood pressure was 120/65, pulse rate was 120/minute and regular, and rectal temperature was 99°F. The child's face was flushed, the skin was warm and dry, and the lips were fissured. Both pupils were dilated and nonreactive to light. Other Deep tendon reflexes were brisk, but equal. The remainder of the physical examination was normal.

On the basis of clinical findings, an atropine-like drug intoxication was suspected. The father, who wore an eye patch, claimed that the only medications in the household were eye drops (0.25% scopolamine, 10% Neosynephrine, and Cortisporin) prescribed for him following a recent eye injury.

Following subcutaneous injection of 5 mg of methacholine, there was no salivation, lacrimation, or perspiration noted. The injection was repeated 25 minutes later, again without effect. The failure to produce typical cholinergic signs strengthened the clinical impression of an atropine-like drug intoxication.[1]

The white blood count was 13,800 and the differential was normal. Blood glucose, serum calcium, electrolytes, and routine urinalysis were within normal limits and a ferric chloride urine test was negative.

Signs and symptoms persisted. Sixteen hours after admission, 0.25 mg of physostigmine sulfate was administered subcutaneously and repeated at 15-minute intervals. No change was noted following the initial dose; an increase in salivation appeared following the second dose; and tearing was noted during administration of the third dose. Ten minutes following the third and final dose, the boy responded to simple commands and was able to pick up small objects with either hand and walk without assistance. The pupils remained widely dilated and nonreactive but returned to normal within 24 hours.

An atropine-like drug was identified in the patient's blood and urine by ultraviolet spectrophotometry and thin layer chromatography. The remainder of the hospital course was uneventful, and prior to discharge, the boy admitted drinking "daddy's medicine" (the scopolamine eye drops).

## DISCUSSION

Intoxication from anticholinergic drugs should not be regarded as a benign reaction of short duration. Atropine and related drugs may produce dual central nervous system effects—stimulatory and depressant—with variations and overlapping between

From the Department of Ophthalmology, The University of Texas Medical School at Houston and Hermann Hospital, Houston, Texas. Dr. Falletta is a resident in the Department of Pediatrics of Baylor College of Medicine, Houston, Texas.

these extremes. Typical central nervous system manifestations include visual hallucinations, restlessness, ataxia, delirium, somnolence, stupor, and coma. Though usually of several hours' duration, these symptoms may persist for days.[2] Toxic reactions may result in the postponement of surgery or the compromise of surgical results. The agitated, delirious patient may seriously impair the functioning of the operating room, recovery room, hospital ward, or office.[3] At least six deaths from cycloplegic agents (notably atropine) have been reported.[2,4,5]

Although toxic effects appear to be dose-related in most cases, patients vary in their degree of susceptibility.[6] Those thought to be particularly susceptible include blond children,[7] patients with spastic diplegia, and those with Down's syndrome.[8] Carpenter[9] cites the case of an 82-year-old man with progressive mental deterioration who was given a total of four drops of 0.2% cyclopentolate (Cyclogyl) instilled topically. This patient developed acute mental decompensation which failed to revert with time. In otherwise healthy individuals, central nervous system symptoms arising from very small doses of anticholinergics may appear as an idiosyncratic response.[6,10] However, difficulty in administering drops, impurities contained in the solution, and variation in concentration due to evaporation make exact dosage of topical solutions difficult to ascertain.

The anticholinergic syndrome is identical to that seen in Jimson weed (loco weed) poisoning.[11] Beside atropine drops[2,5,12] and ointment,[2] usually of 1% concentration, other ophthalmic solutions incriminated include homatropine,[2] scopolamine,[10] and cyclopentolate.[13-16] In a double-blind study, Binkhorst, Weinstein, Bareta, and Clahane[14] presented evidence for a dose-related central nervous system toxicity from topical administration of cyclopentolate.

The use of the anticholinesterase, physostigmine, as an antidote to the central anticholinergic syndrome is well established.[3] The analogues, neostigmine (Prostigmin) and edrophonium (Tensilon), contain a quarternary ammonium group, and hence, they cross the blood-brain barrier poorly.[17] By contrast, the more lipid-soluble physostigmine, a tertiary amine, is readily absorbed and easily enters the central nervous system. Thus, it is an antagonist of both central and peripheral nervous system effects of anticholinergic drugs.[3] Parasympathomimetic drugs, as pilocarpine and arecholine, antagonize only the peripheral nervous system effects of anticholinergics and have no effect on the central nervous system excitation.[11,18]

In a series of 26 consecutive cases of anticholinergic intoxication treated with physostigmine salicylate, 1 mg intramuscularly or intravenously, Duvoisin[3] reported "gratifying results without exception." Crowell and Ketchum[19] administered physostigmine salicylate (5.0 mg/kg) to 33 healthy volunteers at various intervals after intramuscular injection of scopolamine (2.4 mg/kg). They concluded that while physostigmine failed to prevent onset of delirium, it could effectively and safely reverse the delirium once it occurred. The maximum reversing effect occurred 90 minutes after scopolamine injection.

The recommended adult dose of physostigmine is 1 mg, and it may be administered intramuscularly, intravenously, or subcutaneously at the time signs and symptoms of central nervous system toxicity are manifest. From our experience, a dosage of 1 mg/m$^2$ of body surface is safely administered in the pediatric age group. According to the studies of Weiss,[20] man is capable of totally eliminating this dosage within two hours. Accordingly, it may be necessary to repeat administration of physostigmine at this time should toxic symptoms recur. Should the initial dose of physostigmine be ineffective in reversing toxic symptoms, it can be repeated safely in 15-30 minutes.[20,21] In normal individuals without prior anticholinergics, a dose of 1 mg does not produce systemic reaction and Weiss[20] reported no ill effects after two doses given 30 minutes apart.

In view of the relatively innocous effect of physostigmine in the recommended dosage, we feel that all cases of anticholinergic intoxication should be treated.

## Summary

When a 75-year-old woman became somnolent and confused following instillation of 0.25% scopolamine and 10% phenylephrine eye drops, 1 mg of physostigmine salicylate administed subcutaneously resulted in complete clearing of her sensorium within five minutes. When a four-year-old boy ingested 0.25% scopolamine eye drops, he became irritable, combative, and disoriented with generalized muscular hypertonicity and gross, nonrhythmic tremors of all extremities. The pupils were dilated and nonreactive to light. After 16 hours, he failed to improve spontaneously; however, following three doses of 0.25 mg of physostigmine salicylate administered subcutaneously at 15-minute intervals there was rapid improvement.

Physostigmine salicylate is a rapidly effective antidote for the systemic toxic signs of the anticholinergic syndrome.

# ISOLATION OF STROMAL COLLAGENASE IN CORNEAL INFLAMMATION

STUART I. BROWN, M.D., AND CAROL WELLER HOOK, PH.D.
*New York, New York*

Although there have been numerous investigations of infections of the cornea, few report the nature of acute and especially chronic corneal inflammation. The present study establishes a model for acute and chronic corneal inflammation, and in addition, reports the isolation of a stromal collagenase.

## MATERIAL AND METHODS

Albino rabbits weighing from 2 to 4 kg were anesthetized with intravenous pentabarbital and topical tetracaine HCl. Corneal inflammation was produced by injection of 0.05 ml complete Freund's adjuvant in mineral oil (Difco) into the peripheral stroma (2-3 mm from the limbus) with a 25-gauge needle. The corneas were examined daily with loupe and light and were removed at various times before and after onset of inflammation.

The excised corneas were cut into quadrants and each inflamed area was bisected. One piece was saved for a collagenase assay and the other was placed in 3% glutaraldehyde in 0.2M sodium cacodylate buffer for 15 minutes. Following this, it was post-fixed in 2% osmium tetroxide in cacodylate buffer for one hour and dehydrated in alcohols and propylene oxide. Finally, it was embedded in Epon 812 and thick sections (5μ) were cut and stained with basic fuchsin and alkalinized methylene blue.[1]

The tissue saved for collagenase assay was dipped into mammalian Tyrode's solution. The epithelium was scraped free of the stroma and both were cultured on a rigid opalescent gel of 0.2% reconstituted collagen which was incubated at 37° C for up to four days.[2] Clearing of the gel surrounding the tissue explant indicated collagen lysis.

Additional pieces of corneas were excised seven days after intralamellar injection. The epithelium was scraped free and the stromas were trimmed to approximately 2 × 2 mm. Collagenase was harvested from these tissues by growing them in Dulbecco's medium.[3]

The effect of the harvested enzyme on the viscosity of a 0.1% collagen solution was tested using an Ostwald viscometer with a water flow rate of 53 seconds at 25° C and at pH 7.4. All measurements were made at 27° C. The effect of the harvested enzyme on the optical rotation of reconstituted collagen was determined using the MSP-3 photoelectric spectrophotometer at 25° C and 589 mμ.

Three methods were used to determine the cell origin of the stromal enzyme. The first was simply to repeatedly freeze-thaw stromas which were injected five days previously with Freund's adjuvant. This material was then transferred to gels of reconstituted collagen and incubated at 37° C for up to four days.

The second method was to apply puromycin $10^{-3}$M, which is an inhibitor of protein synthesis (and therefore enzyme synthesis), to the surface of the corneal explant twice a day for four days. For controls, alkali burns were produced in rabbit corneas,[2] and when ulcerations were noted, the epithelium which surrounded the ulcers was removed and soaked in puromycin $10^{-3}$M and assayed on collagen gels.

The third method was to reduce the circulating granulocytes by the intravenous injection of mechlorethamine HCl (nitrogen mustard), 5 mg three days before, and 3 mg on the day of intralamellar injection of Freund's adjuvant. Three, six, and 10 days later, the corneas were excised and bisected.

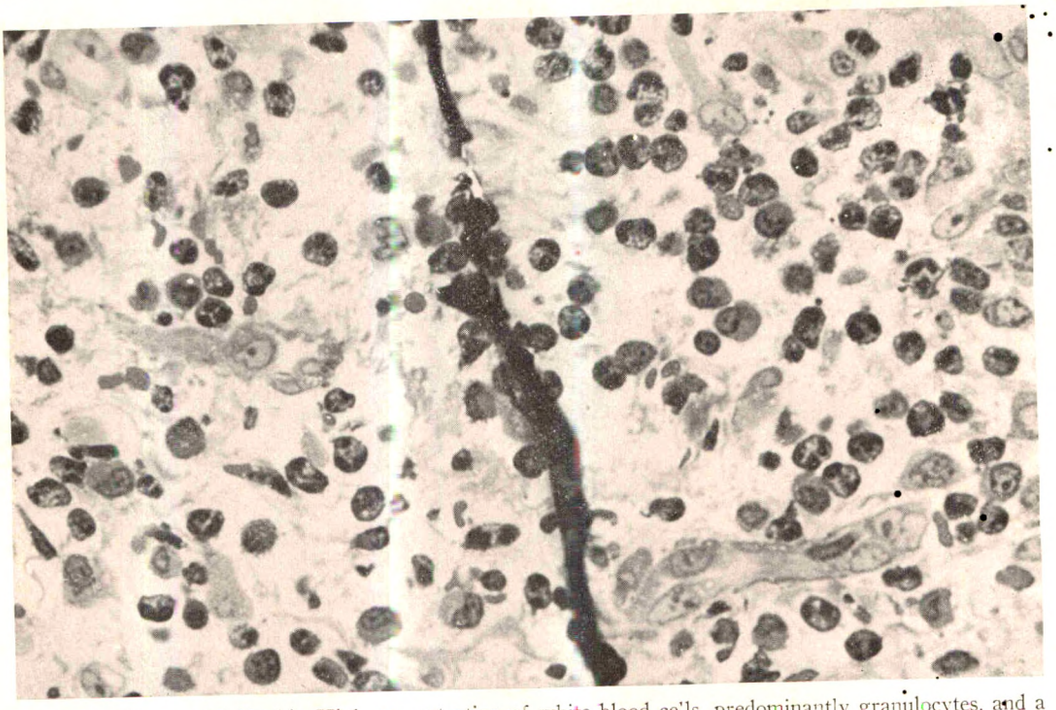

Fig. 1 (Brown and Hook). High concentration of white blood cells, predominantly granulocytes, and a few histiocytes or epitheliod cells (basic fuchsin and alkalinized methylene blue, ×400).

Half of each specimen was assayed for collagenase activity and the other half was examined histologically.

## Results

Grossly, the limbal blood vessels became dilated within 12 hours after injection of Freund's adjuvant. At 36 hours, the corneas were semitranslucent and slightly edematous. Neovascularization began at about four days postinjection. At this time, the stromas were grossly edematous and opaque. Histologic examination of the corneas at 24 hours showed granulocytes and an occasional mononuclear cell. The concentration of white blood cells increased markedly over the next 48 hours, especially in the area of the foreign protein. At four days, there were many granulocytes, and fewer monocytes and histiocytes (Fig. 1).

The cellular infiltrate increased in concentration until the third week, when the number and types of cells in the infiltrate became constant. Six weeks after injection of Freund's adjuvant, all cell types, but especially the granulocytes, began to decrease in number, and the stromal edema was grossly reduced. During postinjection weeks nine to 12 there were only a few histiocytes or epitheloid cells and granulocytes.

The epithelium from the inflamed stromas did not produce detectable collagen lysis in any specimen. On the other hand, in every instance culturing of the inflamed stromas produced collagen lysis at least 10 mm in diameter, beginning at 36 hours and continuing through nine weeks after intralamellar injection of Freund's adjuvant (Table 1).

The specific viscosity of the mixture of harvested stromal enzyme and reconstituted collagen at pH 7.4 gradually decreased over a one-hour period to about 60 percent of the original value (Fig. 2). The optical rotation measurement of reconstituted collagen (−442) was not changed by the addition of the harvested enzyme (−450).

All specimens that had been repeatedly freeze-thawed produced at least 10 mm in di-

|---|---|
| Alkali-burned epithelium plus Tyrode's solution | >10 mm |
| plus puromycin | 0 |
| Granuloma (only stroma) puromycin | >10 mm |

* Five assays for each category.

ameter of collagen lysis. Puromycin completely inhibited collagen lysis by the epithelium from alkali-burned corneas (controls), but allowed lysis by the inflamed stromas.

The nitrogen mustard treatment schedule resulted in a circulating white blood count between 1200 to 1800 on the day of intralamellar injection. The granulocytes in the peripheral blood were mainly blast cells and were about 30% of the white blood cells. Specimens of the corneas of the nitrogen mustard-treated animals did not lyse the collagen gels at four, six, and 10 days after injection of Freund's adjuvant. The inflammatory reaction that resulted from injection of Freund's adjuvant was markedly reduced in comparison with those animals that had not received nitrogen mustard (i.e., there was less edema and neovascularization was delayed to the end of the second week). Histologically, there were many less white blood cells in the stromal infiltrate and these were heavily granulated.

## COMMENTS

Inflammation was consistently produced in the rabbit corneas by the intralamellar injection of Freund's adjuvant. This was first noted in 24 hours, reached its peak in intensity by the end of the third week and began to quiet after two months. The stromal cellular infiltrate surrounding the foreign protein was mainly granulocytic in the first few days, but later took on the characteristics of a granuloma with many large histiocytes or epitheliod cells in addition to the granulocytes. Tissue culture assays showed that the stromas of these corneas caused collagen lysis that was similar in quantity to that caused by the ulcerated alkali-burned cornea.[2] Harvest of the enzyme showed it to be a true collagenase because of its characteristic effect on the viscosity and optical rotations of reconstituted collagen.[4] The molecular weight of the enzyme and the dynamics of its inhibition will be reported.

Gross and Lapiere[5] demonstrated that animal collagenase is produced by living cells (epithelium and possibly fibroblasts) and that destruction of the cells by freezing stops collagenase production. An exception is the collagenase from the granulocytes which originates in the granules and can be detected only *after* cell disruption.[6] Another unusual feature of the granulocyte collagenase is that it is only weakly active against collagen fibrils. Since no other blood cell elements contain collagenase,[6] the only cells that could have produced the collagenase found in the inflamed corneal stromas were either the fibroblasts, the histiocytes, or the granulocytes. Collagenase was detected after freeze-thawing, which indicated that the enzyme originated from the granulocytes. A less likely possibility was that the enzyme was produced and stored in the tissues. Since stored collagenase has never been demon-

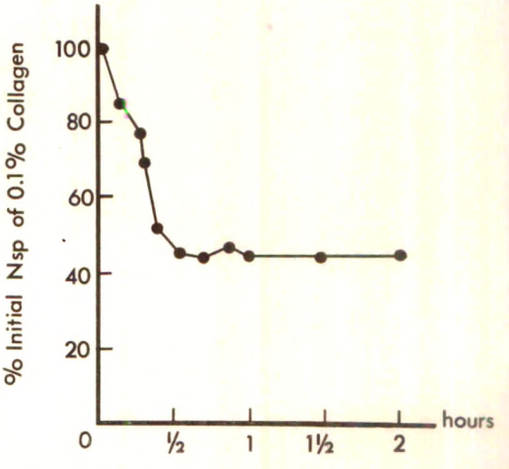

Fig. 2 (Brown and Hock). Graph showing a reduction in specific viscosity of reconstituted collagen after exposure to the stromal collagenase.

strated in tissues before, it is unlikely that the collagenolytic activity after freeze-thawing was from enzyme produced and stored in the tissues by the fibroblasts and the histiocytes before their destruction.

Soaking the inflamed stromas with puromycin, which is a potent inhibitor of protein metabolism, allowed collagenolytic activity. This indicates that the stromal enzyme was not a product of cell metabolism, which again points to the granulocytes as the collagenase carrier. Finally, when the number of the circulating granulocytes was reduced by approximately 80% by intravenous nitrogen mustard, collagenase production was not detected after intralamellar injection. Except for the findings that the harvested enzyme was active against heat-gelled collagen fibrils, the results of the present study indicate that at least part of the collagenase of the stromal granuloma originates from the granulocytes.

The obvious reduction in stromal edema and neovascularization in the animals pretreated with nitrogen mustard suggests that the granulocyte may also play a role in mediating various aspects of the inflammatory response. Studies are in progress to isolate this effect of the granulocyte.

Collagenolytic lysozomal enzymes have been isolated from inflamed tissues in other parts of the body. However, these were effective only when pH acidity fell between 3 and 5.5. There are no studies showing that the pH of inflamed tissue is in the acid range. Consequently, there is doubt that these acid hydrolases could destroy collagen in vivo. The present study demonstrates a neutral collagenase in inflammation of the corneal stroma, indicating the destructive potential of the inflammatory process. Though there was no gross loss of tissue in these inflamed corneas, preliminary study of the electron micrographs of the inflamed areas showed various types of collagen fibril alterations.[7]

Recently, we found that the collagenases of the alkali-burned cornea and the inflamed stroma are each inhibited by dilute concentrations of fresh serum. It may be that the minimal corneal destruction relative to the large amount of collagenase produced by the inflamed stroma is due to enzyme inhibition by elements in the serum. This inhibition would probably be related to new vessel ingrowth into the inflamed area. This will be expanded in a later report.

## Summary

Inflammation of the corneal stroma was produced in rabbits by the intralamellar injection of Freund's adjuvant. The inflammation progressed from a typically acute to a chronic granulomatous type of inflammation. A collagenase was isolated from the inflamed stromas and partially characterized. The enzyme appeared early in the course of the inflammation, thus indicating that it originated in the granulocytes.

# NOTES, CASES, INSTRUMENTS

## NEW FIBER OPTICS COAGULATOR FOR MACULAR HOLES

C. M. J. VELZEBOER, M.D., G. TIESINGA, AND S. VAN RHIJN
*Amsterdam, Holland*

When scleral diathermy is performed in treatment of retinal detachment, localization and coagulation of posterior holes is difficult. This is especially true in treatment of macular holes, when a single coagulation is preferable, despite the fact that localization beforehand is not possible without a good view of the posterior scleral region. This may be extremely difficult or even impossible to attain, especially in strongly myopic patients.

In 1966, Oosterhuis[1] described a procedure in which fiber optics were used with the electrode attached. Thus the electrode formed the central part of an illuminated fundus area. The instrument was adequately curved but rather large for operation in the posterior area. Our technicians, Van Rhijn and Tiesinga, constructed an electrode using tiny silver wires to conduct the diathermy current together with a fiber optics light source. This electrode contains 47 silver wires and 220 glass fibers (Fig. 1). The wires are connected to a Siemens diathermy apparatus, the glass fibers with a simple fiber optic set (Fig. 2). A 4-V otoscope lamp, used on 3-V, was built into the handle of the instrument (Fig. 3). Silk is used for coating; impregnation is with polyester synthetic resin. Leakage and resistance must be measured. The mass of fibers is mounted in a stainless steel tube, and in the handle, a windowed aperture near the lamp provides an external indicator (Fig. 3).

We have achieved an electrode with a diameter of 2 mm and a coagulation surface of

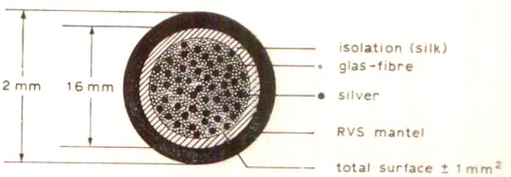

Fig. 1 (Velzeboer, Tiesinga, and van Rhijn). Cross-section of the electrode.

1 mm diameter. The illuminated area is also 1 mm in diameter, and identical with the coagulation.

The curvature is adapted to the shape of the globe. Thus the electrode can easily bypass a relatively small conjunctival incision without separating the muscle. In the posterior region of the eye it can be held in firm attachment to the eye (Fig. 4).

### OPERATING PROCEDURE

The electrode illuminated is passed to the posterior pole. Its position can easily be controlled by the surgeon, and when the correct position is reached, the surgeon can switch on the diathermy apparatus with the aid of a

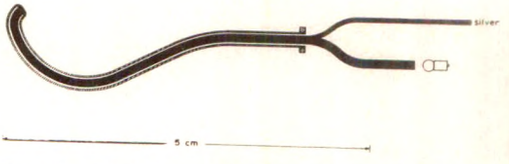

Fig. 2 (Velzeboer, Tiesinga, and van Rhijn). Interconnection of apparatus.

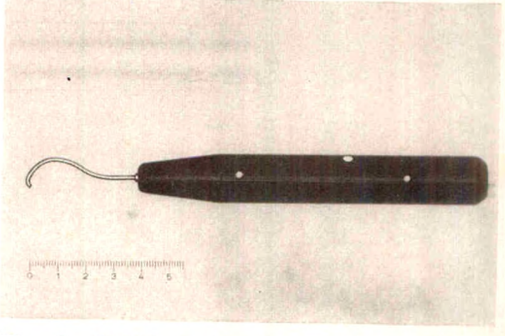

Fig. 3 (Velzeboer, Tiesinga, and van Rhijn). Handle of instrument.

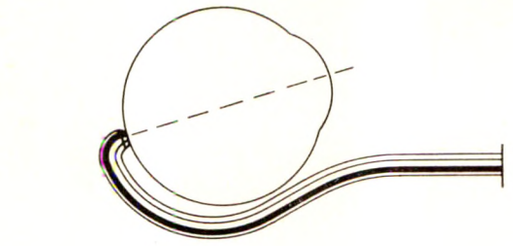

Fig. 4 (Velzeboer, Tiesinga, and van Rhijn). Because of its curvature, the instrument can be held in firm attachment to the eye in the posterior region.

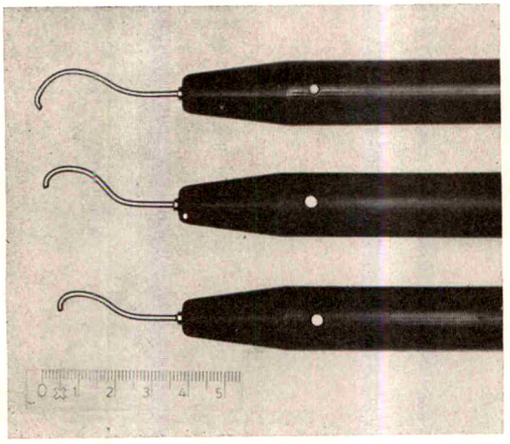

Fig. 5 (Velzeboer, Tiesinga, and van Rhijn). Series of electrodes designed for various procedures.

foot pedal and control the localization as well as the intensity of the coagulation. Using this apparatus, macular holes can thus be treated by a single, correctly placed coagulation.

A series of electrodes has been made in our department, each having different curvatures for macular holes and more peripherally located retinal tears (Fig. 5).

## Summary

A new fiber optics coagulator was designed for use in cases of macular holes. The electrode utilizes silver wires and glass fibers, and these are fused. The illuminated area is identical with the coagulation surface of the electrode, both being 1 mm.

# SIMPLE EPICANTHUS PROCEDURE

Sidney A. Fox, M.D.
*New York, New York*

A simple procedure for the repair of epicanthus is presented. There are no preliminary diagrams to mark out, no lines to measure, and no angles to calculate. Hence the surgery is tailored, as it were, to the epicanthus.

## Technique

The epicanthal fold is picked up and the base on each side is incised, the two incisions meeting below the fold to form angle-A (Fig. 1).

The resultant flap is dissected up, rotated medially, and flattened out. An incision is made along the upper border of the flap.

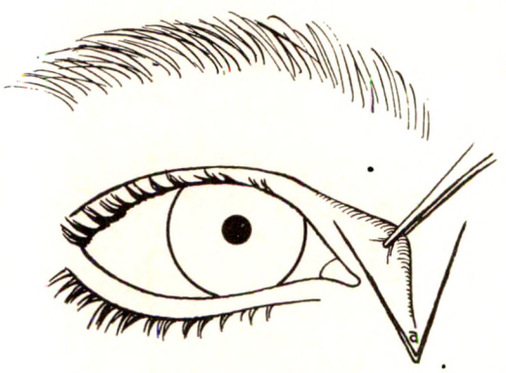

Fig. 1 (Fox). The epicanthal fold is raised and the base on each side incised, the lines meeting below at a point to form flap a.

From the Eye Service, New York University School of Medicine, and Bellevue Hospital.
Reprint requests to Sidney A. Fox, M.D., 11 East 90th Street, New York, New York 10028.

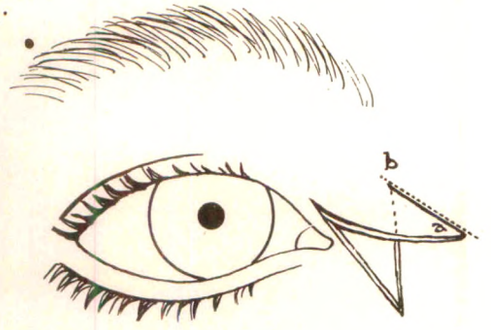

Fig. 2 (Fox). Flap a is dissected up and rotated medially. An incision is made along the upper border of flap and thus creating flap b.

This forms a second flap with angle-B at the apex (Fig. 2).

This second flap is mobilized and rotated down (Fig. 3); the two flaps are thus transposed. They are pulled firmly into position, the needles biting into the subjacent muscle tissue to prevent retraction, and sutured (Fig. 4).

## Discussion

Many of the procedures for epicanthus now in use require painstaking measurements and marking out of lines and angles before surgery. The Blair[1] and Mustardé[2] techniques are cases in point. The distinctive feature of this flap-transposition technique is that the size and shape of the flaps depend on the proportions of each individual epicanthus and not on preconceived diagrams, sometimes quite complicated, to which the epicanthus must be fitted in procrustean fashion. No preoperative planning or measurements are required. The surgery is simple, consisting only of three incisions, hence scarring is minimal and healing rapid.

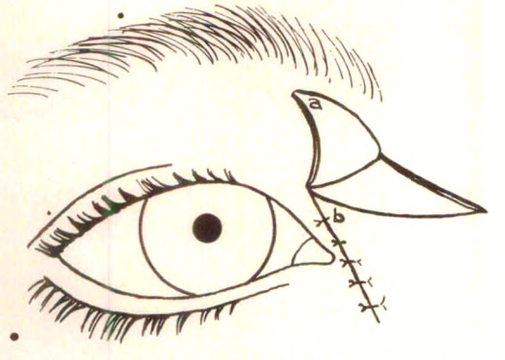

Fig. 3 (Fox). Flap b is dissected up, rotated downward and sutured medially.

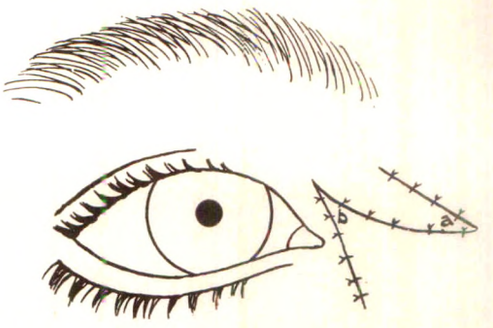

Fig. 4 (Fox). Flap a is then sutured into position.

In epicanthus inversus, the two preliminary incisions meet at an apex *above* the epicanthal fold with the rest of the surgery carried out as described.

# FRENCH-EYE PIGTAIL PROBE FOR LACRIMAL CANALICULUS REPAIR

Matthew C. Kartch, M.D.
*Wayne, New Jersey*

Since 1969, several colleagues and I have been using a modified pigtail probe in the repair of the single laceration through a lacrimal canaliculus. The modification consists of tips containing a tiny "French" eye, with all edges rounded (Fig. 1). This modification avoids the problems of the "crochet hook" tips of the Worst[1] instrument, and the difficulties of threading the tiny eye in the Vincent instrument. The French eye also makes it possible both to push and pull doubled suture material. In a diagnostic situation, the

## MODIFICATION OF THE DOUBLE OCCLUDER

Ferris F. Ketcham, M.D.

*Seattle, Washington*

A double occluder was modified so as to provide greater efficiency in eye examinations.

Fig. 1 (Ketcham). Photograph of the modified occluder.

The instrument measures nine inches in length which provides good balance. The occluder and Maddox rod each measure 2⅛ inches in diameter. All markings are printed on both sides of the instruments (Figure 1).

Adjacent to the Maddox rod is a white strip identifying the angle formed by the streak. The examiner may recognize readily whether the Maddox rod image is vertical or horizontal.

The pupillary diameters rulers read from left to right, regardless of the side used. A 1 mm pinhole is useful for evaluating visual acuity. The pinhole is located far enough from the occluder that it becomes quite obvious if the patient tries to use the pinhole to obtain better vision.

Accommodation lines, modified from the Lebensohn near vision charts, are provided on each side of the occluder. Manufacturing problems made it impractical to duplicate the original.

### Summary

This instrument measures nine inches in length with the occluder and Maddox rod 2⅛ inches in diameter. All markings are printed on each side of the instrument. Adjacent to the Maddox rod is a white strip indicating its angle. A pupillary diameter rule, a pinhole, and accommodation lines are provided.

# A TREPHINE FOR PRIMARY CORNEAL TRANSPLANT IN REPAIR OF CORNEAL LACERATION

ROBERT A. MOSES, M.D.
*St. Louis, Missouri*

AND

OLLE HOLM, M.D.
*Lund, Sweden*

Corneal lacerations crossing the optical zone are conventionally repaired by suture and allowed to scar. Later, transplantation of the scarred cornea may be performed. In many of these cases it would be desirable to perform the transplant as part of the initial repair procedure.

One way of supporting the lacerated cornea and of avoiding damage to the lens during trephination would be to insert some kind of protective plate through a limbal incision. This principal has been proposed for routine corneal transplant,[1-3] but it would seem highly undesirable to make a limbal incision in the presence of radial wounds.

Pittar[4] describes a corneal transplant punch in which the lower jaw resembles a button on a rod. The button is passed through a linear corneal incision into the anterior chamber and drawn upward through the bore of the upper cylindrical punch jaw. The present instrument* is an extension of Pittar's device.

The instrument consists of three parts, a lower clamp jaw, an upper clamp jaw, and a trephine:

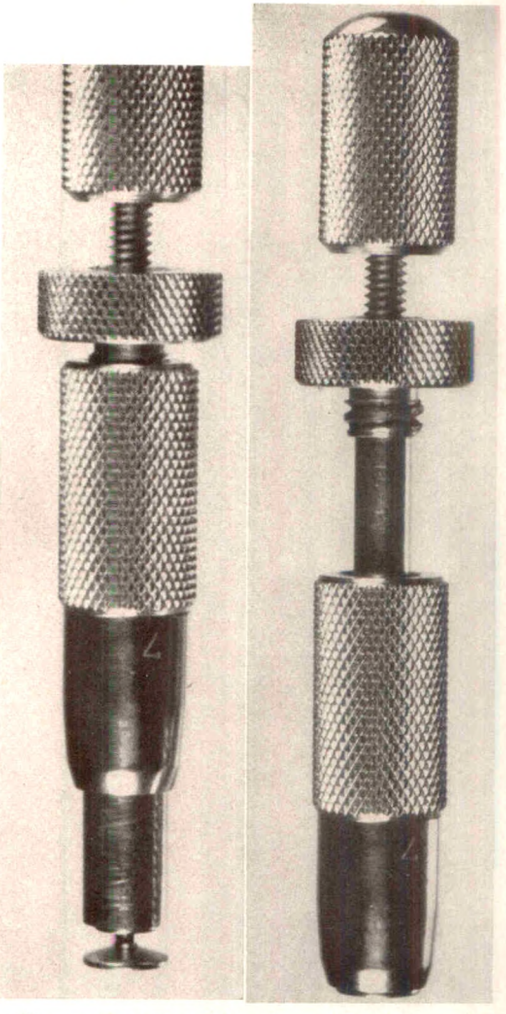

Fig. 1 (Moses and Holm). Left: Trephine for corneal transplant with clamp jaws open and trephine raised. Right: Trephine released.

The lower clamp jaw is mounted on a stem and can be inserted into the anterior chamber through the corneal laceration in a manner similar to passing a button through a buttonhole.

The upper clamp jaw is brought toward the lower jaw by turning the upper knurled knob clockwise, until the cornea is securely clamped between the jaws.

The trephine is held in a raised position by screw threads during the clamping procedure. It is freed by clockwise twisting until it slides freely along the shaft of the upper

From the Department of Ophthalmology, Washington University School of Medicine, St. Louis, Missouri (Dr. Moses), and the Department of Ophthalmology, University Eye Clinic, Lund, Sweden (Dr. Holm). This study was supported in part by Public Health Service Grant EY-00256 from the National Eye Institute.

Reprint requests to R. A. Moses, M.D., Department of Ophthalmology, Washington University School of Medicine, 660 South Euclid, St. Louis, Missouri 63110.

* The instrument was made to our specifications by the Storz Surgical Instrument Company, St. Louis, Missouri.

clamp jaw. A stop prevents the trephine edge from descending below the lower edge of the lower clamp jaw.

Figure 1 shows the instrument (left) with the clamp jaws open and the trephine blade raised, and (right) with the trephine released and down as far as it can go.

The trephine blade may easily be removed from the clamping assembly and attached to a simple handle for cutting the donor button.

## Summary

A trephine for primary transplant in corneal laceration incorporates a clamp to hold the corneal fragments in place and a stop to prevent the trephine blade from striking the lens.

## Ophthalmic miniature

The Captain is walking his quarter deck,
With a troubled eye and a bended neck;
One eye is down through the hatchway cast,
The other turns up at the truck on the mast,
Yet none of the crew may venture to hint
"Our skipper hath gotten a sinister squint!"

Thomas Ingoldsby
*Ingoldsby Legends,* 1840

# MEETINGS, CONFERENCES, SYMPOSIA

EDITED BY THOMAS CHALKLEY, M.D.

## LENS SYMPOSIUM AT UTRECHT

More than 60 investigators actively involved in lens and cataract research met in Utrecht, The Netherlands, from August 23-26, 1971. The participants included anatomists, embryologists, protein chemists, ophthalmologists, and immunologists. The main subjects discussed were: (1) genetic transmission of RNA information for lens protein synthesis, (2) biochemical studies on protein structure and lens metabolism, and (3) embryologic differentiation and lens induction in vitro.

In the lens, the genetic code is transmitted from nuclear DNA to RNA during the process of cell to fiber differentiation following mitosis. Bell (Boston, U.S.A.) described a new type of lens DNA: cytoplasmic (also named metabolic or information DNA). This second type of DNA may provide another avenue for transmitting genetic information, or it may regulate protein or cell synthetic processes at a later stage in the life of the lens, and thus be responsible for cataracts developing throughout many years such as those of the senile type. Nuclear DNA and cytoplasmic DNA can be differentiated by inhibitors such as hydroxyurea, FDU and cytosine arabinoside.

The normal chemical structure of the lens proteins is of great significance for interpretation of possible molecular alterations resulting in cataracts. Electron micrographs of non-polysomal lens protein chains and filaments broken by 8 M urea, trypsin, and pronase were shown by Maisel (Detroit, U.S.A.). These chains of heteropolymers may correspond to the various subunits demonstrated chemically by Bloemendal and associates (Nijmegen, The Netherlands), Delcour and Papaconstantinou (Oak Ridge, U.S.A.), Li and Spector (New York, U.S.A.), and Bours (Utrecht, The Netherlands). The sequential analysis of large polypeptide chains of alpha-crystallin was accomplished by Croft (Oxford, England). This work is an important step in elucidating the secondary and tertiary structure of the lens proteins. The techniques are similar to those used for sequential analysis of insulin, hemoglobin, ribonuclease, etc. A sulfhydryl dependent binding of cortisol to lens proteins, mainly beta-crystallins was found by Ono and associates (Japan), and may point to additional pathogenetic mechanisms for steroid induced cataracts.

The areas of lens metabolism and transport of electrolytes were well covered. Changes in endogenous glycolytic and Krebs cycle intermediates were quantitated during lens exogenous energy deprivation by Cotlier (Chicago, U.S.A.) and Trayhern and van Heyningen (Oxford, England). Effects of increased intraocular pressure on lens metabolism were described by Hockwin (Munich, Germany). These alterations may result in the lens changes occasionally associated with acute increases of intraocular pressure. Reddy (Detroit, U.S.A.) determined protein-bound lens glutathione by a highly specific method. Discussion of these and other presentations was greatly enhanced by the participation of two pioneers in eye biochemistry: Zacharias Dische and Everett V. Kinsey.

Problems of embryonic lens induction were analyzed through genetic microphthalmia in mice by Campbell and associates (Edinburgh, Scotland) and congenital mouse aphakia by Zwaan (Boston, U.S.A.). A primitive lens develops from chick lens placodes cultured in vitro with the remaining optic vesicle even if separated by millipore filter or agar. The inducing factors diffuse through filters with pores of 20 nm or larger and the induction can be abolished by optic vesicle pretreatment with actinomycin D as shown by Jaaskelaneu (Helsinki, Finland)

and van der Starre (Utrecht, The Netherlands). The nature of the diffusable factor, probably a polypeptide, a glycosaminoglycan, or an enzyme, has not been determined yet.

Numerous papers on lens differentiation and regeneration were presented. Answers to the following questions were sought: (1) the regulatory mechanisms for lens mitosis in the epithelium, secondary migration and lens fiber formation; (2) genetic control and initiation of crystallin synthesis by lens fibers; (3) chemical factors in lens regeneration from iris of lentectomized salamanders. An outstanding 10-year review of his work, by Yamada (Oak Ridge, U.S.A.), indicates two phases occur in the regeneration of the newt lens: (1) dedifferentiation and (2) redifferentiation. Agarwal and associates (India) found more active rabbit lens regenerations after extracapsular extractions in eyes receiving fetal eyelid implants. These results are in contrast with other reports on rabbit lens regeneration. Cytological changes occurring after lens rotation in embyros were analyzed in detail by Génis-Galvez (Granada, Spain).

The social functions of the meeting were delightful, including a reception by Prof. Dr. F. van der Blij, Rector Magnificus of the State University of Utrecht. The pictures of Donders and Snelln on the walls of the University were brought to the attention of the Symposium participants, as a reminder of a long and distinguished tradition of eye research at this old Dutch university. Credit for the mammoth task of organizing the symposium should be given to Prof. of Anatomy and the Chairman of the meeting, Professor of Anatomy Dr. van Doorenmaalen, his committee and his able assistants, Dr. J. Bours and Mr. S. A. van Maarsen.

Edward Cotlier

## SECOND CONFERENCE OF INTERNATIONAL SOCIETY OF GEOGRAPHICAL OPHTHALMOLOGY AND JERUSALEM SEMINAR

The Second Conference of the International Society of Geographical Ophthalmology and the Jerusalem Seminar on the Prevention of Blindness were held in Israel from August 23 to 27, 1971. Professors, clinicians, basic research scientists, nutritionists, physiologists and administrators from five continents representing 21 countries convened for the purpose of preventing blindness in both developed and developing countries of the world.

Among the internationally renowned essayists were Profs. Jules François and J. Charamis, President and Past-President of the International Council of Ophthalmology; Gunnar von Bahr, President, International Association for Prevention of Blindness; B. G. Bietti, President of the International League Against Trachoma; M. L. Tarizzo and Dr. Nizetic of the World Health Organization; Drs. H. A. P. C. Oomen, Fred Rodger, and Ida Mann, ophthalmic consultants to WHO; Profs. A. Nakajima and S. Mishima of Japan; Dr. Donald Lowe of Australia; Drs. V. Rambo, N. Chatterjee, G. Venkataswamy of India; Dr. N. E. Christy of Pakistan; Dr. G. G. Bisley of Kenya; Dr. Maurice Luntz of S. Africa; Dr. Elizabeth Cass of Canada; Dr. S. Delthil of France; Dr. V. Clemmeson of Denmark; Profs. A. Pirie and J. Dobree, and Drs. D. P. Choyce, J. Hudson, P. D. Trevor-Roper, and K. Wybar of Great Britain; W. Leydhecker of Germany; Drs. J. ten Doesschate and J. Schappert-Kimmijser of the Netherlands; Drs. A. Edward Maumenee, Gunter K. von Noorden, and Maurice Langham of Baltimore; Dr. Carl Kupfer, Head of the National Eye Institute, and many other leaders of ophthalmology.

The prevalence, geographic and ethnic distribution of eye diseases from Sweden, Japan, India, Israel, Denmark, Nigeria, Italy,

and the United Kingdom was the principal theme of one of the symposia.

Prevention of blindness in developing and developed countries was the principal subject at others. Under the first heading, keratomalacia, corneal opacification, onchocerciasis, and trachoma were discussed. Congenital and heredity eye diseases, diabetic retinopathy, herpes cornea, retinal detachment, glaucoma, cataract, and amblyopia were included.

Mr. John Wilson, C.B.E., Chairman of the Royal Commonwealth Society for the Blind, received a standing ovation for his inspiring report on the international scope of the prevention of blindness, spearheaded by the World Council for the Welfare of the Blind.

Social activities of the Congress included trips to the Walled City of Jerusalem, Bethlehem, the Dead Sea, a sound and light production "A Stone in David's Tower," a visit to kibbutz and other areas of historic interest. Receptions were held by the municipality of Jerusalem and the Israel Academy of Sciences and Humanities. A festive dinner was given at the Knesset building in Jerusalem honoring the Minister of Health.

Dr. and Mrs. I. C. Michaelson's kindness, hospitality, and friendship were paramount factors that contributed to the success of the seminar.

At the conclusion of the seminar the following report was drafted, approved and adopted:

1. CONTINUITY

(a) The Jerusalem seminar should be the first in a series of international conferences on the prevention of blindness. It is possible that the success of this conference was related to the fact that it was convened for a specific purpose and attracted scientists of various disciplines. It appears impractical for financial reasons to convene another international conference on this basis in the foreseeable future and it was accordingly agreed that an international prevention of blindness conference should be held in association with the International Congress of Ophthalmology in Paris in 1974.

(b) In the intervening years, regional conferences should be held in Africa, in Asia, and in Central and South America. The object should not be to discuss prevention in global, abstract terms, but to seek to formulate regional plans of action, indicating national and regional resources, the readiness of governments to take official initiatives, and the extent of overseas aid which might be available. To be effective, these regional conferences should be preceded by action at the national level.

(c) A study group on keratomalacia was formed during the Seminar. Other study groups should be formed, where required, as channels of communication in subjects in which there is a lively movement of professional interest and the possibility of effective action. Such groups might include onchocerciasis (the initiative being taken by F. C. Rodger); trachoma (B. G. Bietti); personnel (I. C. Michaelson). These groups would maintain contact by correspondence and would make their views known to WHO and the non-governmental agencies concerned.

2. INTERCONFERENCE ACTION

An interconference action committee should be formed. The World Prevention of Blindness committee which was formed some years ago as an executive link between the International Association for the Prevention of Blindness, the World Council for the Welfare of the Blind, and the World Health Organization, should be revived and strengthened for this purpose. It would have the additional function of initiating arrangements for future conferences and of assisting with the implementation of the proposals of the conference, particularly for the stimulation of national prevention of blindness committees. This committee, after the initial meeting which was held during the seminar, should continue its work by correspondence and through meetings, where practicable. The Royal Commonwealth Society for the

Blind should be invited to undertake the committee's administration. Expanding the former membership of the committee, it was agreed that the composition should be as follows: In addition to Chairman I. C. Michaelson, there will be four representatives of the International Association for the Prevention of Blindness and the International Congress of Ophthalmology. These are J. François, A. E. Maumenee, G. von Bahr, and John Holmes. There will also be three representatives of the World Council for the Welfare of the Blind, and these are John Wilson, Eric Boulter, and another yet to be nominated. This committee should remain in regular contact with WHO, UNICEF, and any other intergovernmental agency concerned. WHO should be requested to appoint an advisor and liaison, who would be invited to attend, as an observer, any meetings of the committee which might be convened and would receive all circulated correspondence.

### 3. National programs

It was recommended that the attention of national governments be called to the importance of the problem of blindness and loss of vision. Especially in the case of developing countries it may often be necessary to obtain a more complete and accurate information on the prevalence of ocular pathology in order to establish appropriate priorities. Whenever necessary and justified, requests for assistance could be addressed to WHO, either for carrying out this preliminary investigation or for setting up adequate facilities for coping with existing problems.

Depending on local circumstances, and with the aid of WHO and other agencies, teams could be organized which would attack the problem from a multiphase approach, beginning with the education of citizens in hygiene, dietary requirements, and when and where to seek medical assistance. An ophthalmologist should be recruited who would work in close collaboration with existing health services to develop a comprehensive approach to the local problems. He would practice clinical ophthalmology and the necessary facilities and equipment should be supplied to ensure that this care would be of high standard.

### 4. Publicity

There should be issued to the world's press, radio, and other publicity media, a brief statement on the effects of preventable blindness throughout the world and on the need for public awareness of the task and of the opportunity. This statement should be published at the conclusion of this seminar through Israeli media.

### 5. Publication

The main papers presented at this conference should be published, together with an introduction by I. C. Michaelson and A. E. Maumenee, summarizing proposals and ideas —e.g., the need for an interdisciplinary approach to the prevention of blindness, for the effective training and deployment of paramedical staff and public health ophthalmologists, the priority concern expressed over keratomalacia. The major emphasis was placed on prevention and research and it was the conclusion that this was not inconsistent with mass campaigns to treat and cure needless blindness in developing countries.

### 6. Register of ophthalmologists

The secretary general of the International Association for the Prevention of Blindness should establish a register of ophthalmologists and allied scientific personnel prepared to consider assignment in the developing countries. WHO and the nongovernmental organizations concerned should have access to this register.

William John Holmes
*Honolulu, Hawaii*

## BASCOM PALMER EYE INSTITUTE SEVENTH ANNUAL RESIDENTS' DAY

The Bascom Palmer Eye Institute held its seventh annual Residents' Day on June 4 and 5, 1971. The full-time faculty, residents, and fellows presented a total of 35 papers to a large gathering of alumni and local ophthalmologists.

Guy O'Grady and Frank Williams presented fundus photographic and fluorescein angiographic studies on the evolution of temporal retinal changes in premature infants with retrolental fibroplasia. Michael Rosenberg reviewed the fluorescein angiograms of two patients with secondary retinal detachments associated with the hypertension of toxemia of pregnancy. Follow-up angiography revealed changes in the pigment epithelium and choroid. Electrophysiologic studies of Stargardt's disease were reported by Russell Harner, and Robert Clark reported on the histories and follow-up examinations of 10 patients with posterior multifocal placoid pigment epitheliopathy. He reaffirmed the good visual prognosis in this disease despite marked pigment derangement. Central retinal vein occlusions were reviewed by William East, who attempted to relate anticoagulant therapy and good visual prognosis.

Ken Wallace reviewed eight patients with melanocytoma of the optic nerve, five of whom were followed for several years. He confirmed the benign nature of this tumor in respect to visual acuity and visual fields. Henry Clayman reported two interesting cases of retinal pigment epithelial derangement following papilledema in children with acute leukemia who had central nervous system involvement. The histologic findings were correlated with the clinical photographs. Both children had received multiple systemic and intrathecal antimetabolites prior to their deaths. Charles Wilkinson noted a 12% incidence of preretinal membrane formation in the macula after successful scleral buckles on 297 detached retinas. Possible contributing factors were discussed. Donald Gass presented four cases of bullous non-rhegmatogenous retinal detachment which appeared to be caused by idiopathic central serous choroidopathy. Fluorescein angiographic studies were reviewed and the good visual prognosis without treatment was emphasized. Carmine Bedotto discussed the design, surgical application, and radiation safeguards referable to the cobalt-60 applicators which are of growing interest in the therapy of ocular tumors.

Another group of papers dealt with basic research of the retina and vitreous. Helmut Buettner utilized autoradiographic techniques to study protein synthesis and turnover in normal, detached, and reattached owl monkey retinas. It appeared that the increased protein synthesis after reattachment correlated with the structural regeneration in the various retinal layers. The effect of collagenase and chymotrypsin on vitreous viscosity was studied by Randolph Martin. He found that concentrations high enough to affect vitreous viscosity in the owl monkey were also retinotoxic. Steven Charles recorded the early receptor potential in detached and reattached owl monkey retinas and found a slow disappearance after detachment and a gradual return to normal following reattachment. A model for the extracellular recording of the ERG, dark adaptation, and flicker fusion on transplanted photoreceptors of the fly (Muscea volitantes) was reported by Daniel Eichenbaum. He was able to record normal data from his transplanted photoreceptors. Finally, Jay Pollack and Duco Hamasaki recorded a reduced ERG and late receptor potential in light-deprived kittens. The recordings returned to normal after the kittens were exposed to ambient light conditions for eight weeks.

Charles Israel reviewed a series of biopsy specimens and compared the histologic diagnosis with the referring clinical impression. This study re-emphasized the need to biopsy eyelid lesions for accurate diagnosis. Wilson

Wallace presented a historical review of hydrophilic contact lenses and their current status in the United States. Beth Friedland, a Coral Gables high school student, isolated a non-lysozyme, low-molecular-weight, tear factor with 200 times the antibacterial activity of the lysozyme factor. J. Lawton Smith surveyed cases of interstitial keratitis, with emphasis on the serum FTA-ABS test. Three papers were devoted to infectious ocular problems. Richard Forster presented a follow-up on pimaricin-treated fungal corneal ulcers. Since 1968, when pimaricin was first used clinically, 19 of 21 Fusarium solani corneal ulcers have been successfully treated, with 15 patients achieving a visual acuity of 20/60 or better. Experimental bacterial endophthalmitis was easily produced in rabbits by David Tucker. The organism could be isolated by anterior chamber paracentesis after the onset of clinical endophthalmitis, and therefore this diagnostic procedure was recommended. Finally, Bobby Shewmake reviewed cases of orbital cellulitis and revealed the importance of para orbital sinus infection in these cases.

Gary Wallace reviewed 144 cases of surgically treated exotropia and correlated the type of surgery with the results. John Flynn discussed his findings on retinal rivalry in normal, anisometropic, amblyopic, and strabismic amblyopic patients. A method for utilizing random dot stereograms to study binocular vision, neural models, and retinal rivalry was proposed by Michael Hyson and T. Shipley.

The production of acute intracranial hypertension was followed by a rise in intraocular pressure after a short latent period, and Antonio Montalbo postulated several mechanisms for this occurrence. Joel Glaser discussed a 23-year-old woman with a depressed linear scalp lesion (en coup de sabre), optic neuritis, and ocular muscle palsies. These two findings have never been reported in association with facial hemiatrophy. Eight interesting cases of periodic alternating nystagmus with its differential diagnosis were presented by Dale Davis. And finally, Ronald Seeley reported three patients with hypoplasia of the optic nerve, two of whom had cecocentral scotomas and the third had a temporal hemianopia.

The fields of glaucoma and the lens were represented by three papers. Douglas Anderson and Ralph Kirsch presented material on the normal and glaucomatous optic cup. They feel that glaucomatous cupping may be recognized by recession of the entire anterior disk surface, especially superiorly and inferiorly, resulting in a vertically oval cup. Recent interest in trabecular surgery for congenital and medically uncontrollable open-angle glaucoma has resulted in the use of trabeculotomy for treating a small number of patients over the past year. Thomas Coulter reviewed some admittedly early but optimistic results. Joel Kramer and O. E. James continued the annual review of the intraocular lens implants which was begun in Miami several years ago.

Dr. Norton closed the meeting with a presentation of the characteristic retinal detachment that results when there is vitreous traction extending from a cataract wound to the vitreous base. A vitrectomy through the pars plana converts this situation from a problem detachment into one that is more conventionally aphakic.

Following the presentations on Friday, June 4, the alumni association held a business meeting at which new officers were elected, followed by the annual Residents' Day dinner at the Miami Springs Villas. The evening was concluded with remarks on the future of the Bascom Palmer Eye Institute and ophthalmology in Miami by Edward W. D. Norton

## THE SEMICENTENARY OF INSULIN

Frederick Grant Banting (1891-1941), a qualified orthopedic surgeon who received the Military Cross in World War I, returned to Canada to find private practice disappointing. He then secured an appointment in the Department of Physiology of the University of Toronto. While seeking a research project, he read an article by Moses Barron in November, 1920, which noted that after ligation of the pancreatic duct in dogs, the zymogenous acinar cells degenerated but not the islets of Langerhans. Actually, A. J. Carlson had demonstrated this in 1914, but, like Barron, he had not tried injecting an extract of the degenerated pancreas in dogs rendered diabetic by complete pancreatectomy. This Banting resolved to do. Though Professor Macleod knew that Zuelzer (1908) and others had found injections of pancreatic extracts to be very toxic, he granted Banting's request for 10 dogs and the use of the laboratory for two months. Charles H. Best, aged 22, who was interested in carbohydrate metabolism, was assigned to assist him. They began working on May 16, 1921, and under aseptic precautions they prepared a crude extract of the degen-

erated pancreas from their first dog. A small portion of the extract was injected intravenously in a depancreatized dog. The blood sugar fell from 200 to 100 mg/100 ml in two hours. They repeated these experiments until they achieved 10 successes. On Macleod's return from Scotland, he insisted on the continuation of their investigation until they accumulated 60 additional positive results.

On January 11, 1922, the first human patient was treated cautiously at the Toronto General Hospital. Best had found that an effective extract could be prepared from beef pancreas by alcohol extraction which dissolved the insulin and inhibited the digestive ferments. Macleod asked J. D. Collip of the University of Alberta to aid in its purification. Partial success was accomplished by fractional precipitation of the alcoholic extract. Further purification was later effected by isoelectric precipitation. In 1923, the Nobel prize was awarded to Banting and Macleod which was shared by them with Best and Collip.

The word "diabetes," meaning "to run through a siphon," originated with Aretaeus of Cappadocia (c. 81–138); the modifier "mellitus" was added by Cullen (1708–1890). In 1880, Heyl first noted diabetic lipemia retinalis. This appears when the fat content of the blood reaches 5%. Before insulin was available, its appearance signalled oncoming coma and a fatal outcome. Now, after a single injection of insulin, the retinal picture changes to normal in a few hours. In 1909, MacCallum enunciated the relationship of the islets of Langerhans to diabetes. In 1916, David Riesman described the soft eyeball in diabetic coma. In 1930, Houssay observed an improvement of diabetic symptoms in depancreatized animals after hypohysectomy.

Macleod recalled that a fellow Scotsman, Sharpey-Schaefer, used the word insulin in 1910 for the internal secretion of the pancreas, and he adopted the term. Insulin hydrochloride was followed by crystalline zinc insulin (1926), both rapid acting, with peak activity in two to four hours. Then came the long-acting protamine zinc insulin (1936), with its greatest effect at 12-24 hours, globin insulin (1942), NPH insulin (1946), and lente insulin (1950), all with intermediate activity. The usual regimen is a mixture of NPH and regular insulin in the indicated dosage before breakfast, and a small amount of NPH after supper. Analysis revealed that insulin is a protein with 11 amino acids and an essential S-S bond.

Experimental permanent diabetes can be effected surgically by complete pancreatectomy (Minkowski and von Mering, 1889), or by intravenous injection of alloxan, a derivative of uric acid (1943). After injection of 200 mg/kg in the ear vein of a rabbit, the beta cells of the islets of Langerhans disappear in six hours, but the alpha cells are not affected. After the injection, a transient hypoglycemia occurs, due to the liberation of insulin, followed by a permanent hyperglycemia. Cataracts are evident in four to six weeks, the opacities starting in the posterior subcapsular cortex, as in diabetes in man.

The vascular disorders incident to prolonged diabetes in man are now our greatest unresolved problem in the management of diabetes. Early and persistent diabetic control can only postpone the advent of retinopathy. Nettleship (1888) described proliferative diabetic retinopathy with neovascularization and noted that vision was usually lost within a few years. The prognosis has not changed. The vascular alterations, like the susceptibility to infection, are not a consequence of hyperglycemia but depend on biochemical changes not yet discovered.

In establishing the diagnosis of diabetes, a blood sample taken two hours after a regular meal may be more helpful than the fasting blood sugar. The former should not exceed 160 mg; the latter, 120 mg. In a glucose tolerance test, the patient takes 100 g glucose in water flavored with lemon juice, and the blood sample taken two hours later should be under 120 mg.

Thanks to insulin, eye operations on a dia-

betic patient are uneventful if the diabetes is so controlled that the patient is able to take a diet that is nutritionally adequate without developing hyperglycemia or glucosuria. The usual carbohydrate allowance must not be restricted. Preoperative resolution of any infection is imperative. On the day before surgery, liquids should be supplied freely, and food that is easily assimilated should be given within three hours of the operation. Since acidosis is more serious than glycosuria, liquid carbohydrates, such as diluted milk, orange juice, and gingerale, should be given three hours after surgery and allowed freely during the next 24 hours. At least 100 g of carbohydrate should be provided daily, giving enough insulin to insure utilization. After a long operation, such as that for retinal detachment, dextrose should be administered intravenously.

James E. Lebensohn

## A MEMENTO

On September 22, 1896, there appeared at the University Eye Clinic in Leipzig, Germany, an 18-year-old electrician by the name of Georg Sturm who had sustained a perforating injury to his previously normal right eye. He had been seen there previously, in 1891, for a left esotropia. An operation had been recommended, but the patient did not report for it. When seen in 1896, the left eye was found to be severely amblyopic, the vision being reduced to counting fingers at 6 m. The right eye had to be enucleated and the patient was discharged four days later. When he returned after three days, he stated that he saw double with his remaining eye and three weeks later the difficulty continued. On January 4, 1897, the vision had improved to between 6/60 and 6/36 at distance, and J-8 at 10 to 12 cm at near. Because of the confusion which it caused, the diplopia had become more annoying, especially in reading. The young assistant who saw the patient was puzzled and fascinated by the case and described him not only to his chief, Prof. Sattler, but also to the master of visual physiology, Prof. Hering, whose Physiologic Institute was next door to the Eye Clinic, and who performed a number of experiments with the patient.

The young assistant was Alfred Bielschowsky. The study of this case of monocular diplopia launched him on his life-long career in the field of neuromuscular anomalies of the eyes. With his extensive and sound physiologic background, acquired through Hering and through collaboration with F. B. Hofmann, then an assistant of Hering's, and his intensive and continued clinical work, Bielschowsky became the outstanding expert in strabismus in continental Europe during the first third of our century. With his move to the United States in 1935, he extended his salutary strabismus studies among the American ophthalmologists who had always had a special interest in the field.

Bielschowsky was born 100 years ago this month on December 11, 1871. It is meet and just that ophthalmologists here and the world over should be reminded of this centenary.

Hermann B. Burian

## CORRESPONDENCE

### APHAKIC DETACHMENT

Editor,

American Journal of Ophthalmology:

Current remarks in papers and advertisements give the impression that chymotrypsin in cataract extraction is used only at the surgeon's discretion and then in patients under 60 years of age.

From the cataract surgeon's point of view, estimates of detachment in intracapsular cases vary only a little. In 1964, Barraquer[1] recorded 3.7% without chymotrypsin, and 2.9% with chymotrypsin, while in 1967, Pasino[2] recorded 2.6% with chymotrypsin. Such small percentages can reasonably be considered inevitable, but seen from a retinal detachment surgeon's point of view, a

very different picture emerges. In 1964, Norton[3] found that 30% of his detachments were aphakic. The realization that such a small cataract percentage can mean such a large detachment percentage shows that any small improvement in the cataract series can result in a large reduction in the total number of aphakic detachments.

So it may be of interest that in a recent series of 1200 intracapsular extractions, Kelly[4] (1969), with the intention of preventing aphakic detachment, reduced the rate to 0.2% by the use of a combination of well-known procedures (including zonulysis in all cases).

Therefore it is worth considering once again what factors can be modified in intracapsular extraction so as to reduce the small incidence in the cataract series. It is accepted that for highly myopic cases, or for those that have previously had an unexplained aphakic detachment, extracapsular extraction is performed; these circumstances formed some of the reasons for developing the ultrasonic method of Kelman[5] 1967.

Sachsenweger[6] presented two series in 1966, one with zonulysis and one without, in which there was no difference in the incidence. In his opinion the main causes of aphakic detachment were loss of vitreous with its sequelae and a leaking wound, and to a lesser degree a predisposition to detachment in myopic degeneration and in old trauma. By using a beveled section and seven corneal sutures in the superficial part of the section, and suitable anesthesia, we can remove these main causes. Then if a detachment does not occur immediately, any predisposition can be eliminated to some extent by light coagulation, laser and cryotherapy, as soon as the predisposed areas can be seen postoperatively.

Schepens,[7] however, had already warned (1951) that small dialyses and breaks closely related to the meridonal folds over the teeth of the ora of the normal retina can also be responsible for detachment. This trauma might be caused by a section that distorts the eye in the same area where the tears arise. A blunt Graefe knife could act in this way. Therefore, not only should the distortion be avoided, but the lens should be extracted in such a way that there is no excessive pull on the zonule, so that no holes are torn in the teeth by direct or indirect pull. Since the zonule can be strong, even at 85 to 90 years of age, its strength should presumably be reduced in all cases.

For the extraction with the help of zonulysis the erisophake is possibly the most gentle method, but any method carries risk.

Quite the most dangerous method a cryoextraction when used without zonulysis, because of the immense strength of the cryoattachment to the lens, which is said to be 200 time as strong as that of the capsule forceps. This can lead to an easy extraction in which the resistance of the zonule is not fully appreciated. This appreciation is further diminished because one has to consider other problems at the same time, such as avoidance of attachment to the iris. Damage to the teeth of the ora, due to the omission of zonulysis, may begin to show an effect over a wide geographical area in producing a higher percentage of aphakic detachments, but this increase would not be appreciated until either a detachment or cataract surgeon published a series.

May I therefore make a plea for the use of zonulysis in all uncomplicated cases of intracapsular extraction.

T. Stuart-Black Kelly

## BOOK REVIEWS

THE VISUAL FIELDS. A TEXTBOOK AND ATLAS OF CLINICAL PERIMETRY, 3rd ed. By David O. Harrington. St. Louis, C. V. Mosby, 1971. Clothbound, 394 pages, table of contents, bibliography, index, 341 black and white figures, and nine color figures. $21.50

This textbook should be on hand in every opthalmic office, for it is a complete exposition of the techniques of plotting the visual fields on the various instruments designed for this purpose and of their interpretation. Part I includes six chapters which detail the anatomy and vascular supply of the visual pathways, the characteristics of the normal visual field, and the methods of testing the visual fields. Part II is comprised of 10 chapters. This part is devoted to a beautifully illustrated description of the abnormalities encountered in disease processes in each portion of the visual system.

The book is written in a clear, well-organized fashion which should fulfill the needs of every ophthalmologist and his visual field technician.

In general, this third edition is similar to thet second, except that the headings of the various sections are more clearly printed, the illustrations are more closely associated with the text, and in each chapter some pertinent paragraphs have been added. There have been relatively few deletions. Also, chapters 10 and 11 on retinal lesions and glaucoma, respectively, have been rewritten and revised. The index of this edition has been vastly improved. Forty-two recent references have been added to the extensive bibliography.

The author does not mention the theory of macular sparing in occipital lobe lesions which ascribes this phenomenon to overlapping vascular supplies from the calcarine branch of the posterior cerebral artery and the posterior cortical branches of the middle cerebral artery, a theory which seems to the reviewer the most attractive of any so far advanced. In the reviewer's opinion, to accurately depict the visual defects and to most efficaciously localize the site of the responsible lesion, the following isopters should be shown: (1) that of the smallest target visible to the patient, (2) that of the largest target that shows a defect, and (3) that of the smallest target, if any, that produces a normal visual field. Many of the drawings would benefit from additional isopters, although presumably some were deliberately omitted to emphasize the pertinent findings. Finally, figure 15-4, although said to demonstrate right homonymous upper quadrant anopsia due to a ruptured aneurysm of the anterior communicating artery, is depicted only with tiny targets on the tangent screen and with flicker fusion frequency fields in the same area. The peripheral isopters of these fields are necessary for localizing the affected portion of the visual pathway; the defects as shown could well be ascribed to visual cortex involvement in the left occipital lobe.

However, these are minor matters which detract very little from the excellence of this book.

Robert W. Hollenhorst

STRABISMUS - DIAGNOSTIK - SCHIELFORMEN THERAPIE. By J. Lang. Bern, Switzerland, Verlag Hans Huber, 1971. Paperback, 206 pages, table of contents, references, index, 58 black and white figures. Fr. 28

This small volume summarizes well the author's views on certain aspects of the neuromuscular anomalies of the eyes—that is, his views on small-angle strabismus (what he has called microtropia), congenital stra-

bismus, and strabismus of late onset (termed by Lang, normosensory strabismus).

It contains nothing new for the expert in the field, who may well challenge some of the author's statements, presented frequently as his beliefs, without supporting evidence. It is questionable to what extent the book is useful to the novice or the practicing ophthalmologist, to whom it is primarily addressed. The overview of the neuromuscular anomalies is very cursory. This also applies especially to the discussion of the normal sensory and motor cooperation of the eyes. In part, this is due to the extremely concise way in which the book is written. Thus, the statement (p. 24) that the horopter is "a purely imaginary plane in space in the center of which is the fixated object" is followed immediately by the sentence: "Only objects lying on the horopter surface stimulate corresponding retinal points." The idea that object points stimulating retinal elements can be on a purely imaginary surface must surely be confusing to someone who meets these concepts for the first time and tries to understand them. From a didactic point of view, the book has certain other shortcomings. For example, the Maddox Wing test and the Livingston gauge are recommended, but nowhere in the book are these tests described.

One of the attractive features of the book is the author's general attitude toward therapy. He warns against the uncritical application of a given type of treatment to all forms of strabismus without distinction, and against being overly impressed by unwarranted success claims for new or newly resurrected therapeutic measures.

The index is inadequate, but the book is pleasing typographically and its format and flexible binding handle well.

Hermann M. Burian

---

MANUAL OF CLINICAL MYCOLOGY, 3rd ed. By Norman F. Conant, David Tillerson Smith, Roger Denio Baker, and Jasper Lamar Callaway. Philadelphia, W. B. Saunders, 1971. Clothbound, 755 pages; table of contents, index, 299 black and white figures. $13.50

This is the third edition of one of the three standard textbooks of clinical mycology written in English. Unfortunately, none of the available textbooks cover mycotic eye disease with any attempt at completeness. This latest edition is no exception. There are only seven pages devoted to mycotic keratitis and little emphasis has been placed on the opportunistic infections. These "diseases of medical progress" are associated with the use of steroids, immunosuppresives, and radiation therapy. Further, the authors might have added several more species to their list of agents which cause ocular infection, such as Allescheria and Cryptococcus. A discussion of the current thinking concerning the role of fungi in chorioretinitis would surely have been of interest.

This latest edition has been updated to include the newer therapeutic agents. Amphotericin B and nystatin are discussed as eye medications, but no mention is made of their extreme toxicity to the cornea. A discussion of the new agent, pimaricin, is lacking in this volume.

In spite of the text's shortcomings concerning ocular mycology, it remains one of the leading sources of information on the classical diseases of medical mycology. The writing is generally good and the material factual. The references are adequate and chapter 31 on contaminants contains absolutely essential information for every mycologist. This chapter is coupled with a fine methods appendix which make this manual indispensable to the laboratory worker. This latest edition of a classical textbook on medical mycology can be of great value to the practicing generalist.

---

A Synopsis of Ophthalmology, 4th ed. By J. L. C. Martin-Doyle. Baltimore, William and Wilkins, 1971. Clothbound, 280 pages, table of contents, index, five black and white figures. $9.75

This is one of a series of synopses of medical specialties written and printed in Great Britain and distributed in the United States. The synopsis is aimed at the senior medical student, the busy general practitioner and the ophthalmologist in training, as an examination preparation manual. The author's primary sources are textbooks of ophthalmology written by Sorsby and Duke-Elder, and Wolf's *Pathology of the Eye*.

One may, with the above information, readily predict the outcome: a virtual dictionary of ophthalmology which is remarkably inclusive and extremely well organized Some of the material is outdated, and controversial points of management are often not presented. References are sparse at best, but the index is quite thorough and useful. The book would fulfill the author's purposes quite adequately except for the extraordinary paucity of illustrations. I would therefore recommend to medical students or busy practitioners one of the standard ophthalmology textbooks which are more appropriately illustrated and available at a cost within a few dollars of this text.

Paul E. Romano

---

Spirochetes in Body Fluids and Tissues. Edited by James N. Miller. Springfield, Illinois, Charles C Thomas, 1971. Paperback, 72 pages, table of contents, index, 17 black and white figures. $5.50

This little monograph is an outgrowth of a seminar held at the Venereal Disease Research Laboratory in Atlanta, Georgia, in 1969. A committee was appointed, drawn from workers in the field of experimental syphilis and other treponematoses, to suggest standardized methods and reagents. The committee consists of Dr. Miller, the editor, and Virginia H. Falcone, Bruce Golden, Charles W. Israel, U. S. G. Kuhn III, and Robert M. Smibert. The book gives recommended procedures for animal inoculations, serologic tests on blood, spinal fluid, and aqueous humor, and technical details are given concerning paracentesis, lumbar puncture, and staining methods for treponemes in tissues. An appendix lists additional references, commercial companies, and reference laboratories. The manual is concise and well done. It will be of little immediate help to the practicing ophthalmologist for it is really not aimed at him. It will be of very great help to the laboratory investigator in experimental treponematoses.

J. Lawton Smith

---

Traitement Chirurgical des Affections Oculaires. By L. Guillaumat, L. Paufique, and R. De Saint-Martin. Paris, Editions Doin, 1971. Clothbound, 580 pages, alphabetical index, table of contents, 115 B/W figures. 188.00 F

This first of two compact volumes presents a comprehensive review of ophthalmic surgery. In contrast to most American texts dealing with surgery, there are relatively few illustrations. This has allowed the authors, who are the Deans of French Ophthalmology, to devote more space to discussion of operative indications, procedures and complications.

An important section is devoted to anesthesia for ocular surgery followed by a consideration of preoperative care to enhance surgery and emergency operative procedures.

In systematic fashion the authors deal with the surgery of various types of cataracts, glaucomas, traumas, foreign bodies, and chemical and radiation burns to the anterior segments.

It is interesting to note that the authors

list as a routine technique the closure of a cataract incision by a continuous, locked, virgin silk suture. Apparently this technique is well accepted in Europe while it has only been recently described in the Western hemisphere. Also reported as standard procedures are various operations involving the canal of Schlemm and the trabeculum in the treatment of refractory glaucoma.

This volume is of especial merit because of its discursive and authoritative approach to common surgical problems.

Marcel Frenkel

MARKETS FOR THE MEDICAL AUTHOR. John G. Deaton. St. Louis, Warren H. Green, Inc., 1971. Clothbound, 92 pages, table of contents, index. $10.00

A listing of some 336 medical and scientific journals is divided into 25 specialties. Eight journals are listed in ophthalmology; in addition there are listings of university presses, medical book publishers, and paramedical journals, house organs, and medical newspapers. The little volume provides a useful source of addresses.

Frank W. Newell

OPHTHALMIC MINIATURE

Of the poets who used copious colour images, Shelley and Keats were to the fore, Shelley generally using straightforward and commonplace colour names (as yellow, blue, purple, green, etc.), whereas Keats preferred to relate his colours to other (usually tactile) images (as damask, verdurous, Tyrian, rubious, argent), a tendency still more evident with other colourists such as Francis Thompson and Gerard Hopkins.

P. Trevor-Roper

*The World Through Blunted Sight*

New York, Bobbs-Merrill, 1970

# ABSTRACT DEPARTMENT

EDITED BY DAVID SHOCH, M.D.

## ACTA OPHTHALMOLOGICA

PUPILLARY FLOW IN THE WATER PROVOCATION TEST. Wiebert, O. (University Eye Clinic, Lund, Sweden), Acta Ophth. 49: 317-327, 1971.

The author measured the flow of aqueous into the anterior chamber by examination of the bubble of aqueous which appears over the edge of the pupil in an aqueous tinged with fluorescein. The bubbles were photographed and a calculation of flow made from them. The author found that the water provocative test increases the pupillary flow by about 50%. This increased flow remains for at least 90 minutes, a time when the intraocular pressure is already normalized. (4 figures, 5 tables, 8 references)—David Shoch

OCCLUSION OF THE CENTRAL RETINAL ARTERY AND RETINAL BRANCH ARTERIOLES. Karjalainen, K. (University of Helsinki, Finland), Acta Ophth. Suppl. 109:9-96, 1971.

The author was able to follow 91 patients after central retinal artery or branch artery occlusion. After occlusion of the central retinal artery, 58% of the eyes were blind. However, fluorescein angiography revealed that recanalization of the retinal arteries occurred in all cases. The incidence of open angle glaucoma in patients with retinal arterial occlusion was 5%. Therefore, the author feels that glaucoma is not of etiologic significance in the development of retinal arterial occlusion. On the other hand, the incidence of neovascular glaucoma after occlusion was 2%. None of these patients exhibited open angle glaucoma of the opposite eye. Of the nine patients with neovascular glaucoma, three had diabetes and one had an aneurysm of the ipsilateral internal carotid artery. (38 figures, 18 tables, 109 references)—David Shoch

## ANAESTHESIA

PHENOPERIDINE AND DROPERIDOL AS PREMEDICANTS. A CONTROLLED STUDY IN OPHTHALMIC SURGICAL PROCEDURES IN COMBINATION WITH RETROBULBAR BLOCK. Steele, P. R. and Masheter, H. C. (Bristol Eye Hospital, England), Anaesthesia 26: 311-317, July, 1971.

Four different regimes to provide sedation and analgesia in patients undergoing ophthalmic surgery under local analgesia with retrobulbar block have been assessed under double blind conditions. The results showed that droperidol 5 mg and phenergan 25 mg intramuscularly one hour before operation followed by a further 5 mg droperidol plus phenoperidine 0.5 mg intravenously five minutes before retrobulbar block gave the best sedation and postoperative state. A significantly greater incidence of amnesia (33%) was associated with this combination compared with pethidine 50 mg and phenergan 25 mg given intramuscularly. (2 figures, 2 tables, 3 references)—Authors' abstract

## ARCHIV FÜR DERMATOLOGISCHE FORSCHUNG

BASAL CELL NEVUS SYNDROME WITH RETINOPATHIA PIGMENTOSA, RECURRENT INTRAVITREOUS BLEEDING, AND CHROMOSOMAL ABERRATIONS. (German) Happle, R., Mehrle, G., Sander, L. Z. and Hohn, H. (Universitat Freiburg, Germany), Arch. Derm. Forsch. 241:96-114, 1971.

In a patient with various types of tumors (nevoid basal cell carcinoma, neurofibroma, fibroma of the buccal mucosa), skeletal anomalies and a family history of basal cell carcinoma and of other malignant diseases, the diagnosis of a "basal cell nevus syndrome" is proposed. In addition, the patient exhibited further pathological conditions hitherto unreported in basal cell nevus syndrome: retinopathia pigmentosa with complicated cataract on both eyes; recurrent intravitreous bleeding of the left eye; a high frequency of chromosomal breakage in lymphocyte and fibroblast cultures. A marker chromosome (C-group chromosome with satellites at the short arm) was found in fibroblast metaphases of the patient's daughter. (5 figures, 2 tables, 80 references)—Authors' abstract

## Archiv für Klinische und Experimentelle Ophthalmologie

APPEARANCE OF THE FLUORESCENCE OF THE OPTIC NERVE. II. ATROPHY OF THE OPTIC NERVE. (German) Baurmann H. and Wink, B. (Univ.-Augenklinik Bonn, Germany), Arch. Klin. Exp. Ophth. 182: 120-126, 1971.

The absence of coloring by fluorescein does not necessarily indicate avascularity. On the other hand, the presence of fluorescence does not reliably exclude an atrophy. Therefore, fluorescein angiography does not offer any real advantage in diagnosis of atrophy of the optic nerve head. (3 figures, 10 references)—David Shoch

PATHOLOGY OF SHORT PULSE RETINAL PHOTOCOAGULATIONS USING THE GOLDMANN CONTACT LENS. Marshall, J., Fankhauser, F., Lotmar, W. and Roulier, A (Institute of Ophthalmology, London), Arch. Klin. Exp. Ophth. 182:154-169, 1971.

The problem of hypercoagulation and the occurrence of postcoagulative maculopathy have long been associated with xenon arc photocoagulation procedures. The virtual absence of these complications with pulsed ruby laser coagulations has led many workers to experiment with short pulse exposure techniques. The authors show that both systems produce damage only in the outer retinal layer, and result in very similar scar formations, with no involvement of the inner plexiform or nerve fiber layers. (7 figures, 1 table, 22 references)—David Shoch

## Archives of Neurology

EYE MOVEMENTS DURING SLEEP. Jacobs, L., Feldman, M. and Bender, M. B. (Mount Sinai Hospital, 1 E. 100th St., New York 10029), Arch. Neurol. 25:151-159, Aug., 1971.

Eye movements were recorded by DC oculogram in eight normal subjects during 31 nights of sleep. A consistent series of ocular positional changes and movements occurred in every subject. Initially, eyelid closure induced upward movement of the globes. The eyes then remained elevated during 55% to 85% of the time spent in stages 2, 3, and 4. With the onset of stage of rapid eye movement, the eyes moved down abruptly to or below the central position. Movements during this stage were quite unlike waking eye movements but showed a similar pattern in every subject. These movements were 5% to 15% horizontal, 25% to 35% vertical, and 55% to 65% oblique. The movement sequences and the time intervals between movements were not random. The results suggest that during sleep there is a pattern of activity of the oculomotor system which is similar in every subject. (9 figures, 22 references)—Authors' abstract

## Archives of Ophthalmology

OCULAR CHANGES FOLLOWING AIR-BLAST INJURY. King, Y. Y. (University of Arkansas Medical Center, Little Rock, Ark.), Arch. Ophth. 86:125-126, Aug., 1971.

The air blast reported here came from an air hose at a gasoline service station. The air blast apparently perforated the conjunctiva and dissected along the lining of the optic nerve, down the sheath of the carotid artery into the mediastinum. Alternatively, the pneumomediastinum could have resulted from dissection along the cervical neck planes into the mediastinal area. The cause of the optic nerve atrophy was not evident; however, air compression or even optic nerve transection could have occurred. This case demonstrates the possible danger of a common source of air blast. (2 figures)—Author's abstract

LIGHT COAGULATION IN PRESUMED HISTOPLASMIC CHOROIDITIS. Watzke, R. C. and Leaverton, P. E. (University Hospitals, Iowa City 52240), Arch. Ophth. 86:127-132, Aug., 1971.

A controlled study was designed to evaluate light coagulation as treatment for presumed histoplasmic chorioretinitis. Twenty-nine patients were selected. Allocation of patients to a treatment or an untreated control group was made by using a table of random numbers. Results in the two groups were compared over a one-year observation period. The study was designed to minimize measurement and observation bias and the effect of interim remissions and exacerbations of the disease. The results indicate that this therapy is of no value in the long-term management of this disease. (2 fig-

tures, 5 tables, 7 references)—Authors' abstract

HYDROPHILIC CONTACT LENSES IN CORNEAL DISEASE. Takahashi, G. H. and Leibowitz, H. M. (University Hospital, 750 Harrison Ave., Boston 02118), Arch. Ophth. 86: 133-137, Aug., 1971.

Four patients suffering from chronic bullous keratopathy with minimal stromal scarring were fitted with a hydrophilic contact lens. The lens was worn continuously, 24 hours a day, and 5% sodium chloride drops were administered topically every two hours during the day. Two of the four patients experienced a satisfactory response to therapy manifested by decreased epithelial and stromal edema and improvement in visual acuity. Approximately two weeks of therapy were required before clinical improvement could be documented in successful cases. (2 figures, 9 references)—Authors' abstract

FLUOROMETHOLONE. Fairbairn, W. D. and Thorson, J. C. (Allergan Pharmaceuticals, 18600 Von Karman, Irvine, Calif. 92664), Arch. Ophth. 86:138-141, Aug., 1971.

Fluorometholone 0.1% ophthalmic suspension applied topically was found to be an effective treatment in 308 patients with mild to severe noninfectious inflammatory disorders of the eye. The effect of fluorometholone on intraocular pressure was examined in steroid reactors who had accurately documented histories of pressure responses to prednisolone, dexamethasone, or betamethasone. The drug was also tested in a relatively large random patient population, including many with glaucoma, whose intraocular pressures were observed. The results of these studies indicate that fluorometholone shows a substantially reduced tendency to increase intraocular pressure as compared to several other steroids used topically. (4 tables, 13 references)—Authors' abstract

ISCHEMIC RETINOPATHY DUE TO CARBON MONOXIDE POISONING. Bilchik, R. C., Muller-Bergh, H. A. and Freshman, M. E. (Washington University School of Medicine, 660 S. Euclid, St. Louis 63110), Arch. Ophth. 86:142-144, Aug., 1971.

A family of three, exposed chronically to high levels of carbon monoxide in their home, was hospitalized with nonspecific symptoms and physical findings limited to the eyes. Papilledema, retinal hemorrhages, and cotton wool exudates, all believed to reflect tissue ischemia, resolved spontaneously. (3 figures, 15 references)—Authors' abstract

OCCULT INTRAOCULAR PERFORATIONS FROM BROW AND LID LACERATIONS. Goldberg, M. F. and Tessler, H. H. (University of Illinois Eye and Ear Infirmary, 1855 W. Taylor St., Chicago), Arch. Ophth. 86: 145-149, Aug., 1971.

Minor brow and lid lacerations may be associated with scleral and retinal perforations, even when the lacerations are apparently remote from the globe. Reports of three cases in children have been used to illustrate that the classical signs of scleral perforation need not always be present. This appears especially true of injuries caused by narrow, sharp objects such as darts, scissors and knives. The necessity of suspecting perforation injuries to the globe cannot be over emphasized. (5 figures, 13 references)—Authors' abstract

SUBACUTE SCLEROSING PANENCEPHALITIS (SSPE). Landers, III, M. B. and Klintworth, G. K. (Duke University Medical Center, Durham, N. C. 27706), Arch. Ophth. 86:156-163, Aug., 1971.

This report describes for the first time the finding of microtubular structures, probably viral nucleocapsids, by electron microscopy within retinal lesions of a child with subacute sclerosing panencephalitis (SSPE), whose clinical illness began with visual impairment. The tubular structures within the retina were identical to those previously described in the brain tissue of patients with this disease. They were also seen in the cortical neurons and neuroglia of this case and were present in the cell cultures obtained from the frontal lobe at autopsy. A measles virus has now been isolated from the brain. These findings indicate that there is a direct invasion of the retina by the same pathogenic agent affecting the central nervous system. (10 figures, 22 references)—Authors' abstract

RESECTION OF THE FACIAL NERVE FOR BLEPHAROSPASM. Hathaway, H. K. (Medical Towers, 1000 E. Third St., Chatta-

nooga, Tenn.), Arch. Ophth. 86:178-181, Aug., 1971.

Essential blepharospasm is a progressive, involuntary, spasmodic closure of the eyelids. It is probably the result of a focal disturbance in the suppressor strip 4-S of Hines or the bulbar reticular formation. Nonsurgical measures have been found to be of little benefit except in the mildest cases. Alcohol injections have the disadvantage of being painful, have a high failure rate, and produce contraction of the soft tissue. The most effective and long lasting relief seems to be obtained by selective neurectomy of the facial nerve. The technique is based on exposing the main trunk of the facial nerve and serially avulsing the temporal, zygomatic and buccal branches of the nerve. With the aid of a nerve stimulator, the completeness of the peripheral denervation can be determined and special attention focused on the variable buccal branch of the facial nerve. The skin incision used gives an excellent cosmetic result and allows for wide exposure of the main trunk and the branches of the facial nerve to be avulsed. The altered facial expression which follows the operation is less noticeable than the constant blinking. Exposure keratitis has not developed as so often happens after Bell's palsy. (4 figures, 15 references)—Author's abstract

EXPERIMENTAL CYANIDE OPTIC NEUROPATHY. Lessell, S. (Boston University School of Medicine, Boston, Mass.), Arch. Ophth. 86:194-204, Aug., 1971.

Sodium cyanide intoxication of rats produced demyelinative and necrotic lesions in the corpora callosa in 70% and the optic nerves in 20%. The optic neuropathy was bilateral, focal and retrobulbar. All animals with optic neuropathies had marked callosal lesions. Chiasmal involvement was rare. Since callosal lesions are extremely rare in a patient with optic atrophy and since the corpora callosa seem to be particularly sensitive to cyanide, it appears unlikely that cyanide is responsible for human optic nerve diseases. (10 figures, 25 references)—David Shoch

## ARCHIVES OF PATHOLOGY

OPHTHALMIC COCCIDIOIDOMYCOSIS. Olavarria, R. and Fajardo, L. F. (Stanford University School of Medicine, Palo Alto, Calif.), Arch. Path. 92:191-195, Sept., 1971.

A case of disseminated coccidioidomycosis with bilateral involvement of choroid and optic nerves is described. Miliary choroid granulomas probably resulted from coccidioidal endocarditis of mitral valve. A secondary source of hematogenous dissemination was found in a branch of the hepatic vein. Arthrospores, as well as sporangia, were demonstrated in the latter. (5 figures, 14 references)—Authors' abstract

## BRITISH JOURNAL OF OPHTHALMOLOGY

RUBEOSIS OF THE IRIS AND HEMORRHAGIC GLAUCOMA IN PATIENTS WITH PROLIFERATIVE DIABETIC RETINOPATHY. Madsen, P. H. (University Hospital, Arhus, Denmark), Brit. J. Ophth. 55:368-371, June, 1971.

Rubeosis of the iris is relatively frequent in eyes with proliferative diabetic retinopathy and occurred in 43% in the author's series (58 eyes). Fourteen of these eyes developed hemorrhagic glaucoma. Included in this series are 22 patients who had been subjected to hypophysectomy. (1 figure, 3 tables, 9 references)—David Shoch

PROGNOSIS FOR VISION AND FUNDUS CHANGES IN PATIENTS WITH PROLIFERATIVE DIABETIC RETINOPATHY. Madsen, P. H. (University Hospital, Arhus, Denmark), Brit. J. Ophth. 55:373-383, June, 1971.

Sixty-eight patients with proliferative diabetic retinopathy were followed for from 7 to 131 months. At the end of this time, 49 had retained visual acuity of 0.3 in one or both eyes. Progression of the proliferative retinopathy was observed in nearly one-half the eyes, in both hypophysectomized and non-hypophysectomized patients. Hypophysectomy seems to postpone the aggravation of fundus lesions but strict clinical studies are required to prove or disprove this apparent tendency. (11 figures, 9 tables, 17 references)—David Shoch

IRIDOCYCLO-RETRACTION IN NARROW-ANGLE GLAUCOMA. Krasnov, M. M. (Second Medical Institute, Moscow, USSR), Brit. J. Ophth. 55:389-395, June, 1971.

A new surgical procedure (iridocyclo-retraction) has been developed for narrow-angle

glaucoma, especially in cases with synechial iris closure. The iris root is forced back from the filtering zone and kept back by two (sometimes three) interposing autoimplants of scleral tissue. The operation has been successfully tried in 141 cases during a 3-year period. Experiments on rabbits have shown the method to be based on sound principles. Iridocyclo-retraction has substantial advantages over iridectomy and iridencleisis and deserves a wider clinical use. (4 figures, 1 table, 4 references)—Author's abstract

COLOBOMATOUS CUPPING OF THE OPTIC DISC. Rintoul, A. J. (Royal Naval Hospital, Haslar, Gosport, Hants), Brit. J. Ophth. 55:396-399, June, 1971.

Congenital colobomas of the optic nerve head may be mistaken for glaucomatous cupping. The author reports a patient with bilateral colobomas who had a loss of the superior field in the right eye and a typical Bjerrum scotoma in the left. Differential diagnosis from glaucoma was based on the fact that the intraocular pressure was normal and that the field defects were non-progressive. It is important to differentiate these congenital colobomas from glaucoma in order to avoid needless treatment to the patient. (4 figures, 30 references)—David Shoch

## CANADIAN JOURNAL OF OPHTHALMOLOGY

THE HYDROPHILIC (HYDRON) CORNEOSCLERAL LENS IN THE TREATMENT OF CORNEAL DISEASE. Lerman, S. and Sapp, G. (Royal Victoria Hospital and McGill University, Montreal, Canada), Canad. J. Ophth. 6: 1-8, Jan., 1971.

The hydrophilic (Hydron) corneoscleral lens has been employed in the therapy of bullous keratopathy. The possibility that ocular preservatives such as benzalkonium chloride and chlorbutanol might concentrate within these lenses was investigated. These studies showed that this did not occur to any significant extent and the patients were thus able to use whatever ocular medications they required (e.g. antiglaucoma drops) while wearing the lenses. The lens was worn for 24 hour periods, then removed, rinsed and boiled for 10 to 15 minutes in physiological saline, cooled and re-inserted. The majority of the patients obtained rapid and complete relief from their signs and symptoms and have been wearing the lenses for many months. (2 figures, 5 tables, 3 references)—Authors' abstract

THE DOSE RESPONSE OF HUMAN INTRAOCULAR PRESSURE TO PILOCARPINE. Drance, S. M. and Nash, P. A. (University of British Columbia, 2550 Willow St., Vancouver, Canada), Canad. J. Ophth. 6:9-13, Jan., 1971.

The effect of single dose instillations of 1%, 2%, 4% and 8% pilocarpine into one eye of 12 ocular hypertensive patients was studied. It was shown that maximal pressure reduction occurred two hours after the instillation of the single dose and was dose related up to 4% pilocarpine. The duration of 8% pilocarpine was considerably longer and at eight hours following the instillation of a single dose, the dose relationship showed that the 8% pilocarpine retained its maximal pressure reducing qualities for that period of time. (6 figures, 5 references)—Authors' abstract

SIMULATED SUSTAINED RELEASE PILOCARPINE THERAPY AND AQUEOUS HUMOR DYNAMICS. Lerman, S. and Reininger, B. (McGill University, Montreal, Canada), Canad. J. Ophth. 6:14-23, Jan., 1971.

A study was performed in which a simulated form of sustained release pilocarpine therapy was compared with the conventional method of pilocarpine therapy in a series of patients with open angle glaucoma. The results indicate that if a suitable method of prolonged release pilocarpine therapy could be developed, then most patients with open angle glaucoma would require a total 24 hour dose of pilocarpine hydrochloride which would be between 10 and 25 times less than the therapy the patient is presently using. This form of pilocarpine therapy would also have the advantage of maintaining continuous control of intraocular pressure both during the day and night. Since the total concentration of pilocarpine required would be so markedly diminished, it would be of value in those patients who display extreme sensitivity to cholinergic drops. (8 tables, 4 references)—Authors' abstract

VASCULAR FACTORS IN ASTEROID HYALOPATHY. Lamba, P. A. and Shukla, K. N. (Jawaharlal Institute of Postgraduate Medical Education, Pondicherry-6, India), Canad. J. Ophth. 6:46-51, Jan., 1971.

Thirty patients with asteroid bodies in the vitreous have been clinically and biochemically evaluated to determine the association with diabetes mellitus, hypercholesterolemia and hypertension. A significant number of cases were seen to be associated with diabetes, hypertension and evidence of angiosclerosis. It is suggested that vascular changes due to the associated above conditions may play a significant role in altering the permeability of the vessels and the deposition of the asteroid bodies in the vitreous. (5 tables, 17 references)—Authors' abstract

CYTOLOGY OF THE ANTERIOR CHAMBER FLUID IN EYES WITH CORNEAL XENOGRAFTS. Fowlder, J. H. and Basu, P. K. (1 Spadina Crescent, Toronto 179, Canada), Canad. J. Ophth. 6:68-71, Jan., 1971.

Millipore filters have been employed to examine the cytology of the anterior chamber fluid in xenografted and unoperated rabbit eyes and to quantitate the effects of a topical steroid in grafted eyes. The concentration of cells in the aqueous humor of grafted eyes increased to several hundred times that found in unoperated control eyes, during the second and third postoperative weeks. When topical steroids were administered in the third week postoperatively, the aqueous cellular response was reduced to control levels. (1 figure, 8 references)—Authors' abstract

CICATRICIAL ECTROPION IN EPIDERMOLYSIS BULLOSA AND IN CONGENITAL ICHTHYOSIS: ITS PLASTIC REPAIR. Hill, J. C. and Rodrigue, D. (Toronto General Hospital, Toronto, Canada), Canad. J. Ophth. 6: 89-97, Apr., 1971.

The ectropion that occurs in these two diseases is extremely severe and frequently results in the loss of the eye from exposure. The authors point out that the only effective type of repair is free skin grafting since in both these conditions there is a loss of tissue. However, grafting alone is insufficient since the ectropion almost always returns. It is necessary to put in permanent lid adhesions to prevent the recurrence of the ectropion. They point out that patients frequently will demand release of the adhesions but to do so is to invite a return of the ectropion. (14 figures, 8 references)—David Shoch

THE CONTROL OF CORNEAL GRAFT REACTION BY TOPICAL APPLICATION OF ANTIMITOTIC AGENTS (THIO-TEPA AND COLCHICINE): Akinosho, E. A. and Basu, P. K. (University of Toronto, 1 Spadina Crescent, Toronto, Canada), Canad. J. Ophth. 6: 109-114, Apr., 1971.

The effects of two antimitotic agents, Thiotepa and colchicine, on the corneal xenograft reaction in rabbits, were studied. These agents showed an inhibitory action on the vascularization and cellular infiltration of the graft. In the dosage used, colchicine appeared to be slightly less effective than Thio-tepa. (6 figures, 2 tables, 6 references)—Authors' abstract

THE CHANGES IN THE BLOOD SUPPLY OF THE POSTERIOR POLE OF RABBITS WITH OCULAR HYPERTENSION. de Freitas, F. and Morin, J. D. (University of Toronto, 1 Spadina Crescent, Toronto, Canada), Canad. J. Ophth. 6:139-142, Apr., 1970.

Thirty-five albino rabbits were made glaucomatous for one week by injecting methyl cellulose into the anterior chamber. In all the glaucomatous eyes, there was a filling defect in the peripapillary chorodial vessels supplied by the analogue of the circle of Zinn. Furthermore, there was narrowing and obliteration of the central retinal artery which was more easily seen in the latex injected specimens. Cupping was seen in 50% of the specimens. (5 figures, 9 references)—Authors' abstract

IMMUNOSUPPRESSION AND KERATOPLASTY. McCulloch, C. (Toronto General Hospital, Toronto, Canada), Canad. J. Ophth. 6: 161-169, July, 1971.

Graft rejection may involve the entire graft or may involve only one of its layers. The author feels that one might have epithelial rejection, stromal rejection or endothelial rejection without involvement of the whole graft. He describes seven cases in which graft rejection began and in these seven azathioprine was used. In one case the course of rejection was not affected but in the other six, improvement occurred with the use of the drug. For mild rejections, atropine and local steroids may be sufficient but with more severe rejections the author advises the use of immunosuppressive agents. (7 figures, 1 table, 23 references)—David Shoch

A NEW TREATMENT FOR "A" AND "V" PATTERNS IN STRABISMUS BY SLANTING MUS-

CLE INSERTIONS. Boyd, T. A. S., Leitch, G. T. and Budd, G. E. (University of Alberta Hospital, Edmonton 61, Canada), Canad. J. Ophth. 6:170-177, July, 1971.

In addition to the usual recession or resection in cases of A and V strabismus, the authors also recess one border of the muscle more than another. In V exotropia for example, the superior border is recessed more than the inferior border. In V esotropia on the other hand, the inferior border is recessed more than the upper. The authors' patients were compared with a group in which only horizontal surgery was done and there was a clear superiority for their method. (8 figures, 6 tables, 7 references)—David Shoch

## Clinical Science

GENETIC INFLUENCES IN DRUG RESPONSES OF THE EYE AND THE HEART. Bertler, A. and Smith, S. E. (Dept. of Pharmacology, Lund University, Lund, Sweden), Clin. Sci. 40:403-410, May, 1971.

Pupillary responses to locally applied phenylephrine and cardiac responses to intravenous hyoscine N-butylbromide have been studied in ten pairs each of healthy monovular and binovular twins aged between 24 and 60 years. Under identical lighting conditions resting pupil diameters differed widely among individuals, being greater in female subjects and in those with larger irides and smaller with increasing age. Monovular twins, but not binovular twins, showed significant concordance in iris diameter, initial pupil diameter, initial heart rate and responses to both drugs. The results suggest that these responses were dependent on the concordance of peripheral sympathetic and parasympathetic tone within each twin pair. It is concluded that much of the variability in response to drugs acting on the autonomic nervous system is determined by physiological factors and that these are genetically influenced. (2 figures, 2 tables, 18 references)—Authors' abstract

## International Ophthalmology Clinics

TUMORS INVOLVING THE ORBITAL REGION. Smith, B. (Manhattan Eye, Ear and Throat Hospital, New York), Int. Ophth. Clin. 10:3-10, 1970.

Various tumors of the lids and orbit are reviewed and the author outlines the appropriate surgical therapy. He concludes that the most common complication of surgical treatment of tumors around the eye is the failure to execute radical or complete extirpation of the entire neoplasm at the initial operation. Conservative, that is, incomplete resection results from the surgeon's failure to create a sufficient tissue defect because he is timid or uninformed concerning the proper methods of closing the defect created by surgical eradication of the tumor. Although post-surgical complications such as trichiasis, entropion, ectropion, etc. may occur these can usually be rectified by competent secondary surgery.—David Shoch

CONGENITAL AND SURGICAL ANOPHTHALMIA. Spaeth, E. B. (Wills Eye Hospital, Philadelphia, Penn.), Int. Ophth. Clin. 10:11-21, 1970.

In congenital anophthalmia the first procedure necessary is a subconjunctival implantation of a gold ball into the socket, usually through the lower lid. The second procedure should be a creation of superior and inferior cul-de-sacs which in infants must usually be constructed from skin grafts since there is not sufficient mucous membrane available. Thirdly, metal or plastic conformers should be used and gradually increased as the child's face grows until a satisfactory prothesis can be fitted and worn. (7 figures)—David Shoch

EPIPHORA AND RELATED DISORDERS OF THE LACRIMAL SYSTEM. Cherubini, T. D. (Manhattan Eye, Ear and Throat Hospital, New York), Int. Ophth. Clin. 10: 23-22, 1970.

The author feels that where possible, reconstruction of the lacrimal system is the treatment of choice for most problems. The only real indication for dacryocystectomy is the presence of a tumor. Further, he feels that surgery is indicated even in the presence of an acutely inflamed dacryocystitis. Establishment of an open system and the use of postoperative antibiotics cure the infection without incident. —David Shoch

ECTROPION AND ENTROPION. Silver, B. (Washington University School of Medicine, St. Louis, Missouri), Int. Ophth. Clin. 10:33-45, 1970.

For ordinary senile entropion the author feels that the excision of a base down triangle of tarsus gives the best result. On the other

hand the most definitive operation is a modified Wheeler orbicularis transplant. For cicatricial disease, generally freeing of the scars is necessary with insertion of a skin graft. Since grafts tend to shrink, it is particularly important to overcorrect a cicatricial ectropion. (11 figures, 5 references)—David Shoch

BAGGY LIDS. Beyer, C. K. (Massachusetts Eye and Ear Infirmary, Boston, Mass.), Int. Ophth. Clin. 10:47-53, 1970.

The most important point in correction of baggy lids is conservatism. Ectropion is very difficult to correct and undercorrection is preferable to overcorrection. This is particularly true for the lower lids. Further, meticulous hemostasis is essential to avoid postoperative hematomas and disruption of the desired result. (3 figures, 14 references)—David Shoch

TRAUMA AND BURNS. Tenzel, R. R. (Bascom Palmer Eye Institute, Miami, Florida), Int. Ophth. Clin. 10:55-69, 1970.

An important point the author makes is that for trauma to the orbit it is essential that a Water's view be ordered. Routine skull films do not reveal orbital fractures. For chemical burns, the most important thing is irrigation. The author advises inserting an intravenous type catheter through the skin of the lid into the inferior cul-de-sac. The end of the Intracath tubing is pulled out from the cul-de-sac and flamed with a match which causes flanging of the end of the tube. This is pulled back until the tube is just in the cul-de-sac and through this tubing a continuing irrigation of balanced salt solution mixed with an antibiotic can be dripped round the clock. (12 figures)—David Shoch

ENDOCRINE EXOPHTHALMOS. Wilkins, R. B. and Sessions, R. B. (Hermann Hospital, Houston, Texas), Int. Ophth. Clin. 10:71-84, 1970.

A distinction should be made between the ocular manifestations of thyrotoxicosis and endocrine exophthalmos, which are only indirectly related. Endocrine exophthalmos is a functionally and cosmetically treatable condition. The preoperative evaluation must rule out conditions not treated by decompression. The otorhinolaryngologist and ophthalmologist, with a combined approach, are best equipped to evaluate, treat, and follow these patients. The transantral orbital decompression is the surgical procedure of choice. (6 figures, 24 references)—Authors' abstract

THE SURGICAL APPROACH TO ENDOCRINE OPHTHALMOLOGY. Langham, III, J. E. (University of California Medical Center, San Francisco, Calif.), Int. Ophth. Clin. 10:85-95, 1970.

Each of the complications of endocrine ophthalmopathy is presented and appropriate therapy discussed. For lid retraction, the best treatment is separation of the levator from the upper border of the tarsus. Occasionally only the involuntary levator should be separated but in most cases it is necessary to separate the attachments of the voluntary aponeurosis as well. For muscle problems the appropriate therapy is recession of the restricted muscle with freeing of any adhesions, if present. Finally, for cases that need decompression of the orbit, the author advises an antral decompression. (15 references)—David Shoch

BLEPHAROPTOSIS: CLINICAL EVALUATION AND THERAPEUTIC RATIONALE. Beard, C. (University of California Medical School, San Francisco, Calif.), Int. Ophth. Clin. 10:97-115, 1970.

Examination of a patient with ptosis is outlined and appropriate therapy for mild, moderate and severe ptosis is given. Very specific recommendations are made for the type of surgery to be done and for the amount of surgery in each of these three divisions. The author feels that whenever possible the operation of choice is a levator muscle resection. (5 figures, 20 references)—David Shoch

LEVATOR RESECTION FOR MINIMAL PTOSIS. Fasanella, R. M. and Servat, J. (Yale-New Haven Medical Center, New Haven, Conn.), Int. Ophth. Clin. 10:117-130, 1970.

For patients with a minimal ptosis, that is, not more than 1.5 to 2 mm, who have a good lid fold, the authors advise a block resection which is done by simply grasping the upper edge of the tarsus and the conjunctiva and the levator between two curved hemostats. The tissue is excised and the defect closed with either silk or cat gut. This block resection appears to give a good cosmetic and functional result in cases with minimal ptosis. (12 figures, 8 references)—David Shoch

THERAPEUTIC CONTACT LENSES. Gould, H. L. (Manhattan Eye, Ear and Throat Hospital, New York), Int. Ophth. Clin. 10:131-141, 1970.

The most dramatic indication for the use of a flush-fitting shell is painful bullous keratopathy. The pain is relieved completely within a few days of insertion of the shell. In some cases an optical modification can be made which gives the patient reasonable vision. A second important use for flush-fitting shells is in the treatment of Stevens-Johnson syndrome. Finally, the custom molded shell is ideal as a cosmetic cover over a disfigured globe. (6 figures, 8 references)—David Shoch

THE PREPARATION OF METHYL METHACRYLATE IMPLANTS FOR REPAIR OF ORBITAL FRACTURES. Miller, G. R. (University of Miami School of Medicine, Miami, Florida), Int. Ophth. Clin. 10:143-144, 1970.

The technique for molding an implant at surgery is described, but the author advises that the use of premolded, flat, thin plates saves time and avoids the heat generated during polymerization in vivo. Wiring of the plate to the rim in acute fractures is not necessary. (1 reference)—David Shoch

THE PALPEBRAL SPRING FOR PARALYSIS OF THE UPPER EYELID. Guy, C. L. and Ransohoff, J. (University Hospital, New York), Int. Ophth. Clin. 10:145-151, 1970.

The palpebral spring is used for patients who have had complete or transient paralysis of the facial nerve and are unable to close the involved eye. The spring is fashioned so that on relaxation of the levator, it passively closes the upper eye lid yet allows the levator to overcome the power of the spring and open the eye at will. Twenty-four such springs were inserted and of these 19 are still in place and appear to be working well. (3 figures, 4 references)—David Shoch

## INVESTIGATIVE OPHTHALMOLOGY

THE EFFECT OF HYPERBARIC OXYGENATION ON RETINAL ISCHEMIA. Flower, R. W. and Patz, A. (Applied Physics Laboratory, 8621 Georgia Ave., Silver Spring, Md. 20910), Invest. Ophth. 10:605-616, Aug., 1971.

Retinal circulation was occluded by direct burning of the arterioles with an argon laser. In a second group of experiments the retinal circulation was occluded by increasing intraocular pressure but this also decreased the choroidal blood flow. The viability of the retina following these occlusions was measured by noting the amplitude of the ERG. This is a reliable and a sensitive indicator of viability of the retinal layers. Results indicate that hyperbaric oxygen significantly increases the range of oxygen diffusion from the choroid to supply ischemic inner retinal layers following retinal arterial occlusion. To be effective, oxygen therapy must be administered under hyperbaric pressures. Breathing 100% oxygen at sea level pressure produced little or no protection for ischemic inner retinal layers. (6 figures, 15 references)—David Shoch

## JOURNAL OF PEDIATRICS

NORRIE'S DISEASE: AN X-LINKED SYNDROME OF RETINAL MALFORMATION, MENTAL RETARDATION, AND DEAFNESS. Holmes, L. B. (Genetics Unit, Massachusetts General Hospital, Fruit St., Boston, Mass.), J. Pediatrics 79:89-92, July, 1971.

A family is reported in which six males in four generations had Norrie's disease, an X-linked recessive syndrome of retinal malformation, deafness, and mental retardation. It would seem that this disease may be frequently misdiagnosed as retrolental fibroplasia, retinoblastoma, retinal pseudoglioma, or congenital toxoplasmosis. Although this is only the third reported American family, it is likely that this disease will be more frequently recognized once it is better known. (2 figures, 10 references)—Author's abstract

CYCLOPENTOLATE (CYCLOGYL) TOXICITY IN PEDIATRIC PATIENTS. Adcock, III, E. W. (Fitzsimmons General Hospital, Denver, Colo. 80240), J. Pediatrics 79:127-129, July, 1971.

A 4½-year-old white male developed a generalized postganglionic cholinergic blockade after receiving six drops of 2.0% Cyclogyl over a period of one-half hour. (14 references)—Joel G. Sacks

THE CEREBRORETINAL DEGENERATIONS. Menkes, J. H., Andrews, J. M. and Can-

cilla, P. A. (UCLA Center for the Health Sciences, Los Angeles, Calif. 90024), J. Pediatrics 79:183-196, Aug., 1971.

An excellent article that tabulates the lipid storage diseases. The authors divide these into three groups: those without marked visceromegaly (Tay-Sachs, Batten-Bielschowsky); those with marked visceromegaly (Gaucher's, Niemann-Pick) and those with white matter degeneration (metachromatic leukodystrophy). The clinical characteristics of each entity are listed and where known, the enzymatic defect. (8 figures, 2 tables, 62 references)—David Shoch

ULTRASTRUCTURAL STUDIES IN LATE-ONSET AMAUROTIC IDIOCY: LYMPHOCYTE INCLUSIONS AS A DIAGNOSTIC MARKER Witzleben, C. L., Smith, K., Nelson, J. S., Monteleone, P. L. and Livingston, D. (Cardinal Glennon Memorial Hospital, 1465 Grand Blvd., St. Louis, Mo. 63104), J. Pediatrics 79: 285-293, Aug., 1971.

Light and electron microscopic studies have been carried out on brain and white blood cells from a patient with juvenile amaurotic idiocy. A variety of lipid inclusion, including both "multilamellar cytosomes" and "fingerprint" inclusions, were present in the brain, suggesting that these two morphologic types of inclusions may not always define separate metabolic disorders. In the lymphocytes, ultrastructurally striking lamellar cytoplasmic inclusions were found. Such inclusions have not previously been described in this disorder. The demonstration of these inclusions by electron microscopy may prove to be a distinctive and relatively simple diagnostic marker of the disease, or at least of the "type" of late-onset amaurotic idiocy present in this patient. (6 figures, 14 references)—Authors' abstract

## JOURNAL OF PEDIATRIC OPHTHALMOLOGY

CONGENITAL ESOTROPIA: DEFINITION, COURSE AND MANAGEMENT. Romano, P. E. (Children's Memorial Hospital, Chicago, Illinois), J. Pediat. Ophth. 8:38-92, May, 1971.

The term congenital esotropia should be reserved for those children with an esodeviation who have never had an opportunity for normal binocular vision. In clinical terms, any child with a proven constant esodeviation at four months of age should be considered to have congenital esotropia. This condition is hereditary but otherwise of unknown etiology. It is typically characterized by a large deviation, cross fixation and limited abduction bilaterally. There is, in addition, an apparent congenital defect for central fusion and the best functional result which can be obtained is a monofixation syndrome, microtropia, or microstrabismus. Although less than perfect, such a result is desirable because it is stable and is accompanied by a fair degree of binocular cooperation. Management starts with early and accurate diagnosis and early treatment of amblyopia to establish alternating or cross fixation. To obtain maximal function results, surgical correction of the deviation should be completed by age two to two and a half. Earlier surgery will not produce better functional results but may be indicated for cosmetic reasons. (11 references)—Author's abstract

TENDON TRANSPLANTATIONS FOR LATERAL RECTUS PARALYSIS. Billet, E. (Bronx Eye Infirmary, Bronx, New York), J. Pediat. Ophth. 8:102-104, May, 1971.

Four cases of congenital lateral rectus paralysis showed no improvement in abduction after temporal tendon transplantation of the vertical recti. Many favorable results in the literature following the Hummelsheim operation or one of its many modifications were cases of traumatic as opposed to congenital lateral rectus paresis. It is considered that traumatic paresis may improve even with simple horizontal muscle surgery, particularly the weakening of a contractured antagonist. Combined surgery, i.e., the one-stage horizontal and vertical operation, may have an additive effect which cannot be accomplished with these same procedures in two stages. However, the occasional severe postoperative complications from four rectus muscle surgery should preclude this operation. (19 references)—Author's abstract

## KLINISCHE MONATSBLÄTTER FÜR AUGENHEILKUNDE

RESULTS OF PROPHYLACTIC CRYORETINOPEXY. (German) Boke, W. and Voigt, G. (Univ.-Augenklinik Kiel, Germany), Klin. Mbl. Augenh. 159:12-21, July, 1971.

Ninety-eight patients (108 eyes), who had been treated prophylactically with low temperatures (cryoretinopexy), for retinal detachment were followed for two months to three years after the operation. Statistical data on the kind and distribution of the retinal degeneration are reported. Altogether, serious complications arose in three of the 108 eyes (detachment of the retina in two, and intraocular bleeding in one) of which two were relieved without sequelae. The complication rate is therefore by no means higher, but apparently lower than with prophylactic diathermy or photocoagulation. (1 figure, 6 tables, 62 references)—David Shoch

TRAUMATIC DAMAGE OF THE OPTIC NERVE. (German) Schmaltz, B. and Schurmann, K. (Klinik der Univ. Mainz, Germany), Klin. Mbl. Augenh. 159:33-51, July, 1971.

Over a 14 year period the authors treated 250 patients with craniocerebral injuries. Among these there were 13 cases of posttraumatic blindness. Nine of these had a primary complete loss of vision and in none of these was there any return of vision following decompression of the optic nerve. There were four cases where the visual deterioration occurred later; in only one of these was there a return of vision. Therefore, in general the authors counsel against decompression of the optic nerve in cases of traumatic injury. (2 figures, 91 references)—David Shoch

## LANCET

HIGH FREQUENCY OF DIABETES MELLITUS IN YOUNG ADULTS WITH CONGENITAL RUBELLA. Forrest, J. M., Menser, M. A. and Burgess, J. A. (Royal Alexandra Hospital for Children, Sydney, Australia), Lancet 2:332-334, 1971.

In 1967, fifty young adults with congenital rubella were reviewed. Diabetes mellitus was detected in one of the fifty patients. Subsequently four other patients with congenital rubella and diabetes mellitus were found from other sources. The original group of fifty young adults was then reassessed, with special attention to the detection of diabetes mellitus. Of forty-four patients available for review, five (including the original patient) had diabetic glucose-tolerance tests, and a further four had slight abnormalities in glucose tolerance together with abnormal insulin responses suggestive of latent diabetes mellitus. The combined incidence of diabetes and latent diabetes in this group of patients was nine out of forty-four (20%). These findings suggest a causative relationship between congenital rubella infection and diabetes mellitus. (3 tables, 23 references)—Authors' abstract

## PROCEEDINGS OF THE ROYAL SOCIETY OF MEDICINE

RETINAL PHOTOGRAPHY IN PREMATURE INFANTS: FORME FRUSTE RETROLENTAL FIBROPLASIA. Baum, J. D. (Institute of Child Health, Hammersmith Hospital, London), Proc. Royal Soc. Med. 64:777-779, July, 1971.

Ophthalmoscopy is no replacement for direct frequent arterial $Po_2$ measurement in premature infants receiving oxygen. In the infants at greatest risk of oxygen toxicity to the eye, those of less than 32 weeks gestation, the retina is not clearly visible because of the persistent tunica vasculosa lentis. Even if it were, the services of an expert ophthalmologist would be required every few hours, day and night, and even then he would be looking for a sign which probably points to established retinal damage. The finding of tortuous retinal arteries in surviving contemporary premature infants in whom oxygen thereapy has been given in the most carefully monitored fashion serves as a reminder that the limits of safety in prescribing an oxygen-enriched environment for premature infants are very narrow indeed. (2 figures, 1 table, 10 references)—Author's abstract

# NEWS ITEMS

EDITED BY THOMAS CHALKLEY, M.D.
*700 North Michigan Avenue, Chicago, Illinois 60611*

For adequate publicity, notices of postgraduate courses, meetings and lectures must be received *at least* three months prior to the date of occurrence.

### SEEING EYE OFFERS SCHOLARSHIPS

The Seeing Eye, Inc., Morristown, New Jersey, will make a few post-doctoral fellowships and medical school scholarships available to qualified candidates who wish to pursue a career in investigative ophthalmology. Details of this program may be obtained by writing to the Director of Grants, The Seeing Eye, Inc., Morristown, New Jersey 07960.

### RECENTLY DESCRIBED $CO_2$ LASER CALLED DANGEROUS

The 10-watt $CO_2$ laser described in the September issue of Scientific American is highly dangerous according to C. H. Knowles, President of Metrologic Instruments, Inc. He stated that its power is approximately 2000 times the safe level recommended by the Electronic Industries Association.

### POSTGRADUATE COURSE AND ALUMNI MEETING: WALTER REED ARMY MEDICAL CENTER

The fourth Walter Reed Ophthalmology Postgraduate Course and Alumni Meeting will be conducted at Sternberg Auditorium, Walter Reed Army Medical Center, Washington, D.C., on April 10-13, 1972. Speakers will include Alston Callahan, Harvey Thorpe, Thomas Walsh, Guillermo Pico, Arthur Linksz, Arthur Keeney, John Harris, Richard Lubow, Richard Richards, Mansour Armaly, Henry Allen, William Havener, and others, including alumni. There is no tuition fee, and advance registration is recommended but not mandatory.

For additional information contact Course Director Col. Budd Appleton, Box 4, OSC, Walter Reed General Hospital, Washington, D.C. 20012.

### CLINICAL CONFERENCE: WILLS EYE HOSPITAL

The 24th annual clinical conference of the Wills Eye Hospital will be held on February 3-5, 1972, at the Bellevue Stratford Hotel, Broad and Walnut Streets, Philadelphia, Pennsylvania. The Arthur J. Bedell Lecture will be given by Lorenz E. Zimmerman, Washington, D.C. There will be symposia on causes of failure in cataract surgery and how to avoid them, and on retinal vascular occlusive disease. Workshops will be held in plastic surgery, retinal diseases, refraction, motility, anesthesia, and neurology.

Inquiries should be addressed to Robert D. Mulberger, M.D., Chairman, Annual Clinical Conference Committee, Wills Eye Hospital, 1601 Spring Garden Street, Philadelphia, Pennsylvania 19130.

### NEURO-OPHTHALMOLOGY COURSE: BASCOM PALMER EYE INSTITUTE

The ninth annual ophthalmology course of the Bascom Palmer Eye Institute at the University of Miami will be held January 4-7, 1972, at the Americana Hotel, Miami Beach, Florida. The first two days will be devoted to a basic course in neuro-ophthalmology aimed at the level of residence with no previous training. The final two days will be devoted to an advanced clinical seminar on genetics in ophthalmology.

The fee is $100 for practitioners and $40 for residents. Further information is available from the Neuro-ophthalmology Course, Inc., 11300 S.W. 179th Street, Miami, Florida 33157.

### CONTACT LENS COURSE: NEW ORLEANS ACADEMY OF OPHTHALMOLOGY

The New Orleans Academy of Ophthalmology and the Rudolph Ellender Medical Foundation have coordinated the 1972 programs concerning contact lenses. On April 8-9, 1972, the Ellender Eye Foundation will present a personalized instruction course in fitting techniques of hard and flexible lenses. The annual symposium of the New Orleans Academy of Ophthalmology will be held April 10-14, 1972. The lectures will include didactic material on all phases of medical contact lens practice and experience. The course will not duplicate materials. Guest speakers of the New Orleans Academy of Ophthalmology will include Chester J. Black, Jorge N. Buxton, Herber L. Gould, Peter Halberg, Herbert E. Kaufman, Ian Mackie, Perry Rosenthal, and Whitney G. Sampson.

### UNIVERSITY OF IOWA CLINICAL COURSE: ECHOGRAPHY OF THE GLOBE AND ORBIT

An intensive course for ophthalmologists and technicians in the performance of clinical echo-ophthalmography will be held at the Department of Ophthalmology in Iowa City May 8-10, 1972. The tuition for this course will be $150 for practicing physicians and $100 for residents.

For further information contact Karl Ossoinig, M.D., Department of Ophthalmology, University of Iowa Hospitals, Iowa City, Iowa 52240.

### CLINICAL SYMPOSIUM: ARKANSAS MEDICAL CENTER

The annual clinical symposium of the Department of Ophthalmology of the University of Arkansas Medical Center, will be held February 5-6, 1972. The session will be devoted primarily to dis-

cussion of current cases. Guest speakers include Henry L. Van Dyk and Thomas Acers.

Further information is available from Mrs. Lee Hallmark, Department of Ophthalmology, University of Arkansas Medical Center, Little Rock, Arkansas 72201.

### Corneal surgery course: Brooklyn Eye and Ear Hospital

A three-day course in surgery of the cornea will be given under the direction of A. Benedict Rizzuti and the staff of the Brooklyn Eye and Ear Hospital May 10-12, 1972. Surgical keratoplasty techniques will be demonstrated on patients. Special instrumentation, microscopic surgery, keratoprosthesis and related subjects will be discussed. Matriculants will perform corneal grafting procedures on animal eyes under supervision.

Tuition is $175, and the course is limited. Registration forms may be obtained from Mr. Vernon Dressler, Administrator, Brooklyn Eye and Ear Hospital, 29 Greene Avenue, Brooklyn, New York 11238.

### Ophthalmic radiology course: Columbia University

A postgraduate course in ophthalmic radiology will be presented by Columbia University, College of Physicians and Surgeons, under the direction of Guy D. Potter on Friday and Saturday, April 21 and 22, 1972. The course will deal with normal radiographic anatomy, tomography of the orbit and paranasal sinuses, congenital anomalies, the orbit in children including retinoblastoma, rhabdomyosarcoma, exophthalmos, orbital calcification, the sella turcica, trauma, foreign body localization, orbital contrast studies and orbital tumors. The faculty includes Jackson Coleman, William Cooper, Kenneth Dolan, Robert Ellsworth, Guy Potter, William Seaman, Michael Tenner, Patricia Tretter, Stephen Trokel, Galdino Valvassori, and Judah Zizmor. The course will be directed to ophthalmologists and radiologists.

For further information, please contact Dr. Guy D. Potter, Columbia-Presbyterian Medical Center, 622 West 168th Street, New York, New York 10032.

### Mid-winter Seminar: Colorado Ophthalmological Society

The mid-winter seminar sponsored by the Colorado Ophthalmological Society will be held in Snowmass-at-Aspen, January 31 through February 3, 1972. The speakers are Frederick C. Blodi, Arthur J. Jampolsky, Alex E. Krill, and Robert J. Brockhurst.

Further information is available from James M. Hersey, M.D., Colorado Ophthalmological Society, 1809 East 18th Avenue, Denver, Colorado 80218.

### Summer scholarships: Delta Gamma Foundation

Delta Gamma Foundation is offering summer scholarships for the training of orthoptists and teachers and consultants for visually handicapped children. Applicants are considered on individual merit and the amount of each grant depends on the cost of the specific training involved. Application deadline is March 15, 1972.

Further information may be obtained from Mrs. David Dunbar, 20 Elm Court, Anderson, Indiana 46011.

### Fight for Sight applications now being accepted

The Fight for Sight, founded in 1946 with the primary purpose of encouraging and financing eye research, has awarded $284,217 for the current year in support of basic and clinical research projects in ophthalmology and related sciences. Charles A. Perera, Chairman of the organization's Scientific Advisory Committee, stated that an intensive self-study of the research awards program of the Fight for Sight has resulted in a number of procedural changes, all designed to simplify application methods so that the administrative burdens might be eased for individual candidates, chiefs of departments, institutions and the Fight for Sight itself.

Applications for Fight for Sight fellowships and grants for the 1972–73 awards year are being accepted now and may be submitted until March 1, 1972. Requests for application forms should be directed to The Secretary, Fight for Sight, Inc., 41 West 57th Street, New York, New York 10019. Recipients of 1970–71 awards are as follows:

#### Grants-in-aid

| Investigator and Institution | Project title | Amount |
|---|---|---|
| Adams, Dr. Calvin K.<br>Willis, Dr. Richard D.<br>University of Florida<br>Gainesville, Florida | An animal model for prosthetic vision | $5,160 |
| Allansmith, Mathea, M.D.<br>Stanford University<br>Stanford, California | The etiology of corneal epithelial keratitis | 3,000 |

GRANTS-IN-AID

| INVESTIGATOR AND INSTITUTION | PROJECT TITLE | AMOUNT |
|---|---|---|
| Bigger, John F., M.D.<br>Washington University<br>St. Louis, Missouri | Steroid responsiveness in tissue culture fibroblasts | 5,295 |
| *Candia, Oscar A., M.D.<br>Mount Sinai School of Medicine<br>New York, New York | Electrolytes and water movement across isolated amphibia lens | 2,070 |
| Carr, Ronald E., M.D.<br>Siegel, Irwin M., Ph.D.<br>New York University<br>New York, New York | Ophthalmologic testing of tyrosinase positive and negative forms of generalized albinism: A pilot study | 1,820 |
| Cohen, Adolph I, Ph.D.<br>Washington University<br>St. Louis, Missouri | Role of the pigment epithelium in regulating the fluid volume of the subretinal space | 4,500 |
| Davidowitz, Jacob, Ph.D.<br>New York University<br>New York, New York | Osmic acid perfusion of extraocular muscle for correlated light and electron microscopy | 2,682 |
| *Dawson, William W., Ph.D.<br>University of Florida<br>Gainesville, Florida | Preliminary tests of a primate model for retinal pathology associated with chronically elevated intraocular pressure | 4,000 |
| Enoch, Jay M., Ph.D.<br>Washington University<br>St. Louis, Missouri | The application of the modulation transfer function test (of Fergus Campbell) to a clinical population | 4,500 |
| Eriksson, Aldur W., M.D.<br>Population Genetics Unit<br>Helsingfors, Finland | Continuation of studies on X-chromosomal retinoschisis in Finland | 6,240 |
| *Fischbarg, Jorge, M.D<br>Columbia University<br>New York, New York | The physiological role of the corneal endothelium in the preservation of the corneal transparency | 4,200 |
| *Forster, Richard K., M.D.<br>University of Miami<br>Bascom Palmer Eye Institute<br>Miami, Florida | Diagnosis and management of fusarium keratomycoses | 4,000 |
| Guvenc, Serpil, M.D.<br>Case Western Reserve University<br>Cleveland, Ohio | Development of a microcalorimetric device for the measurement of output power of ultrasonic diagnostic transducers | 9,175 |
| Henkind, Paul, M.D.<br>Albert Einstein College of Medicine<br>Bronx, New York | The embryology of the perimacular and peripapillary straight capillaries | 3,800 |
| *Holland, Monte, M.D.<br>Tulane University<br>School of Medicine<br>New Orleans, Louisiana | A clinical investigation of the effects of 6-hydroxydopamine in augmenting the adrenergic pressure-lowering response in the human glaucomatous eye | 2,000 |
| *Isa Abdallah M., Ph.D.<br>Meharry Medical College<br>Nashville, Tennessee | Characterization of antibodies to TRIC (Chlamydiae) agents | 5,000 |

GRANTS-IN-AID

| INVESTIGATOR AND INSTITUTION | PROJECT TITLE | AMOUNT |
|---|---|---|
| Kenyon, Kenneth R., M.D.<br>Johns Hopkins Hospital<br>Baltimore, Maryland | Ultrastructural studies in ocular pathology and development | 3,000 |
| Kobayashi, Shoji, M.D.<br>Retina Foundation<br>Boston, Massachusetts | Virus-induced embryonic gliomas of the retina | 5,977 |
| *Loeb, Gerald E.<br>The Johns Hopkins University<br>Baltimore, Maryland | Developmental work on a visual prosthesis | 4,500 |
| Maurice, David, Ph.D.<br>Stanford University<br>Stanford, California | Pressure relationships under the lids and under a contact lens | 3,500 |
| Nesburn, Anthony B., M.D.<br>Estelle Doheny Eye Foundation<br>Los Angeles, California | Experimental adenovirus infection of the rabbit eye | 7,150 |
| O'Rourke, J., M.D.<br>University of Connecticut Health Center<br>Hartford, Connecticut | Improved methods for study of uveoretinal uptake and distribution of radioactive zinc | 3,000 |
| Peyman, Gholam A., M.D.<br>University of Illinois<br>Chicago, Illinois | Peroxidase blood-brain barrier in the optic nerve | 1,750 |
| Podos, Steven M., M.D.<br>Washington University School of Medicine<br>St. Louis, Missouri | Cortisol suppression, diphenylhydantoin and primary open-angle glaucoma | 6,723 |

| Murphy, Charles L.<br>Department of Biochemistry<br>University of Georgia<br>Athens, Georgia<br>(William N. Creasy fund) | Dr. John Lee | Photoenzymes | 750 |

## CLINICAL RESEARCH SERVICE PROJECTS

Fight for Sight Children's Eye Clinic, Columbia-Presbyterian Medical Center, New York, Philip Knapp, M.D., Director (established 1961) ..... $18,000

Fight for Sight Children's Eye Clinic, New Jersey College of Medicine and Dentistry, Newark, New Jersey, (initial award). Paul T. McAlpine, M.D., and Walter T. Rados, M.D., Acting Directors 15,000

Fight for Sight Children's Eye Clinic, Eye and Ear Hospital of Pittsburgh, Pennsylvania, David A. Hiles, M.D., Director (established 1967) ..... 17,000

Fight for Sight Children's Eye Clinic, Wills Eye Hospital, Philadelphia, Pennsylvania, Robison, D. Harley, M.D., Director (established 1964) ..... 17,500

### Special award

Travel grant to Almen L. Barron, Ph.D. of State University of New York at Buffalo to help defray transportation costs for a visiting professorship at Hebrew University, Jerusalem, Israel, for study of the immunologic aspects of trachoma and training in electron microscopy .....$920

## Personals

### Gerald L. Portney

Gerald L. Portney was appointed chairman of the Department of Ophthalmology in the School of Medicine at the University of California, Davis.

Before coming to Davis, Dr. Portney was an assistant professor of ophthalmology and director of the Glaucoma Service at Stanford University Medical Center in Palo Alto, California.

Dr. Portney received his M.D. degree from Northwestern University in 1962. He interned at Cook County Hospital and trained in ophthalmology at the University of Illinois Eye and Ear Infirmary. He served as clinical ophthalmologist on the Navajo Indian Reservation and then as medical research officer and ophthalmologist on the Papago Indian Reservation with the US Public Health Service.

He was an NIH Special Fellow at the University of Michigan where he received a M.A. in mathematics.

### R. Townley Paton

R. Townley Paton, Southampton, Long Island, received the Lighthouse award for distinguished service in recognition of his contribution to the field of blindness, toward the advancement of keratoplasty, and as a founder of the Eye Bank for Sight Restoration, and his services to this cause in New York City and across the nation.

---

## INSTRUCTIONS FOR SUBMITTING NEWS ITEMS

Each news item intended for publication in the American Journal of Ophthalmology must be submitted in typewritten form. Each news item must be submitted on a separate sheet of 8½ × 11 heavy bond paper, the typing should be double-spaced, and each item should be written in narrative style; names, titles, and offices should not be listed separately, but included in the body of the announcement.

News items should include full information regarding the event publicized (who, what, when, where, and occasionally, why), and should provide the name and address of the person responsible for the accuracy of the item. All news items must be submitted *four months in advance of publication,* and should be mailed directly to the office of the News Editor: Thomas Chalkley, M.D., 700 North Michigan Avenue, Chicago, Illinois 60611.

## THE BASIC SCIENCE COURSE IN OPHTHALMOLOGY

UNIVERSITY OF PENNSYLVANIA
SCHOOL OF MEDICINE
OFFICE OF GRADUATE MEDICAL EDUCATION
July 10, 1972 through October 28, 1972

The sixteen week basic science course in ophthalmology is especially designed to give medical graduates entering their residency training in ophthalmology an excellent basic foundation for their work. Instruction is by lecture, demonstrations, laboratory work, conference and practice clinics. Full use is made of the University's facilities. The program is under the organization and supervision of Dr. Harold G. Scheie, Professor and Chairman of the Department of Ophthalmology. The faculty is composed of members of the basic science and clinical departments of the University of Pennsylvania School of Medicine supplemented by the following guest lecturers:

Boeder, Paul Antonkurt, Ph.D.
Donaldson, David D., M.D.
Dowling, John, Ph.D.
Ellis, Philip P., M.D.
Falls, Harold F., M.D.
Fine, Ben S., M.D.
Forster, H. Walter, Jr., M.D.
Frayer, William C., M.D.
Friedman, Ephraim, M.D.
Gass, J. Donald, M.D.
Haas, Joseph S., M.D.
Hallett, Joseph W., M.D.
Harris, John E., Ph.D., M.D.
Hoover, Richard E., M.D.
Johnson, Robert J., M.D.
Kinsey, Everett V., M.D.
Koelle, George B., Ph.D., M.D.
Krill, Alex E., M.D.
Kurz, George H., M.D.
Lambertsen, Christian J., M.D.
Lemoine, Albert N., M.D.
Linksz, Arthur L., M.D.
Rose, Edward, M.D.
Stone, Hrant H., M.D.

Subjects include: anatomy, principles of anesthesia, bacteriology, biochemistry, biomicroscopy, blind patient care, cryosurgery, electron microscopy, embryology, fundamentals of glaucoma and gonioscopy, genetics, immunology and tissue transplantation, light coagulation, microbiology, neuroophthalmology, ocular motility, ocular photography, optics, pathology, perimetry, pharmacology-physiology, principles of laser energy, refraction, roentgenology, statistics, principles of tonometry and tonography, ultrasound in ophthalmology and current concepts of uveitis.

To enroll in this program physicians must return a completed application. Students will not be accepted for isolated portions of the course and a certificate is awarded upon completion. Tuition for the course is $575.00. The American Board of Ophthalmology has indicated that the time spent in this course is acceptable as credit.

Applications should be made promptly. Persons wishing further information should write to:

THE DIRECTOR
OFFICE OF GRADUATE MEDICAL EDUCATION
UNIVERSITY OF PENNSYLVANIA SCHOOL OF MEDICINE
PHILADELPHIA, PENNSYLVANIA 19104

Spectacle Indirect
Split personalities can have problems, ask Dr. Jekyll. However when two separate identities perfectly tuned to their individual roles join forces there can never be problems. You'll find no problems with this revolutionary new system.

The light, bright, stereo-vision Spectacle Indirect Ophthalmoscope (that's fitted so easily) converts in seconds to a spectacle magnifier, with a removable light source and flip-up loupes.

Split personality or marriage of the year? Either way you win with the Spectacle Indirect.

## THE RETINA SERVICE WILLS EYE HOSPITAL
### PHILADELPHIA, PENNSYLVANIA

Announces a Course on
**MACULAR DISEASES**

To be held at the Philadelphia County Medical Society Building, Philadelphia, Pennsylvania

March 10 and 11, 1972

Faculty for the course will include:

William H. Annesley, M.D.
Harold Cross, Ph.D., M.D.
Jay Federman, M.D.
Richard Goldberg, M.D.
Alfred Lucier, M.D.
P. R. McDonald, M.D.
Charles J. Rife, M.D.
Merlyn Rodriguez, M.D.
L. K. Sarin, M.D.
George Spaeth, M.D.
William Tasman, M.D.
A. Zimmermann, M.D.

The course will cover the clinical fluorescein and pathologic aspects of heritable macular disorders, choroidal diseases causing detachment of the retina and pigment epithelium, serous detachment of the retina secondary to hypertensive and collagen diseases, macular dysfunction secondary to vitreous abnormality, retinal inflammatory and toxic disease affecting the macula, macular dysfunction secondary to trauma, tumors of the posterior pole and the sphingolipidoses.

Tuition will be $100. Special rate of $40 available for residents upon application from their Department Head. Checks should be made payable to Retina Service, Wills Eye Hospital and mailed to William Tasman, M.D., Retina Service, Wills Eye Hospital, 1601 Spring Garden Street, Philadelphia, Pa. 19130.

The Eye Foundation of America

# SYMPOSIUM ON STRABISMUS

WITH EMPHASIS ON NEURO-OPHTHALMOLOGICAL ASPECTS

Friday and Saturday, March 3 and 4, 1972

TOPICS

Indications and contraindications for: combined vertical and horizontal muscles surgery, multiple horizontal muscle surgery, recess-resect operations, bilateral resection operations, bilateral recession operations; strabismus and reading problems; dyslexia; the forced traction test; diagnosis of superior oblique palsy; management of superior oblique palsy; management of complete paralysis of ocular muscles; NRC-ARC—what is its place in diagnosis and prognosis?; the management of congenital esotropia; intentional vs. unintentional overcorrections in eso deviations; intentional vs. unintentional overcorrections in exo deviations; prisms in the management of strabismus; the present status of miotics versus bifocals; refractive errors in strabismus management; comparative methods for assessing rotation defects; management of endocrine-eye muscle problems; management of adult acquired strabismus.

Write to George M. Haik, M.D., Professor and Head,
Department of Ophthalmology, L.S.U. Medical Center,
1542 Tulane Avenue, New Orleans, Louisiana 70112.

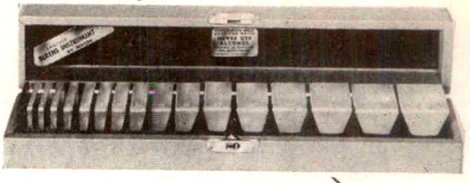
## STANFORD BASIC SCIENCE COURSE IN OPHTHALMOLOGY

**July 5 through September 8, 1972**

**Stanford University Medical Center, Stanford, California**

For residents and prospective residents—approximately 290 hours of instruction with a faculty of forty-five.

Sections include:



1. Anatomy (25½ hours)
2. Microbiology and Immunology (39 hours)
3. Pathology (69 hours)
4. Physiology (39 hours)
5. Neuro-ophthalmology and Neuroanatomy (33 hours)
6. Optics and Theory of Refraction (33 hours)
7. Embryology and Genetics (9 hours)
8. Motility (30 hours)
9. Biochemistry (9 hours)
10. Pharmacology and Toxicology (29 hours)

Some of the lecturers are as follows: Crowell Beard, Raynold Berke, Paul Boeder, Brooks Crawford, Phil Ellis, William Green, Arthur Jampolsky, Alan Scott, Robert Shaffer, Richard Sogg, William Spencer, Phillips Thygeson.

Tuition $575.00. For further information and application forms please write to J. W. Bettman, M.D., Division of Ophthalmology, A230, Stanford Medical Center, Stanford, California 94305.

REGISTRAR: Charles Regan, MD, 243 Charles Street, Boston, MA 02114

The First International Surgical Eye Symposium in Ophthalmology will be held in Bologna, Italy on April 23, 1972. The format of the program is rather unusual and should prove to be a most exciting one. Outstanding and renowned surgeons will perform live surgery on patients to demonstrate a variety of techniques in cataract, glaucoma, cornea and plastic eye surgery. Ancillary subjects related to ophthalmic surgery will be presented by a roster of outstanding ophthalmologists. Operative sessions will be televised and simultaneous translations will be held in Italian, English and French. For further details contact:

Announces a Symposium on

# OPHTHALMIC PLASTIC AND CORNEAL SURGERY

To be held at the Diplomat Hotel,
Miami Beach (Hollywood), Florida

March 26-31, 1972

Faculty for the course will include:

| | |
|---|---|
| Dr. Crowell Beard | Dr. J. H. King |
| Dr. Jorge Buxton | Dr. James Major |
| Dr. Ramon Castroviejo | Dr. A. E. Maumenee |
| Dr. Claes Dohlman | Dr. Gordon Miller |
| Dr. Max Fine | Dr. Edward W. D. Norton |
| Dr. Richard Forster | Dr. Frank Polack |
| Dr. J. Donald M. Gass | Dr. Marvin Quickert |
| Dr. Russell Harner | Dr. Norman Sanders |
| Dr. Danny Jones | Dr. Byron Smith |
| Dr. A. Dalma Kende | Dr. David Soll |

Dr. Richard Tenzel

This symposium will cover the corneal and ophthalmic plastic field. Multiple lectures will be given with ample time for panel discussion and questions from the registrants.

Afternoons will be set aside for recreation including tennis and golf tournaments. There will be planned entertainment for most evenings.

Tuition will be $175, breakfasts included. Special rate of $75 available for residents upon application from their Department Head. Checks should be made payable to "Bascom Palmer Eye Institute" and mailed to Ophthalmic Plastic and Corneal Surgery Symposium, Bascom Palmer Eye Institute, P.O. Box 875, Biscayne Annex, Miami, Florida 33152.

## Announcement of
## TWELFTH ANNUAL INSTRUCTIONAL COURSE IN CONTACT LENS FITTING BY THE OPHTHALMOLOGIST

**April 8-9, 1972**

Sponsored by
The Rudolph Ellender Medical
Foundation, Inc.

Co-ordinated with the
New Orleans Academy of Ophthalmologist's
Meeting on "Contact Lenses"
April 9-14, 1972

PLACE

Roosevelt Hotel, New Orleans, La.

TUITION

$85.00 ($40.00 Out of State Residents and M.D.'s Technicians)

PANEL MEMBERS

Colonel Budd Appleton, M.D., Walter Reed Hostp., Washing. D.C.
Jos. A. Baldone, M.D., New Orleans, Louisiana
Antonio R. Gassett, M.D., Gainesville, Florida
Herbert L. Gould, M.D., White Plains, New York
G. Peter Halberg, M.D., New York, New York
Jack Hartstein, M.D., St. Louis, Missouri
Frank Hoefle, M.D., New York, New York
Whitney G. Sampson, M.D., Houston, Texas
Keith Whitham, Buffalo, New York

TOPICS

Practical technics of fitting of hard and soft gel lenses will be actually demonstrated, audience participation in handling of lenses.

Full description of the Series System (Inventory System) fitting technic of hard lenses.

Didactic lectures will be held to a minimum (in co-operation with the New Orleans Academy's Program which follows).

WORKSHOP

For M.D.'s Technicians in evening

LADIES DAY

Saturday, April 8, 1972 with planned activities.

## INDIRECT OPHTHALMOSCOPY OF THE PERIPHERAL RETINA

Purpose: To teach this new technique—the normal anatomy of the peripheral retina to residents and ophthalmologists.

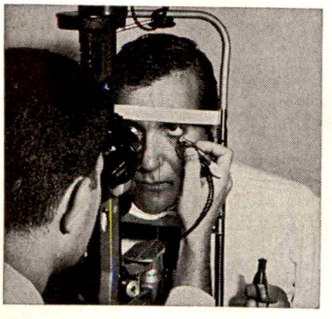
Contents: Demonstrates and discusses normal anatomy of the equatorial and oral region of the retina as viewed during indirect ophthalmoscopy and scleral indentation. All normal anatomy and variations are discussed, and presented in views of post mortem eyes and shown in scenes taken with the Stenstrom cine. This technique demonstrates the actual views of the fundus as seen during clinical examinations.

Running Time: 41 minutes—16 mm sound

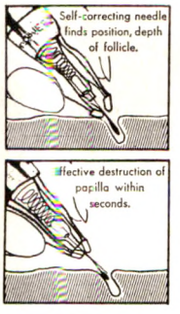
Cost: Rental $25.00 per week
Purchase price $300.00

For information contact: Retinal Service
Department of Ophthalmology
University of Iowa College of Medicine
Iowa City, Iowa 52240

## NATIONAL SPRING MEETING
THE AT
*Greenbrier*
April 26-29, 1972



*Ophthalmology Speakers*
Miles A. Galin, M.D., New York, N.Y.
Louis J. Girard, M.D., Houston, Tx.
Frank W. Newell, M.D., Chicago, Ill.
John T. Simonton, M.D., New York, N.Y.
Frederick Stocker, M.D., Durham, N.C.



*Otolaryngology Speakers*
Phillip Anthony, M.D., Fort Worth, Tx.
William R. Hudson, M.D., Durham, N.C.
Jerrie Cherry, M.D., Nashville, Tenn.
James R. Leonard, M.D., Philadelphia, Pa.

Sponsored by W.Va. Academy of Ophthalmology and Otolaryngology

RESERVATIONS—Write directly to the Greenbrier, White Sulphur Springs, W.Va. for hotel accommodations.

ADVANCE REGISTRATION—Fee of $75 required; checks payable to W.Va. O & O. Send to J. Elliott Blaydes, Jr., M.D. 107 Federal Street, Bluefield, W.Va.

## Perma Tweez®

## ELECTROLYSIS FOR EYELASH REMOVAL

This permanent hair remover features the only patented self-correcting needle in existence. Battery operated instrument sterilizes itself when current flows. No puncture safety feature helps prevent infection. Simple enough to be used by laymen (for cosmetic purposes only).

Thousands of units sold for such varied professional application as removal of inverted eyelashes to cosmetic use.

☐ PERMA TWEEZ EPILATOR . . . . $16.95

☐ ATTACHMENT
(For Treating Patient) . . . . . $ 2.50

30 DAY FREE TRIAL EXAMINATION
(MAY BE RETURNED WITH NO OBLIGATION)

SEND PERMA TWEEZ AND ATTACHMENT NOW AND BILL AFTER 30 DAY TRIAL

# Apollo Space Flight Veteran: Methulose, for dry eyes!

Methulose artificial tears lubricate sensitive ocular tissues to provide comfortable, soothing relief from eye dryness and irritation without blurring vision. Little wonder it is a big item on Apollo flights where dry eyes could present serious problems.

Meanwhile, back on earth, Methulose might be the simple solution to the dry-eye problems of many of your patients. A non-irritating buffered aqueous solution containing Methylcellulose U.S.P. preserved with Benzalkonium Chloride 1:25,000, it is available in 15cc and 30cc direct application plastic containers. Write for a generous supply of 5cc starter samples.

## There's no biting sting with "comfort strength" Epifrin ½%, 1%

Epifrin® (l-epinephrine) has long offered the most economical, convenient l-epinephrine available to glaucoma patients. Now, with "comfort strength" Epifrin ½% and 1%, the biting sting is gone too! Evaluate our "comfort strengths" with your glaucoma patients. Have them compare the comfort of EPIFRIN ½% with any other l-epinephrine. You'll find there is no significant difference in patient acceptance. There is growing documentation of the efficacy of these lower concentrations. (1, 2) Lower concentrations also mean reduced side effects and no blurring or impaired vision. Now the economy and convenience of "comfort strength" Epifrin® ½% and 1% make a lot more sense.

**References:** 1. Kronfeld, P.C.: Invest. Ophth. 3258 (June) 1964. 2. Harris, L. S.; Galin, M.A.; and Lerner, R.: Annals of Oph. 219 (June) 1970. **Prescribing Information:** Contains: levo-epinephrine (as the HC1)...2%, 1%, ½%, with: benzalkonium chloride, sodium metabisulfite, disodium edetate, and purified water. **Indications:** Chronic simple glaucoma. **Contraindications:** Should not be used in patients who have had an attack of narrow angle glaucoma since dilation of the pupil may trigger an acute attack. **Warnings:** Undesirable side reactions may include: eye pain or ache, browache, headache, conjunctival hyperemia, and allergic lid reactions. Adrenachrome deposits in the conjunctiva and cornea after prolonged epinephrine therapy have been reported. Epinephrine has been reported to produce macular edema in some aphakic patients. **Precautions:** Should be used with caution in patients with a narrow angle since dilation of the pupil may trigger an acute attack of glaucoma. **Dosage:** The usual dosage is one drop in the affected eye(s) once or twice daily. However, the dosage should be adjusted to meet the needs of the individual patient. **Note:** Protect from excessive light and heat. If the solution discolors or a precipitate forms it should be discarded. **How Supplied:** 0.5% and 1.0% strengths in 15 cc plastic dropper bottles. 2% in 5 cc and 15 cc plastic dropper bottles. On prescription only.
